Tidbinbilla, located near Canberra, Australia, with an average spacing between observations of  $\sim 10$  d. A 26-m diameter antenna is being used at an observing frequency of 2,295 MHz. For the Vela pulsar 25 integrated pulse profiles are recorded on magnetic tape during an observation lasting  $\sim 20$  min. Typically, data from such an observation give a mean arrival-time having an uncertainty of 20  $\mu$ s. Propagation times to the Solar System barycentre are computed using an ephemeris provided by I. I. Shapiro of the Massachusetts Institute of Technology. As data have not been recorded for a full year, the pulsar position cannot yet be computed from the arrival-time data; the Molonglo position, RA 08 h 33 min 39.44 s, dec  $-45^\circ 00' 10.2''$  (ref. 4), was assumed.

Data recorded between 21 May 1975 and 25 September 1975 can be fitted quite closely by a parabolic curve; the parameters obtained from this fit are given as the pre-jump data in Table 1, where the errors quoted are dominated by the uncertainty in pulsar position. Significant residuals from the fitted curve, apparently resulting from intrinsic variations in the pulsar period, are observed. The r.m.s. residual for the 127-d period including 13 independent observations, is 165  $\mu$ s, large compared to the 20  $\mu$ s observational uncertainty. This pre-jump period agrees within a few parts in  $10^7$  with that extrapolated from parameters determined after the August 1971 event<sup>3</sup>, implying that no similar jump occurred between then and May 1975.

Pulse arrival times obtained on and after 15 October do not lie on the parabola extrapolated from these previous data. A least-squares fit of a parabola to data recorded from 15 October to 14 November gives the post-jump parameters listed in Table 1. Based on extrapolation of the pre-jump data, the period at JD 2442700.5069 would have been  $0.089\,234\,889\,53 \pm 15$  s. The magnitude of the period change was therefore  $175.6 \pm 0.2$  ns, corresponding to  $|\Delta P|/P = \Delta\Omega/\Omega = 1.97 \times 10^{-6}$ , and to a phase drift of about 1.9 cycles  $\text{d}^{-1}$  with respect to the pre-jump period. Because of this large drift it is not possible (by extrapolating the post-jump data backwards) to determine on which day the period decrease occurred. It can only be said that it occurred between JD 2442680.64 (September 25) and JD 2442700.51 (October 15).

Table 1 Timing parameters for the Vela pulsar

Pre-jump data	(JD 2442553-2442680)
Period	$0.089\,233\,318\,26 \pm 7$ s (A.1)
$dP/dt$	$(124.096 \pm 0.010) \times 10^{-15}$ s $\text{s}^{-1}$
Epoch (JD)	2442553.9595
Post-jump data	(JD 2442700-2442731)
Period	$0.089\,234\,713\,88 \pm 7$ s (A.1)
$dP/dt$	$(125.03 \pm 0.01) \times 10^{-15}$ s $\text{s}^{-1}$
Epoch (JD)	2442700.5069

The data in Table 1 also show that there was an increase in the rate of change of the period of  $(0.93 \pm 0.02) \times 10^{-15}$  s  $\text{s}^{-1}$ , apparently coinciding with the decrease in the period. The corresponding value of  $\Delta P/\dot{P} = |\Delta\Omega|/\dot{\Omega}$  is  $7.5 \times 10^{-3}$ . Because of possible systematic variations in the period and its derivatives following the jump, and the superimposed random irregularities, the post-jump parameters must be considered preliminary values only.

The parameters of this third jump are remarkably similar to those of the previous jumps in spite of the fact that the interval between the second and third jumps is over 60% greater than that between the first and second. Values of the period decrease for the 1969, 1971 and 1975 events are, respectively,  $\sim 200$  ns, 178.6 ns and 175.6 ns. For the 1969 event the period derivative increased by  $\sim 1.00 \times 10^{-15}$  s  $\text{s}^{-1}$ , compared to  $0.93 \times 10^{-15}$  s  $\text{s}^{-1}$  for the 1975 event. The increase in  $dP/dt$  for the 1971 event was comparable.

Further analysis of the variation in period for before and after this third discontinuity will be undertaken when additional post-jump data are available.

We thank T. Reid and the staff of the NASA station at Tidbinbilla whose efforts have made these observations possible, and Lynette M. Newton for assistance with the data analysis.

## B-emission stars and X-ray sources

SEVERAL transient X-ray sources with decay times of the order of weeks to months have been reported<sup>1</sup>; the discovery of four new sources of this type, A1118-61 (refs 2 and 3), A0535+26 (refs 4-6), A1742-28 (P. W. Sanford, personal communication), A1523-61 (ref. 7), in less than 1 yr of operation of the X-ray satellite Ariel V, indicates that these objects are rather common. Important for the understanding of this phenomenon is the optical identification of the sources: it has been proposed that, A1118-61 and A0535+26, coincide with bright B stars with emission lines ('Be' stars)<sup>8,9</sup>, while A0621-00 is identified with a completely different object, which showed a nova-like behaviour optically, simultaneous with the X-ray outburst<sup>10</sup>. Here we discuss X-ray emission from systems containing Be stars.

Be stars are appealing candidates for X-ray transients for the following reasons: first, a number of these stars are single-line spectroscopic binaries with periods of  $\sim 10$  d (ref. 11). It is suggested that many Be stars have an evolved, invisible, close companion. The very rapid rotation of these stars is then naturally explained by mass exchange from the envelope of the presently invisible (though initially more massive) companion. Second, evolutionary considerations<sup>12</sup> show that if some mass loss from the system occurs during the first stage of mass transfer, compact stars (neutron stars or black holes) can be formed as companions of main-sequence stars of masses as low as  $8-10 M_{\odot}$ . This corresponds to main-sequence spectral type as late as B3-B4 (Be stars are indeed main-sequence stars, and are generally found in the entire B-type spectral region). The lifetime of main-sequence stars of  $8-10 M_{\odot}$  is  $\sim 2 \times 10^7$  yr. Third, Be stars characteristically show a central absorption component in the Balmer lines, indicating the presence of circumstellar material. It is generally thought that this matter is ejected from the equatorial regions where, because of the extremely rapid rotation of the Be stars, the effective gravity is almost zero. The emission features vary over time scales of 1-100 yr (ref. 11).

We propose that sudden variations in the rate of mass ejection from Be stars in the presence of a compact companion could produce transient X-ray emission, which might recur over a period of years, like the observed optical emission of Be stars. The companion star should be a neutron star, rather than a white dwarf, because the spectrum of the transients is rather hard ( $\alpha = 1.0$  for pulsating sources, and 2-4 for the others) and the luminosity rather high ( $\approx 10^{37}$  erg s<sup>-1</sup>). The total amount of accreted matter required for an outburst is, for a neutron star,  $\Delta M \approx 10^{23}$  g, which is only a few per cent of the amount of mass in the envelopes of Be stars required for producing the observed emission lines.

Two of the transients (A1118-61 and A0535+26) vary periodically with very stable periods of 405 s and 104 s, respectively. If these are rotation periods for neutron stars they

are very slow, but nevertheless conceivable, since the lifetime of these systems can be  $> 10^7$  yr. On such a time scale the rotation could have been slowed down by the propeller mechanism<sup>13</sup>. The X-ray binary Vela X-1 is a slow pulsar ( $P = 283$  s (ref. 14)), and this supports the idea that these slowly pulsing transients might be neutron stars in binaries with orbital periods of the order of days. (Early B stars are observed<sup>15</sup> to have weak winds that can provide sufficient braking for a neutron star companion on this time scale<sup>16</sup>.)

Other systems identified with objects optically similar to Be stars are 3U0352+30 (X Per) and Cen X-3 (Krziminski's star). X Per has been classified as an extremely rapidly rotating (peculiar) B0Ve star<sup>17</sup> and Krziminski's star is an O6V-III emission star (rather close to the main-sequence, and not a clear Of star, since strong 4640 Å and 4686 Å emission is absent<sup>18</sup>). In two other cases, 3U1145-61, 3U1223-62 there are Be stars in the error boxes (HD 102567, Wray 977). If the identification with X Per is correct, 3U0352+30 has an X-ray luminosity of  $\sim 10^{33}$  erg s<sup>-1</sup>, which seems to be modulated with a period of 22 h (N. E. White, P. W. Sanford and K. O. Mason, unpublished). It is a remarkable fact that the maximum (break-up) rotational velocity for a B0V star corresponds to a rotation period of  $\sim 1$  d. We therefore suggest that the X-ray period represents the orbital period of a binary system, and that X Per rotates synchronously with this orbital period. The low X-ray luminosity would arise from either a low rate of mass transfer or a source which is almost completely buried by a supercritical mass accretion rate<sup>19</sup>. Such weak sources are measurable at the Uhuru sensitivity, only to within 0.5-1 kpc. It is, therefore, possible that 3U352+30 is a 'low' state for a transient X-ray source, and is observable only because it is close ( $\sim 170$  pc).

It seems important that the X-ray behaviour of Cen X-3 is in many respects similar to that of the pulsating transient X-ray sources, in that it turns 'off' for as much as a month at irregular intervals; when it turns on, its X-ray spectrum shows intense low-energy absorption<sup>20</sup>, very similar to the peak behaviour of the transients seen by Ariel V. A further similarity with these two transients is that Cen X-3 shows regular X-ray pulsations (though with a much shorter period ( $\sim 5$  s)).

If our suggestion that a class of X-ray transients is associated with Be stars is correct, it follows that the total number of these types of transients in a quiescent state is given by the number of Be transients per year ( $\sim 4$ ) divided by the frequency of active periods in Be stars ( $\sim 10^{-1}$  yr<sup>-1</sup>). Therefore—on the binary model—Be transients in a quiescent state should be approximately as numerous as steady galactic X-ray sources.

*Note added in proof:* After submission of this paper, 3U0352+30 (X Per) and 3U1223-62 (Wray 977) were discovered to be slow pulsars with periods of 13.924 and 11.64 min, respectively<sup>21,22</sup>. This seems a strong confirmation of our above suggestion (based on their association with Be Stars) that these sources are related to the slowly pulsating transients and to sources like Cen X-3.

## Does Mercury have a molten core?

THE Mariner 10 mission has discovered a magnetic field associated with the planet Mercury<sup>1</sup>. The preferred explanation of the source of this field based on these observations, is an internal dynamo<sup>2</sup>. A necessary condition for such a dynamo is the existence of an electrically conducting liquid region within the planet. In this letter, we investigate whether or not Mercury could contain a molten metallic core.

Internal temperature distributions for a solid, undifferentiated Mercury have previously been calculated by Majeve<sup>3</sup>. Siegfried and Solomon<sup>4</sup> considered the effects of melting and fractionation. They concluded that Mercury would have a metallic core fully differentiated from the silicate mantle if the uranium and thorium abundances are taken from the cosmochemical model of Lewis<sup>5</sup>. According to Siegfried and Solomon, such models predict a present-day temperature profile rising from the surface temperature to the melting curve in the upper 300 km, a molten mantle and a slowly cooling core either at or below the melting curve of iron. It has been pointed out<sup>6,7</sup> that such a thermal constitution would prevent dynamo generation. We have extended the work of Reynolds *et al.*<sup>8</sup> and Fricker *et al.*<sup>9</sup> to study the possible thermal evolution of a metallic core in Mercury. The calculations involve the solution of the equation of heat conduction for a spherically symmetric body with internal heat sources. Modifications have been incorporated to take into account the latent heat of fusion, and the redistribution of radioactive heat sources as a consequence of melting. The numerical methods used follow the method described in ref. 8. For the internal structure of Mercury, the work of Reynolds and Summers<sup>10</sup> was used. Following Lewis<sup>5</sup>, it was assumed that the condensation of U, Th and Fe was complete at the orbit of Mercury and that, like other volatile and chalcophile elements, K can be neglected. For a model of Mercury with a metal weight-fraction of 66%, an average U concentration of  $2.25 \times 10^{-8} \text{ g g}^{-1}$  as estimated by Wasserburg *et al.*<sup>11</sup> for the Earth would correspond to a U content of  $4.4 \times 10^{-8} \text{ g g}^{-1}$ , if the Fe/U ratio of the Earth is applied. This value together with a Th/U ratio of 3.7 has been used. The calculated heat conduction for the silicate material relies on the data given by Schatz and Simmons<sup>12</sup> for the mantle material of the Earth; it includes the contributions of lattice conductivity and radiative transfer. The conductivity of iron was taken as  $2.5 \times 10^8 \text{ erg cm}^{-1} \text{ K}^{-1} \text{ s}^{-1}$ . The heat capacity of the silicate material was assumed to be  $1.2 \times 10^7 \text{ erg g}^{-1} \text{ K}^{-1}$ , that of iron  $0.6 \times 10^7 \text{ erg g}^{-1} \text{ K}^{-1}$ . For the bulk melting temperature of the silicates, the melting curve of diopside (Fig. 1) was adopted<sup>13</sup>. The surface temperature was held constant at a value of 75 °C (ref. 14).

Interpretation of the recent Mariner results suggests that extensive igneous activity has occurred on the surface

Fig. 1 The heavy curve is the calculated temperature profile of Mercury  $4.6 \times 10^9$  yr after core formation. The diopside and iron melting curves are shown. The molten core region is  $\sim 500$  km thick.

of Mercury: there is evidence that global differentiation occurred very early in the planet's history, resulting in the formation of a metallic core<sup>15,16</sup>. The high initial temperatures required for an early differentiation process have evidently also prevailed in the other terrestrial planets and the moon, as well as in the relatively small meteorite parent bodies<sup>8,17,18</sup>. Therefore, the calculation was started with an initial temperature distribution corresponding to the melting curve of iron<sup>19,20</sup>, and the core was assumed to have formed essentially coincident with planetary formation,  $4.6 \times 10^9$  yr ago. As a result of the melting and differentiation process, the radioactive heat sources are assumed to be concentrated in the outermost layers. Other assumptions regarding the initial state of the planet tend to result in higher interior temperatures at the present time, since core formation is delayed and less time is available for cooling.

The boundary between the iron core and the silicate mantle at a pressure of  $7 \times 10^9 \text{ Pa}$  ( $1 \text{ Pa} = 10^{-5} \text{ bar}$ ) coincides with a substantial difference in melting temperatures: the melting curve of diopside is  $\sim 200$  °C higher than the melting curve of iron at this point. This difference holds also for other silicate materials, which are depleted in volatile and chalcophile elements<sup>21</sup>. In addition, the presence of Ni, or of other minor constituents, in the core, would tend to lower the assumed iron melting curve. The core-mantle boundary separates two contrasting thermal conductivity regimes. The differences in melting temperatures and transport properties has a crucial role in the thermal evolution of the interior of the planet. Because of the higher melting temperature in the deep mantle and the lower conductivity of the mantle material in comparison with iron, the core-mantle boundary represents an effective heat transfer barrier in the absence of efficient solid convection in the mantle. This barrier permits temperatures in the outer core to rise above the melting curve of iron, with a corresponding reduction of the temperature gradient at the core-mantle boundary. If the barrier did not exist, the heat flux from the interior would be at least equal to the product of the iron thermal conductivity and the melting curve gradient, a value sufficient to solidify the entire core in  $< 2 \times 10^9$  yr. The models of Siegfried and Solomon<sup>4</sup> neglect the melting temperature discontinuity, and therefore predict solidification of the core and a large molten region in the mantle.

The temperature profile predicted by the thermal history calculations for  $4.6 \times 10^9$  yr, using the above initial conditions and parameter values, is given in Fig. 1. For our model, the inner 1,400 km of the core would now be solid, while the outer 500 km of the core remains molten. This model, therefore, fulfils a necessary requirement for a dynamo: at least a portion of the core is molten. It is also consistent with the apparent lack of recent degradation of surface features by magmatic activity, since the mantle is solid.

We wish to emphasise the following: the result that a molten shell exists now, and is a direct consequence of the discontinuity in melting temperatures at the core-mantle boundary. This result is independent of the density of planetary heat sources and the particular initial conditions imposed, as long as a molten core once existed and in so far as solid convection in the mantle can be ignored (see below). Core formation later than  $4.6 \times 10^9$  yr ago, retention of radioactive heat sources in the core or deep mantle, and the action of other energy sources (such as tidal dissipation or electrical heating) would all result in a larger present-day molten region than in our model.

The calculations described here do not include the effects of solid convection in the mantle, which could solidify the core under certain circumstances. Cassen *et al.*<sup>22</sup> have discussed this aspect of the problem, and find that it is necessary that a density of heat sources at least comparable with the Earth's mantle-wide average be retained throughout Mercury's mantle if the core is to remain molten in the presence of solid convection. (This requirement is additional to the melting temperature discontinuity at the core-mantle boundary.)

Finally, we note that our calculated temperature gradients in the molten region of the core are subadiabatic. Therefore, although a dynamo is possible in this model, it would have to be driven mechanically, rather than by thermal convection. Gubbins<sup>23</sup> has discussed the energy requirements of a convective dynamo.

## Mid-latitude ionospheric scintillation fading of microwave signals

MEASUREMENTS of the amplitude of microwave (1,550 MHz) signals from the NASA ATS-5 geostationary spacecraft were made from December 1973 to July 1974. These data have been analysed for diurnal, geomagnetic and seasonal variations, and also for dependence on the boundary of the high latitude scintillation region in the direction of the Equator.

The signal to the spacecraft, at a frequency of 1,650 MHz, was transmitted from the DOT/TSC/Westford Propagation Facility at Westford, Massachusetts (42.6°N; 71.5°W, geographic). It was produced as follows: a 2-W signal from an L-band exciter was used to drive a 200-W travelling wave amplifier. The signal was carried through 15.2 m of rigid feedline to a 4.6-m diameter parabolic reflector antenna whose feed was such that right-hand circular polarisation was transmitted. A high power narrow-band filter after the output of the final amplifier insured that no out-of-band spurious emissions were transmitted.

This signal was frequency shifted by the L-band transponder of the spacecraft, in the narrow-band frequency translation mode, to a frequency of 1,550 MHz and re-emitted. The power level in the uplink was high enough to saturate the ATS-5 L-band transponder by > 7 dB thus assuring that the amplitude variations on the downlink were 'safe' from uplink fading contamination by 7 dB.

The signal beam crossed the 350-km level in the ionosphere at 30.1°N, 75.8°W (near Philadelphia) because the ATS-5 had a subsatellite longitude of 105°W. The invariant latitude  $\Lambda$  was 54°N (ref. 1) ( $\Lambda = \cos^{-1}(1/L)$ , where  $L$  is McIlwain's coordinate<sup>2</sup>).

The downlink signal was then received at the Westford facility on three independent receiving systems where its amplitude was recorded in both analogue and digital form.

Each system consisted of a 3.1-m diameter parabolic reflector antenna with a preamplifier mounted at its spiral feed so chosen that right-hand circular polarisation was received.

Two of the receiving systems converted to a frequency of 30 MHz and then to 10 MHz, the signal from the other receiving system was converted to 136 MHz, then to 55 MHz and finally to 10 MHz. These 10-MHz signals were each filtered with a 30-kHz crystal filter, re-amplified and square-law detected. A portion of each filtered 10-MHz signal was also fed to three vector voltmeters which were used as narrow-band receivers with their 10-MHz reference signal coming from a frequency standard at the station. The vector voltmeters had a bandwidth of 1 kHz and employed a square-law detector following the narrow-band filter.

The 30-kHz detector voltage from each of the three receivers was recorded on an analogue strip-chart simultaneously with the detector voltage from each of the three vector voltmeters on a 6-channel strip-chart recorder. The calibration of the recorder was simplified by the identical calibration of the three vector voltmeters and of the three 30-kHz detected voltages.

Three independent receivers, each with a narrow- and wide-band mode, were used on the received signal to assure that the drift caused by gain instabilities could be isolated from shifts of frequency in the spacecraft's transmitter. During the measurement programme, a frequency drift in the spacecraft's transmitter was never observed.

The three detected voltages were digitised, preprocessed and recorded on magnetic tape for later computer processing<sup>3</sup>. An example of the analog data and the computer calculated statistics for April 1, 1974 are presented in Fig. 1. The strip-charts of the 30-kHz detectors are shown.

**Fig. 1** Example of analog data and computer calculated statistics for scintillation on April 1, 1974. ATS-5 subsatellite longitude:  $105^{\circ}\text{W}$ , Westford elevation angle:  $30.5^{\circ}$ ; Azimuth angle:  $224^{\circ}\text{SW}$ . The reason for the spiked fence appearance of the strip-chart recording is that the ATS-5 spacecraft was spinning with a period of 785 ms and thus traced out its L-band antenna pattern during each sweep. DOT/TSC/Westford propagation facility: NASA/ATS-5 spacecraft in NBFT Mode; WPF uplink at 1651.270 MHz; Downlink at 1550.250 MHz at  $S/N = 30$  dB;  $BW = 1$  kHz; median signal level =  $-117.5$  dBm (West) and  $-120.0$  dBm (Combo); Start time = 1415 EDT; file duration = 12 min.

Note how all three channels fade simultaneously. The calculated probability densities<sup>4</sup> for two of the three channels are also presented, as well as the cumulative amplitude distribution for the 12-min measurement interval.

In each of the 2,500 12-min data samples the best channel (that with amplitude drift  $< 0.2$  dB) was analysed. The 12-min data samples were statistically analysed to determine mean values, root-mean-squares (r.m.s.), probability density functions and probability distribution functions. The value of the 12-min distribution function at the 90% level was termed a 'scintillation index'. These 12-min 'scintillation index' values were grouped into 1-h and 3-h intervals to form '1-h scintillation index' (1-h SI) and '3-h scintillation index' (3-h SI) values, respectively.

The 3-h SI values were associated with the corresponding planetary magnetic index values which are computed for standard 3-h intervals<sup>5</sup>. The results, presented in Fig. 2 show that the higher values of magnetic activity are associated with the higher values of the 3-h SI.

Figure 3 presents the diurnal variations of the microwave ionospheric scintillation as expressed by the 1-h SI. For low  $Kp$  ( $Kp < 4$ ) there seem to be slight maxima at 1800, 2000 and 0000 LMT. For high values of  $Kp$  ( $Kp > 4$ ) there are slight maxima at 1800 and 0000 LMT.

Also plotted on Fig. 3 is the latitudinal variation of the mid-latitude scintillation boundary, as determined by

Kersley *et al.*<sup>6</sup>. The appropriate microwave scintillation data ( $Kp < 4$ ) do not seem to be directly related to the position of the scintillation boundary as determined by the measurements at 40 MHz. There is, however, a well-defined peak during the period when the statistically averaged scintillation boundary crosses the  $54^{\circ}$  parallel. Although the two sets of data were taken at different phases of the sunspot cycle and different geographical longitudes, the data do fit together.

During the solstices the data looked relatively calm with only a few r.m.s. signal level fluctuation measurements  $> 0.4$  dB during December and January, or June and July. During the vernal equinox, however, the r.m.s. signal level did have values in the  $0.4$ – $0.6$  dB range as would be indicated by the conclusions of Oksman and Taurianien<sup>7</sup>.

The following are our conclusions so far: first, ionospheric scintillation at microwave frequencies does exist at mid-latitudes. Second, of the 250 h of observations analysed, 10.2% were found to be undisturbed with a r.m.s. fluctuation level of  $\leq 0.22$  dB. Also, 0.84% of the observation periods were found to have disturbed propagation conditions with the 90% levels exceeding 1 dB which corresponds to a  $\sim 2$  dB peak-to-peak fluctuation level. Third, the largest peak-to-peak fluctuation that was observed on the strip-chart recording was 3 dB. Likewise, the smallest r.m.s. fluctuation level for an observing period was 0.15 dB.

Fig. 2 Comparison of 3-h SI with the planetary magnetic index,  $K_p$ , (December 1973–July 1974).

Fourth, mid-latitude ionospheric scintillation is related to magnetic activity, in that higher levels of magnetic activity are associated with higher levels of microwave scintillation. Fifth, mid-latitude scintillation has some diurnal variations<sup>8</sup>. Sixth, some seasonal variation was indicated, with the smallest scintillation activity during the winter solstice, and the maximum scintillation activity around the vernal equinox.

Fading of the amplitude of microwave signals has been reported for equatorial regions<sup>9–11</sup> and for auroral or polar

Fig. 3 Diurnal variation of microwave ionospheric scintillation for two ranges of planetary magnetic index shown with the scintillation boundary determined by Kersley *et al.*<sup>6</sup> from 40-MHz transmissions from the BE-B satellite.

regions<sup>12</sup>. Which has led to studies of the spectrum of ionospheric irregularities particularly in the F-region from *in-situ*<sup>13</sup> and ground-based measurements<sup>14</sup>. As far as we are aware, the observations reported here represent the first cases of scintillation fading due to F-region irregularities for frequencies in the microwave band at mid-latitudes.

Data used in connection with this article were obtained from WDC-A for the ionosphere. We thank Mr Paul Podlesny for his assistance at the Westford Facility.

## Long conductors as antennae for gravitational radiation

To date, the antennae used in the search for gravitational radiation have been mechanical in nature, that is they involve the detection of small displacements or strains in mechanical systems. Here we demonstrate that a conceptually simple system of two long conducting wires of different metallic composition constitutes, in principle, a non-mechanical antenna for gravitational radiation, and that if the conductors are sufficiently long such a system may be of practical use. Very briefly, the principle of operation of the system is that gravitational radiation produces a greater force on the ions in a metal than on the electrons, which, to preserve charge neutrality, necessitates a compensating electric field which is, in principle, detectable.

The effect of a constant gravitational field on a conductor has been studied by a number of authors; we note in particular the theoretical work of Barnhill and Schiff<sup>1,2</sup>, and of Dessler, Michel, Rorschach, and Trammell<sup>3</sup>. The result of this work is the prediction that a vertical electric field will exist inside and in the vicinity of such a conductor with magnitude

$$E = \Lambda mg/e \quad (1)$$

Here  $m$  is the mass of an ion in the metal,  $e$  is the charge of the electron,  $g$  is the acceleration due to gravity, and  $\Lambda$  is a constant representative of the metal, typically  $\sim 0.1$ – $1$  (ref. 3). We may understand this result qualitatively as follows: the gravitational force on the ions is  $mg$ ; on the much lighter electrons it is thousands of times less. To preserve charge neutrality it is necessary that the electrons experience an electric force  $eE$  of the same order of magnitude as  $mg$ . Equation (1) expresses the equality of these forces.

If we consider a conductor in rapid rotation it is evident that similar considerations will apply if we replace the gravitational force  $mg$  by the centrifugal force, which can be made quite large by the use of high rotation rates.

$$mg \rightarrow m\omega^2 l; E = \Lambda m\omega^2 l/e \quad (2)$$

Here  $\omega$  is the rate of rotation of the conductor and  $l$  is the distance from the axis of rotation. The field predicted in equation (2) has in fact been observed, with the correct order of magnitude, in an experiment by Beams<sup>4</sup>. This experimental

verification is central to our discussion, and we shall henceforth consider equations (1) and (2) as firmly established.

Using a few basic ideas of the theory of general relativity, we can show that a force analogous to a centrifugal force acts on the ions and electrons in a conductor in a gravitational radiation field. Consider a one-dimensional system along the  $x$  axis. The metric for plane wave gravitational radiation moving in the  $z$  direction<sup>4,5</sup> is

$$ds^2 = dt^2 - (1 + h(t-z))dx^2 \quad (3)$$

(We use units in which  $c = 1$ , and assume the radiation has '+' linear polarisation.) The radiation field,  $h$ , is dimensionless and constitutes a very small perturbation on the flat-space metric. In this metric field, a freely-falling test particle experiences no coordinate acceleration, and thus two test particles at rest and separated by coordinate distance  $dx$  will remain so<sup>6</sup>. On the other hand the measurable physical separation, given by<sup>5,8</sup>

$$l = (1+h)^{1/2}dx \simeq (1+h/2)dx \quad (4)$$

will change as a function of time, and the two test particles will experience a relative acceleration. On this basis, we may associate a Newtonian tidal force with the radiation field, equal to the mass of a test particle times its acceleration referred to a fiducial test particle. From equation (4) this force is given by

$$F = m\ddot{h}dx/2 \simeq m\ddot{h}l/2; \ddot{h} \equiv d^2h/dt^2 \quad (5)$$

It is clear that this result must be general, and the tidal force will act on all particles, freely falling or not.

To visualise the effect of this gravitational tidal force on the ions and electrons in a conductor, it is convenient to consider a conductor whose centre ( $l = 0$ ) is in free fall. Then a force  $(\frac{1}{2}m\ddot{h})l$  will act on an ion at distance  $l$  from the centre, and in complete analogy with equation (2), an electric field  $E$  and associated voltage  $V$  must result

$$E = \Lambda m\ddot{h}l/2e; V = \Lambda m\ddot{h}l^2/4e \quad (6)$$

We must emphasise the theoretical foundation of this result. It rests entirely on equation (2), which we consider to be experimentally established, and on equation (5). If gravitational radiation exists, it is hard on dimensional grounds alone to conceive of a gravitational theory in which an equation analogous to (5) does not hold. Equation (6) would thus seem to rest on equally firm ground.

We can estimate the voltage  $V$  in equation (6) for some radiation sources studied by ref. 9. For the Crab pulsar a very rough estimate is  $h \sim 10^{-27}$  at a frequency  $\omega = 2\pi(60) \text{ Hz} = 377 \text{ Hz}$ ; then with  $m$  taken as the mass of a copper ion and  $l$  as 2 km we obtain a very small value of  $\sim 10^{-23} \text{ V}$ . For a typical supernova in the Virgo cluster of galaxies  $h \sim 10^{-21}$  at a characteristic frequency of  $\omega \sim 6 \text{ kHz}$ ; with  $\ddot{h} \sim h\omega^2$  we then obtain a more optimistic value of  $\sim 10^{-15} \text{ V}$ . Such supernova occur about once a month. Supernovae in our Galaxy would give a voltage  $\sim 3$  orders of magnitude greater, but are of less interest since they occur about once a century.

It is amusing to speculate very briefly on the qualitative design of a practical antenna based on these ideas. To obtain the voltage differences calculated above over a small distance we might consider two conductors of different metals many kilometres in length, the voltage difference at the ends then being proportional to the difference in the values of  $\Lambda$  for the two metals. It would presumably be preferable to use superconductors to minimise thermal and other spurious noise, and a superconducting cover has the added advantage of being a perfect shield against external electromagnetic radiation.

Discussions with B. Zeks and R. Tabensky, have been most helpful. This work has been supported in part by Banco do

Desenvolvimento Econômico, Conselho Nacional de Pesquisa, and CAPES (Brazil), and in part by the US Energy Research and Development Administration.

## Palaeozoic and Mesozoic age trends for some ring complexes in Niger and Nigeria

OVER 40 individual granitoid ring complexes exhibiting similar petrological and geochemical variations have been recognised in Nigeria<sup>1</sup>. They range in size from 1,500 km<sup>2</sup> to < 2 km<sup>2</sup>. The ring complexes form part of a more extensive chain along the ninth meridian, extending from the north of the Air Massif through southern Niger and northern Nigeria to the north-western margin of the Benue Trough in Nigeria (Fig. 1). In

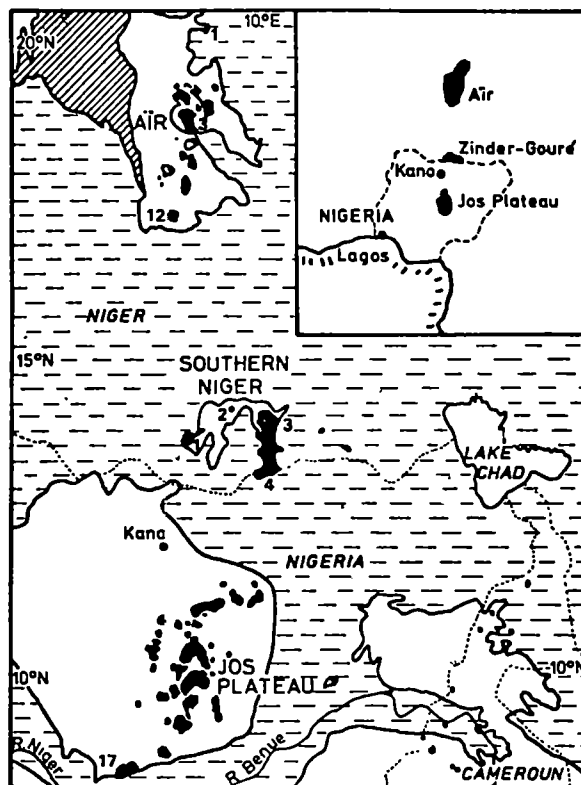

Fig. 1 Distribution of the Palaeozoic and Mesozoic ring complexes in Niger and Nigeria. The identification numbers of individual complexes are taken from ref. 1: 1 Air (mid-Palaeozoic); 1 Adrar Bous, 3 Tamgak-Enfoud group, 12 Tarraouadi; southern Niger (Upper Palaeozoic); 1 Zinder, 2 Tchouli-Zarniski, 3 Gouré, 4 Matsena; Nigeria (Mesozoic), 17 Afu. Shading: clear, Precambrian 'Basement'; diagonal, Palaeozoic; horizontal, Cretaceous-Recent.

Fig. 2 Rb-Sr whole-rock isochron for the Gouré complex, Mounio Massif, southern Niger. Open circles with G numbers 8–28 represent samples from Gouré. Two additional samples G29 and G30 shown by closed circles, were collected from Adoumchi 20 km south of Gouré airport.  $\lambda = 1.39 \times 10^{-11} \text{ yr}^{-1}$ .

general the suite of Nigerian complexes are concentrated in a 200-km wide north-south zone and centred around the Jos Plateau. We have previously<sup>2</sup> investigated the group of ring complexes forming the central zone of anorogenic magmatism in Nigeria, and found a southerly decreasing age trend from early Jurassic to mid-Jurassic times. We give here further evidence for this trend, and point out that its recognition may be useful in ascertaining the drifting motion of the African continent.

The radiometric evidence<sup>2</sup> we found was consistent with cross-cutting relationships of individual complexes, but the validity of any systematic age sequence in chains of igneous ring complexes has been questioned<sup>3–5</sup>. We wish to draw attention to the following observations. New geochronological data for Zaranda, a syenite-related granitoid complex in northern Nigeria<sup>6</sup>, yields an age of  $190 \pm 10$  Myr. In contrast the Afu complex, which represents the southernmost Nigerian ring structure exposed beneath the Cretaceous–Recent sedimentary cover, has yielded a mean age of  $144 \pm 2$  Myr. This range of dates indicates that the individual granitoid ring complexes were not emplaced into the upper crust at the same time (150 Myr

ago) but evolved during the Upper Triassic and Jurassic. Many of the complexes display a complete magmatic cycle, and evidence suggests that the development of an individual centre was established  $\leq 5$  Myr and then migration continued.

There are two anorogenic ring complex sub-Provinces in Niger represented geographically by southern Niger and by the Air Massif. The southern Niger region<sup>1</sup>, consists of the complexes of Zinder, Tchoumi-Zarniski and the southerly trending Mounio Massif from Gouré to Matsena (Fig. 1), a series of overlapping centres similar to the Sara-Fier Complex in Nigeria<sup>7</sup>, together with several isolated centres further to the east. Seven subvolcanic granites and porphyries from the Gouré Complex plot on a concordant isochron (Fig. 2) corresponding to an age of  $302 \pm 5$  Myr. Two samples from Adoumchi, the subsequent centre south of Gouré, plot slightly below the isochron suggesting a younger age of  $\sim 295$  Myr. The granite at Zinder yields an age of  $330 \pm 6$  Myr. The age-range for the southern Niger region remains to be confirmed in detail, but it is reasonable to conclude that anorogenic magmatism took place between 340 and 290 Myr ago, and that this period should be regarded as chronologically different from the younger period of Nigerian anorogenic magmatism. On the chronostratigraphic time scale<sup>8</sup>, the ring complexes of southern Niger are Carboniferous in age, and therefore in spite of petrological and geochemical similarities, these structures are considerably older than the equivalent centres in Nigeria.

The ring complexes in the Air Massif<sup>1</sup> are generally more peralkaline than their counterparts in Nigeria, with sub-alkaline biotite granite absent or only a minor component in most of them. A further contrast is provided by the occurrence of massive coarse-grained anorthosite, in several complexes, and olivine gabbro, at Adrar Bous in the extreme north of Niger<sup>9</sup>. Six of the ring complexes lie in a southerly trending zone 250 km long, but there is a pronounced central concentration of overlapping complexes, the Tamgak-Enfoud Group (Fig. 1). Previously, the Air ring structures were believed to have been emplaced during the same interval as the 'Younger Granite' magmatism in Nigeria, although subsequent estimates based on common lead<sup>9</sup> and K–Ar (ref. 10) methods gave inconsistent dates between 200 and 300 Myr. Preliminary new Rb–Sr whole rock and mineral age determinations for Adrar Bous and Enfoud give dates of  $429 \pm 4$  Myr and  $430 \pm 15$  Myr respectively. The concordant isochron for Adrar Bous is shown in Fig. 3. If this age is accurate for the granites at Adrar Bous, it means that anorogenic magmatism commenced in the Air region during early Silurian times. Stratigraphic evidence at Adrar Bous does not support that, however: the ring complex intrudes and metamorphoses sedimentary rocks which have been assigned a Lower Devonian age<sup>9</sup>. Nonetheless, if our age data are accepted, it means that the anorogenic granites in the north and central areas of the Air Massif are mid-Palaeozoic in age and are chronologically different from their counterparts in southern Niger and Nigeria. An unpublished age ( $\sim 380$  Myr) for Tarraouadji, the southernmost complex in the Air Massif (G. Marinelli, R. Black, personal communication) suggests that the Air ring complexes evolved during the Silurian and Devonian periods.

Accepting the concept of sublithospheric heat sources for mid-plate magmatism<sup>11</sup>, the chains of ring structures in the Niger–Nigerian Province may be useful in charting the continental drift of Gondwanaland before fragmentation. According to Briden<sup>12</sup>, there were quasistatic intervals during the Palaeozoic and Mesozoic eras when the Gondwana palaeomagnetic pole positions were stationary for varying lengths of time. Although there is some disagreement regarding the exact chronostratigraphic timing of the palaeomagnetic pole groupings in the Upper Palaeozoic, an earlier Middle-Palaeozoic quasistatic interval is recorded<sup>13</sup> which coincides with the evolution of the ring complexes in Air. The systematic age range for the Nigerian ring complexes also falls within a later Mesozoic quasistatic interval. Most workers accept that actual polar wandering does not normally occur, but that the continents

Fig. 3 Rb-Sr whole-rock and mineral isochron for the Adrar Bous complex, Air Massif, northern Niger. O, Whole rocks (SA) □, alkali feldspar separates (F1 and F2).  $\lambda = 1.39 \times 10^{-11} \text{ yr}^{-1}$ .

themselves have drifted rapidly during palaeomagnetic pole shifts and have remained either stationary or moved slowly during quasistatic intervals. It is perhaps significant that in the Niger-Nigerian Province there exists three groups of granitoid ring complexes which could, with more geochronological evidence and palaeomagnetic measurements, provide a complete record of the movement of the African continent from the beginning of the Silurian to the end of the Jurassic. The age trends of the ring complexes represent the intervals during the Palaeozoic and Mesozoic eras when Africa moved slowly; the absence of intervening ring structures indicating that Africa drifted rapidly.

The long time span from Adrar Bous (429 Myr) to Afu (144 Myr) compared with their small degree of latitude separation is, however, at variance with the palaeomagnetically predicted amount of drift over a single fixed point heat source.

We thank the Royal Society, the Carnegie Trust and NERC for financial support. The Geological Survey of Nigeria and the Sahara 74 Expedition provided transport and assistance in the field.

## Age of the migmatisation in the Dalradian of Shetland

WE have dated samples of schistose granite from Shetland using Rb-Sr methods. This provides further evidence for the early phase of Caledonian high grade metamorphism and migmatisation (the Grampian event) which has been detected all the way from western Ireland to northern Norway.

The Colla Firth Group, part of the East Mainland Succession of Shetland, is predominantly composed of steep to vertically-dipping regionally metamorphosed felspathic sandstones with a thickness of up to 4 km (refs 1, 2). These rocks have been correlated with the middle Dalradian of Scotland<sup>2,3</sup>. They contain a conformable belt of gneiss 1-2 km wide called the Colla Firth permeation belt<sup>1</sup> which can be followed from the southern end of Shetland for ~ 50 km to the north where it is intersected by the Nesting fault and offset 16 km to the south. The offset part of the belt can be followed for a further 20 km to the north-east before it disappears into the sea (Fig. 1). K-Ar ages of ~ 420 Myr have been obtained from nearby rocks<sup>4</sup>.

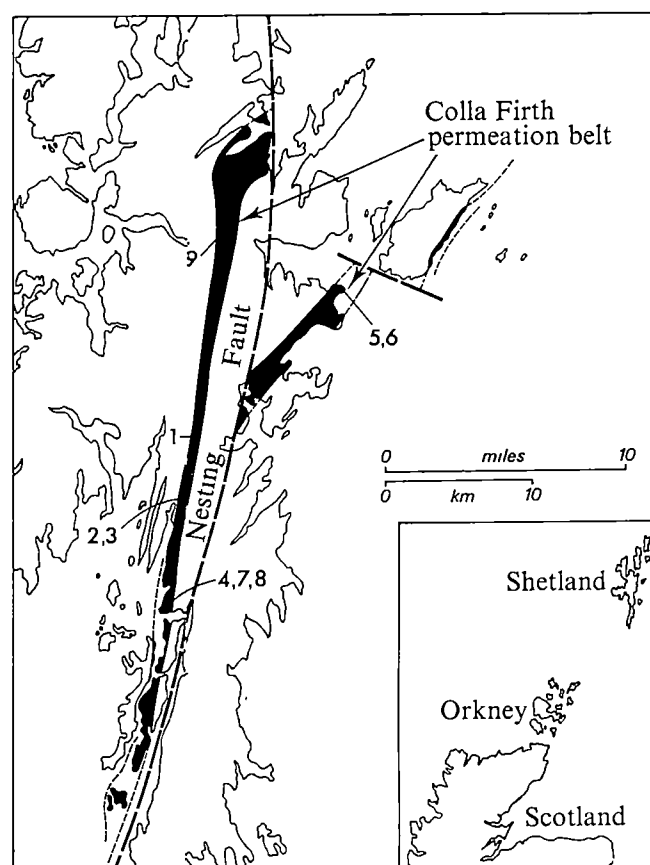

Fig. 1 Location of specimens.

Along most of the length of the belt the regionally metamorphosed rocks have been changed from semipelites and psammites to gneisses, characterised by streaks of coarse quartz and felspar, and to rather homogeneous granitoid gneisses. Along its entire exposed length the belt contains frequent intrusive sheets of non-schistose pegmatite and of schistose granite. In places it contains much larger masses of the schistose granite a kilometre or more across. All of these intrude both the gneisses and the adjacent unmigmatized rocks. It has been argued elsewhere that the migmatite belt was formed after the tectonising regional metamorphism of the adjacent rocks, this latter metamorphism being the earliest one discernable in the Colla Firth Group<sup>2,3</sup>. According to this interpretation, the schistosity in the granite veins and the tectonite fabric of the gneisses are the result of late movements accompanying the migmatisation. May<sup>5</sup> has claimed, however, that the schistosity in the granite veins and the schistosity in the regional metamorphic rocks are the same, so that the migmatisation and the regional metamorphism must have occurred at the same time.

To determine the age of migmatisation, eight whole rocks samples of schistose granite were analysed for Rb and Sr.

Table 1 Analytical data

Sample number	Rb(p.p.m.)	Sr(p.p.m.)	<sup>87</sup> Rb/ <sup>86</sup> Sr	<sup>87</sup> Sr/ <sup>86</sup> Sr
1	219.3	147.4	4.31	0.7540
2	238.9	135.4	5.22	0.7597
3	187.8	164.0	3.41	0.7460
4	190.0	164.9	3.43	0.7416
5	102.1	243.9	1.21	0.7313
6	162.0	193.1	2.43	0.7402
7	209.9	133.8	4.54	0.7555
8	248.6	54.99	13.24	0.8206
9	171.9	172.1	2.90	0.7376

Fig. 2 Rb/Sr whole-rock isochron.

They are all composed of quartz, muscovite, plagioclase, microcline and biotite. Specimen 9 is from a granite gneiss intermediate in nature to the schistose granites and the migmatite gneisses. It was included to determine whether it could be correctly classed as a schistose granite.

Following preliminary analyses by X-ray fluorescence to determine Rb and Sr contents for sample selections and for spiking purposes all samples were analysed by standard isotope dilution techniques and the results of these analyses are given in Table 1 and plotted in Fig. 2. Sample 9 is not included in the isochron calculation which, using York's method II<sup>6</sup>, yields an age of  $530 \pm 25$  Myr with an initial  $^{87}\text{Sr}/^{86}\text{Sr}$  ratio of  $0.7210 \pm 0.0015$ . This age and all other Rb-Sr ages quoted are calculated using  $\lambda^{87}\text{Rb} = 1.39 \times 10^{-11} \text{ yr}^{-1}$ ; the errors given are all  $2\sigma$ . Considering the distribution of the data points, it is possible that sample 4 is associated with 9, and that 8, because of its relatively high Rb/Sr ratio, has a different source. As no geological or petrographical evidence could be found to support these possibilities they have not, however, been excluded. In fact, the ages obtained by excluding various selections of these data points from the isochron calculation all fall within the lower uncertainty limit of the preferred value given above.

The initial  $^{87}\text{Sr}/^{86}\text{Sr}$  ratio of 0.7210 is in accordance with a crustal melting source for the schistose granite veins and thus with their derivation from the gneisses of the permeation belt. The age of  $530 \pm 25$  Myr for the schistose granite veins is thus believed to be a good estimate of the age of the permeation belt as a whole. If May<sup>5</sup> is correct this is also the age of the main phase of the regional metamorphism, but it is more likely that this took place earlier.

This age of  $530 \pm 25$  Myr for migmatization in Shetland is in complete agreement with ages determined for this event in Connemara,  $520 \pm 30$  Myr (refs 7, 8) and North Norway,  $530 \pm 35$  Myr (refs 7, 9). In Scotland, Bell's<sup>10</sup> determination of the age of the Ben Vuirich granite has been recalculated by Dunning<sup>7</sup> to be 511 Myr. This granite is about the same age as adjacent migmatites in middle Dalradian rocks, the Duchray Hill Gneiss, according to H. J. Bradbury (personal communication). The age of the schistose granite from Shetland agrees with ages for the main phase of high grade metamorphism in the other parts of the Caledonian fold belt.

## Simultaneous measurements of $\text{H}_2\text{O}$ , $\text{NO}_2$ and $\text{HNO}_3$ in the daytime stratosphere from 15 to 35 km

USING Fourier transform spectroscopy in the far infrared with a Michelson interferometer, and helium-cooled bolometric detectors, it is possible to study the emission spectrum of the stratosphere at high resolution ( $0.05 \text{ cm}^{-1}$ ) in the spectral range  $5-45 \text{ cm}^{-1}$  (see refs 1-3).

We report here initial results from two daytime high altitude balloon flights undertaken during the past year, using far infrared Michelson interferometers, to measure concentrations of several trace gases to altitudes of about 35 km. The aim of the work was to investigate the concentrations of several gases simultaneously, using the wide bandwidth and high resolution capabilities of the Fourier technique. It is possible to obtain information on  $\text{H}_2\text{O}$ ,  $\text{O}_3$ ,  $\text{HNO}_3$ ,  $\text{N}_2\text{O}$  and  $\text{NO}_2$  in one scan of the far infrared interferometer. Results on  $\text{H}_2\text{O}$ ,  $\text{HNO}_3$  and  $\text{NO}_2$  only are presented here, measured at 1200 LT.

The flights were made from the Centre National d'Etudes Spatiales (CNES) balloon launching facility at Aire-sur-l'Adour in south-western France, on September 12 and September 20, 1974. Launches were achieved at about 0900 LT, and observations at altitude (34-36 km) were made during the local noon period.

The experimental system was similar to that used in previous aircraft experiments, though with several modifications and improvements to accommodate the more

Fig. 1 Portion of a far infrared emission spectrum obtained while floating at 35 km, at a zenith angle of  $92^\circ$ . The curve is an average of five runs each taking 8 min to record. The spectral resolution is  $0.07 \text{ cm}^{-1}$  (unapodised). Shaded line, range of possible centre wavenumbers for the  $\text{NO}_2$  Q branch, as judged from theoretical and experimental sources, arrows, resolution width and signal-to-noise ratio (estimated from reproducibility of different spectra).

Fig. 2 Vertical profile of mixing ratio for  $\text{H}_2\text{O}$ ,  $\text{HNO}_3$  and  $\text{NO}_2$ , measured during the flight of September 20, 1974 at  $44^\circ\text{N}$   $0^\circ\text{W}$ . Uncertainties given in the text. Mass units are given for  $\text{H}_2\text{O}$  and volume units for  $\text{NO}_2$  and  $\text{HNO}_3$ .

difficult and remote operating conditions encountered on a balloon flight. A full description will be given elsewhere, but it should be noted that limb scanning was used to build up a vertical profile of concentration while the package floated at ceiling. The instrument was stabilised against motions of the gondola by reference to the solar elevation angle which was measured in real time; these motions proved to be very small (amplitude less than  $0.1^\circ$ ). A helium-cooled InSb electron bolometer was used.

Figure 1 shows a portion of a typical spectrum, for the range  $34\text{--}39\text{ cm}^{-1}$ , at a spectral resolution of  $0.07\text{ cm}^{-1}$ . Features seen are attributable to  $\text{H}_2\text{O}$ ,  $\text{O}_2$ ,  $\text{O}_3$  and  $\text{NO}_2$  (refs 2–6); other features attributable to these gases, and to  $\text{HNO}_3$  and  $\text{N}_2\text{O}$ , occur at lower wavenumbers.

The results of the September 1974 flights for  $\text{H}_2\text{O}$ ,  $\text{HNO}_3$  and  $\text{NO}_2$  between 15 and 35 km are shown in Fig. 2. It is an important feature of our technique that the profiles were measured simultaneously; the measurements were made during the period  $\pm 1\text{ h}$  around noon on September 20, 1974. The uncertainties are typically  $\pm 15\%$  for  $\text{H}_2\text{O}$ ,  $\pm 25\%$  for  $\text{HNO}_3$ , and  $\pm 35\%$  for  $\text{NO}_2$ , and are attributable to uncertainties in radiometric calibration, line intensity measurement, observation angle, and spectroscopic parameters such as integrated line strength.

The results for  $\text{H}_2\text{O}$  show a gradual increase in volume mixing ratio from about 3.0 p.p.m. (by volume) at 15 km to about 5.5 p.p.m. at 33 km. For  $\text{NO}_2$  we found about 4 parts per  $10^9$  at 25 km rising to about 18 parts per  $10^9$  at 33 km, with slight evidence of a maximum at this level. In the case of  $\text{HNO}_3$  a pronounced maximum occurs at about 25 km with mixing ratios of about 9 parts per  $10^9$ .

The water vapour result agrees well with previous measurements made from aircraft<sup>2,3</sup> and with data obtained from an earlier single balloon flight over the UK<sup>7</sup>. We have not previously observed such a marked increase of mixing ratio with altitude as is shown in Fig. 2, however, though several measurements support the occurrence of somewhat more humid layers of air above 30 km (refs 8, 9 and 16) in some cases with mixing ratios up to 10–20 p.p.m. There remains a considerable degree of

variability between results above about 30 km, however, and it must be accepted that our understanding of the humidity of the upper stratosphere is far from complete. It should be noted that the apparent increase with height observed in the present results is significant in terms of the relative uncertainty attributable to random errors at different altitudes, since most of the uncertainty indicated in Fig. 2 arises from systematic effects.

In the case of nitric acid, our results agree well with those of Murcray *et al.*<sup>10</sup>, who at mid-latitudes have reported volume mixing ratios around 5 parts per  $10^9$  volume at about 23 km. The extensive data reported by Lazrus *et al.*<sup>11</sup> seem to be consistently lower in absolute value than our own results and those of Murcray, however. A nitric acid profile suggested by Fontanella *et al.*<sup>12</sup>, for a similar latitude to that at which our measurements were taken shows a lower peak (nearer 20 km) but absolute values of mixing ratio similar to our own.

Turning to nitrogen dioxide, there have been a large number of measurements in the past two years of this species, with some disparity between the different results. Murcray *et al.*<sup>10</sup> report values ranging from 1.5 parts per  $10^9$  at 20 km to 5 parts per  $10^9$  at 28 km. Fontanella *et al.*<sup>12</sup> report values of about 1 part per  $10^9$  at 20 km and 0.3 parts per  $10^9$  at 15 km. The last two sets of data refer to sunrise or sunset conditions since the solar absorption/limb-sounding method has been used in each case, and the exact timing of the measurements relative to local sunrise/sunset is not available. It is important to identify this relative time very accurately since it is now known that the concentration of  $\text{NO}_2$  varies rapidly at dawn and sunset (some recent data have been obtained on the variability of  $\text{NO}_2$  at sunrise from our own measurements, and these will be published shortly). Farmer *et al.*<sup>13</sup> have also reported  $\text{NO}_2$  measurements using the solar absorption technique, and obtained about 1.8 parts per  $10^9$  between 15 and 20 km.

Daytime, as well as early morning and evening measurements of  $\text{NO}_2$  have been reported by Brewer *et al.*<sup>14</sup>. They report values of around 50 parts per  $10^9$  at 30 km at mid-day, but Johnson<sup>15</sup> has reinterpreted the data and has obtained values nearer 10 parts per  $10^9$ , with only slightly lower values at dawn. Results obtained by Chaloner *et al.*<sup>16</sup> show midday profiles ranging from about 6 parts per  $10^9$  at 20 km to 15 parts per  $10^9$  at 35 km.

Clearly, therefore, there is a range of results; at 25 km for example, values vary from about 1 to 10 parts per  $10^9$ . Our own value here is  $\sim 3.5$  parts per  $10^9$ . In measurements as difficult as this, however, it is in our view reassuring that such close agreement is obtained, and, certainly natural variations must be allowed for in assessing the various results.

Further balloon flights have been made, in April 1975, which spanned sunrise. The results of these flights will be reported shortly, and contain information on the diurnal variability of  $\text{NO}_2$ .

We thank Dr N. W. B. Stone for his help and comments on this work. The work was supported by the Committee on the Meteorological Effects of Stratospheric Aircraft.

## Search for correlation between geomagnetic disturbances and mortality

It is generally accepted that the Sun affects the Earth's magnetosphere and ionosphere by variations in the ultraviolet and X-ray radiation and in the solar wind due both to short lived disturbances such as flares<sup>1</sup> and to long lived effects such as that associated with the 'sector structure' of the interplanetary magnetic field<sup>2</sup>. There have, however, been repeated claims<sup>3,4</sup> for well over a century that the Sun influences many other processes on Earth, including terrestrial weather and human disorders. Friedman, Becker and Bachman<sup>5-7</sup> have presented evidence for an association between geomagnetic storms, cosmic-ray flux variations and psychological behaviour. The term geomagnetic storm is used for worldwide fluctuations in the Earth's field with a scale of about 100γ over a period of several hours, caused by the impact of a solar plasma front on the magnetosphere. A number of Russian scientists<sup>8-10</sup> have claimed that there is a real association between geomagnetic storms and the incidence of various human diseases. Within this general area, one of the most active areas of current research seems to be the correlation of solar activity and myocardial infarction and stroke. We have searched for a similar correlation in the USA but have failed to find one.

Gnevyshev and Novikova<sup>10</sup> refer to the work of several other groups, published in Russian and unavailable to us. Seventeen papers are referenced, all of which are said to suggest the possibility of direct effects of solar activity on living organisms. They present evidence of two types: first, the results of direct experiments in which biological systems were placed in artificially induced electromagnetic oscillations and second, studies of correlation between geomagnetic indices and mortality due to heart disease and stroke, using the method of superposed epochs and comparison of averaged medical data on days of different geomagnetic activity. The results presented seem to indicate positive correlations, but no estimates of statistical significance are given. We therefore performed similar statistical analyses using US data. Daily numbers of deaths due to specific causes were obtained from the National Center of Health, referring to the actual date of death rather than the registration date.

Geomagnetic activity is measured by magnetic indices. Local *K* indices are based on the measured amplitude of variation over a 3-h interval; corrections for local effects are applied to give world *Ap* indices. Another form of geomagnetic activity is due to hydromagnetic emissions which are enhanced after geomagnetic storms and produce ultra low frequency (~ 1 Hz) fluctuations in the terrestrial magnetic field. This type of activity is measured by a local *W* index which represents the number of 15-min intervals in a 24-h day that contain hydromagnetic emissions.

We compared daily numbers of deaths in the USA due to coronary heart disease and stroke for 1962-66 with the corresponding *Ap* indices using three methods. Mortality data were normalised to remove weekly and seasonal variations and a long term secular trend, since we were looking for short term correlations with natural events. This was done by renormalising with respect to average yearly and weekly curves for the 6-yr period and a linear ramp obtained by least-squares fitting. Mortality and geomagnetic data are shown in Fig. 1.

Our first method was to calculate the correlation coefficient  $r_k$  between daily deaths  $D_i$  and  $A_i$ , the daily value of *Ap*, where  $i (= 1, \dots, N)$  enumerates days. In the formula

$$r_k = \frac{\sum_{i=1}^{N-k} (A_i - \bar{A})(D_{i+k} - \bar{D})}{(N-k)\sigma_A\sigma_D} \quad (1)$$

$k (>0)$  represents the number of days *D* lags *A*;  $k < 0$  indicates a lead;  $\bar{A}$ ,  $\bar{D}$  are means of the time series;  $\sigma_A$ ,  $\sigma_D$  are the standard deviations. The standard error of  $r_k$  is given by

$$\sigma_{r,k} = (N - |k| - 1)^{-1/2}(1 - r_k^2) \quad (2)$$

Fig. 1 *a*, Daily US mortality from coronary heart disease, 1962-66. Averaged deaths: Sunday, 1489.1; Monday, 1551.3; Tuesday, 1493.9; Wednesday, 1487.9; Thursday, 1489.6; Friday, 1504.9; Saturday, 1527.3. *b*, Normalised data obtained from *a*. Averaged deaths are the same for each day of the week and equal to 1507.1. *c*, Daily US mortality from stroke, 1962-66. Averaged deaths: Sunday, 549.3; Monday, 555.8; Tuesday, 547.8; Wednesday, 546.4; Thursday, 543.0; Friday, 547.1; Saturday, 552.3. *d*, Normalised data obtained from *c*. Averaged deaths are the same for each day of the week and equal to 549.1. *e*, Geomagnetic *Ap* index, 1962-66.

**Fig. 2** Superposed epoch diagrams for mortality due to coronary heart disease and stroke for the period 1962–66. An event occurs when  $A_p$  on day zero lies in the ranges given. Mean daily deaths for the total sample and standard deviations ( $\sigma$ ) about the mean: coronary heart disease 1507.1, 57.9, stroke 549.1, 27.3. Departures from the mean are measured in units of  $\sigma/\sqrt{n}$  where  $n$  is the number of events.

Results for  $-14 \leq k \leq 14$  are given in Table 1. We found no evidence for correlation at the  $3\sigma$  significance level, a criterion we used throughout the analysis. For nearly all  $k$ , the correlation coefficient is negative, indicating that a small, long term anticorrelation exists. This effect, which is not relevant to our study, arises from low frequency trends in the data.

As an alternative procedure, we constructed superposed epoch diagrams for deaths on days with  $A_p$  in selected ranges. Results are shown in Fig. 2, plotted as deviations from the mean daily deaths of the total sample. The deviations were scaled by  $\sigma/\sqrt{n}$  where  $n$  is the number of superposed events and  $\sigma$  is the standard deviation from the mean of the total sample, so that each plot would have the same width of scatter if the selected subsets were simply a random selection from the total sample. This allows direct comparison of the diagrams and easy detection of statistically significant deviations. In most of the diagrams, the averaged superposed daily deaths throughout the period are less than the total sample mean, another manifestation of the small long term trends already noted. No diagram gives evidence for a statistically significant association between daily deaths and magnetic index.

The third method of presentation was to plot averaged deaths as a function of magnetic index for  $-20 \leq k \leq 20$ . Again there was no evidence for a significant effect.

Since Gnevyshev and Novikova<sup>10</sup> studied the relationship between mortality levels and geomagnetic indices for individual cities, rather than an entire nation, the above analyses were repeated for 3 metropolitan areas. Daily deaths during 1964 and 1965 due to coronary heart disease in Phoenix, Honolulu and Washington, DC were compared with local  $K$  indices. Some results for zero lag are given in Fig. 3, using the third method of presentation. None of the results shows any evidence for correlation.

Finally, we compared daily deaths due to coronary heart disease in San Francisco in 1964 and 1965 with the  $W$  index for micropulsations. We did this test because Gnevyshev and Novikova attribute their claimed relationship between geomagnetic activity and mortality levels to low frequency fluctuations in the geomagnetic field. Some results for zero lag are given in

**Fig. 3.** These analyses also showed no evidence for an association.

In summary, our study does not support the findings of Gnevyshev and Novikova, nor their proposal for a new branch of science—heliobiology. It is possible that the correlations they find are either not statistically significant or not due to a causal relationship between geomagnetic disturbances and

Deaths lag behind geomagnetic event if  $k > 0$ , and lead if  $k < 0$ . Standard error in  $r_k$  is constant to 3 decimal places and equal to 0.023.

Fig. 3 Averaged mortality due to coronary heart disease as a function of magnetic index for zero lag. *a*, Washington, DC; *b*, Phoenix; *c*, Honolulu; *d*, San Francisco. For *a*, *b* and *c* the magnetic index used was the sum of local *K* indices for the day; *d* the local *W* index was used.

coronary heart disease and stroke. If their correlations are indeed indicative of a causal relationship, it will be necessary to determine whether it is sensitive to geographical location, to phase of the solar cycle or to some other parameter which might distinguish the samples we have analysed from those of the Soviet scientists.

We wish to thank Professor P. Switzer for helpful discussion

and Dr A. C. Fraser-Smith for providing us with the *W* indices. This work was supported by the NSF and NASA.

## Hardy-Weinberg ratios and rare male mating advantage

PETIT<sup>1</sup> and others have shown that in a variety of *Drosophila* species the mating success of male genotypes is often dependent on their frequency in the population. This frequency-dependent mating effect seems to be relatively unimportant in females, and by favouring rare male genotypes represents a possible mechanism by which genetic variation can be maintained in a population. Whether or not this form of selection is widespread in natural populations is unknown, although, in the laboratory at least, it has been shown that the phenomenon occurs in insects other than *Drosophila*<sup>2,3</sup>.

Can this type of selection be detected in the wild without resorting to mating experiments? Unfortunately precise mathematical analysis of the problem, even at the simplest level, is complex and requires the choice of specific functions to describe how male mating success changes with gene or genotype frequency<sup>4</sup>. A more general approach can, however, be adopted, which, while not providing exact answers, highlights two possible problems in detecting frequency-dependent mating effects in natural populations.

Consider a single autosomal locus segregating *n* alleles in a large population of some sexual species. Assume that the generations are separate and that all *n* alleles are maintained in the population by frequency-dependent male mating effects. Other selective forces are assumed to be equal over all alleles. Let the mating success of a male of genotype *ij* be denoted by the function *F<sub>ij</sub>* (which may be dependent on any number of the allele frequencies), the frequency of that genotype be *g<sub>ij</sub>* and the frequency of allele *i* be *p<sub>i</sub>*.

The frequency of each genotype in the next generation can now be calculated by considering the two populations of gamete types. The frequency of each allele in the pool of eggs is unaffected by selection but in the pool of sperm the frequency of allele *i* will be

$$p_i' = (g_{ii}F_{ii} + \sum_k g_{ik}F_{ik}/2)/\bar{w}$$

where *i* ≠ *k*, and  $\bar{w}$  ensures that the sum of all frequencies is one. The genotype frequencies in the next generation are given by

$$g_{ii}' = p_i p_i' \quad (1a)$$

$$g_{ij}' = p_i p_j' + p_i' p_j \quad (i \neq j) \quad (1b)$$

At equilibrium the new genotype frequencies are the same as the old and substituting (1a) and the equivalent relationship

for the homozygote  $j/j$  into (1b) yields the set of equilibrium equations

$$\hat{p}_i \hat{p}_j \hat{g}_{ij} = \hat{p}_i \hat{g}_{ji} + \hat{p}_j \hat{g}_{ii} \quad (2)$$

Given the formula relating an allele frequency to its constituent genotype frequencies and that both allele and genotype frequencies sum to one, then the equilibrium form (2) defines the Hardy-Weinberg ratios. Thus, in the conditions of this model, selective forces acting on the sexual success of only one sex cannot be measured, or even suspected, by looking for deviations from the Hardy-Weinberg ratios in a population at, or close to, genetic equilibrium.

A second approach, possible when females are fertilised by only one male per brood, is to assess the frequency of different matings. In particular, consider the mating of the two genotypes  $i/j$  and  $k/l$ . Provided that not all of  $i, j, k$  and  $l$  are the same, it is then possible to compare directly the frequency of such crosses when the female is  $i/j$  to when the male is  $i/j$ . The ratio of these two frequencies gives a direct estimate of the relative fitness of the two males ( $F_{kl}/F_{il}$ ).

The direct comparison of mating frequencies can be extended further in populations at genetic equilibrium, since genotype and allele frequencies can then be related by the Hardy-Weinberg result. For example, if the alleles,  $i, j, k$  and  $l$  are all different then the expected frequency of an  $i/j$  female mating with a  $k/l$  male is  $(2\hat{p}_i\hat{p}_j)(2\hat{p}_k\hat{p}_l)F_{kl}/\bar{w}$  and that for a  $k/j$  female mating with an  $i/l$  male is  $(2\hat{p}_k\hat{p}_j)(2\hat{p}_i\hat{p}_l)F_{il}/\bar{w}$ , thus the ratio of these two frequencies again gives a direct estimate of the relative fitness of the two males ( $F_{kl}/F_{il}$ ). The size and number of groups of matings which can be compared in this way depend on the number of alleles segregating. Table 1 shows examples of the largest groups of matings which can be compared directly for two, three and four or more alleles. Of course, all possible comparisons could be made, but this method has the advantage that expectations are independent of genotype and allele frequencies.

**Table 1** Examples of the largest number of direct mating frequency comparisons which can be made in an equilibrium population segregating 2, 3 or 4+ alleles

Number of alleles	Mating ♀	♂	Expected frequency (with selection)	Expected ratio (no selection)
2	1/2	1/2	$4p_1^2p_2^2F_{12}/\bar{w}$	4
	1/1	2/2	$p_1^2p_2^2F_{22}/\bar{w}$	1
	2/2	1/1	$p_1^2p_2^2F_{11}/\bar{w}$	1
3	1/2	2/3	$4p_1p_2^2p_3F_{23}/\bar{w}$	2
	2/3	1/2	$4p_1p_2^2p_3F_{12}/\bar{w}$	2
	1/3	2/2	$2p_1p_2^2p_3F_{22}/\bar{w}$	1
	2/2	1/3	$2p_1p_2^2p_3F_{13}/\bar{w}$	1
4+	1/2	3/4	$4p_1p_2p_3p_4F_{34}/\bar{w}$	1
	3/4	1/2	$4p_1p_2p_3p_4F_{12}/\bar{w}$	1
	1/3	2/4	$4p_1p_2p_3p_4F_{24}/\bar{w}$	1
	2/4	1/3	$4p_1p_2p_3p_4F_{13}/\bar{w}$	1
	1/4	2/3	$4p_1p_2p_3p_4F_{23}/\bar{w}$	1
	2/3	1/4	$4p_1p_2p_3p_4F_{14}/\bar{w}$	1

In the case of a sex-linked locus, the female population (assumed to be homogametic) is still in Hardy-Weinberg ratios at equilibrium (the males representing the allele frequencies directly). Therefore direct comparisons analogous to those of Table 1 can be made, although the maximum number of matings in each group of comparisons is reduced to two for a pair of alleles or to three otherwise (but note that the number of male genotypes is also reduced).

The use of direct mating comparisons in equilibrium populations can indicate and measure mating selection but the method has the disadvantage of not being powerful enough to dismiss

the possibility of even strong frequency-dependent effects. This is because under such circumstances selective values may be very similar at genetic equilibrium, and thus equilibrium analysis, however detailed, may be fruitless.

The preceding suggests that if frequency-dependent (or indeed constant) sexual selection is acting on one sex to maintain a polymorphism, then, at genetic equilibrium, deviations from Hardy-Weinberg ratios are not expected, but an analysis of the occurrence of specific matings may reveal the selection. Failure to demonstrate selection at equilibrium does not imply that it is not acting or that it is not important. Only the analysis of perturbation experiments can be used to eliminate this form of selection as an important stabilising influence.

I would like to thank Maurice Dow for his valuable comments.

## Energetic cost of locomotion in Australian hopping mice

THE mode of locomotion of the hopping mouse can be compared with that of the kangaroo moving bipedally at speed. Because the latter cannot be monitored due to technical difficulties, I have used the hopping mouse in a study of the energetics of this type of locomotion at speeds of 0.5-7 km h<sup>-1</sup>. I found that at 2.5-3 km h<sup>-1</sup>, the stride frequency stabilised, as did steady-state oxygen consumption. Above 5 km h<sup>-1</sup> oxygen consumption again increased although stride frequency did not. The result of this pattern was that the costs of hopping in *Notomys cervinus* were markedly below those predicted for a quadruped. The overall pattern had similarities with those displayed by kangaroos<sup>1</sup>.

I used three specimens (34-38 g) of *N. cervinus*, the fawn hopping mouse, native to Australia, collected in stony desert in western Queensland. This species can be trained on a treadmill and hops readily. Energy cost was estimated from steady-state oxygen consumption measured for 15-30 min while the animals travelled at speeds of 0.5-7.0 km h<sup>-1</sup> inside a Perspex chamber (40×10×15 cm) with a flexible seal at its base. Air was drawn through the chamber at approximately 4 l min<sup>-1</sup>, and nitrogen, bled into the chamber at a constant rate, indicated that, at all speeds, there was no leakage of air out of the chamber. Oxygen consumption was measured with a Beckman F-3 paramagnetic analyser with a full scale of 20.5-21% oxygen. Air temperature was maintained at 26-28 °C so that shivering did not affect the oxygen consumption at lower speeds—such an effect was apparent in initial experiments at 17-19 °C. Strides were monitored using a video camera with a slow motion playback capability. Twenty sequences of twenty strides were counted for each animal at each speed, and stride length was calculated from stride frequency and treadmill speed.

Oxygen consumption was similar for all three animals, although one had a consistently higher consumption (Fig. 1). Between 0.5 and 2.5 km h<sup>-1</sup> oxygen consumption increased linearly with increasing speed. At these speeds the mice either 'trotted' with the hind legs moving independently or 'galloped' quadrupedally with the hind legs

Fig. 1 Steady-state oxygen consumption of the hopping mouse *N. cervinus* as a function of speed. The mean values at each speed (●) are joined by the solid line. Values for individual animals are indicated by different symbols. The dashed line represents the oxygen consumption predicted for a mammal the same weight as the mean weight of the hopping mice, 36.6 g.

moving together. During this phase the energy cost did not diverge markedly from that predicted for a quadruped<sup>2</sup>. An increase in speed in this range was accomplished by increases in stride frequency and length (Fig. 2).

As in the case of kangaroos<sup>1</sup>, oxygen consumption reached a plateau at the speeds at which stride frequency became nearly constant, 3 km h<sup>-1</sup>. This stability in energy cost did not persist, however, although stride frequency remained constant at speeds > 7 km h<sup>-1</sup>. At > 4.5 km h<sup>-1</sup>, oxygen consumption again increased with an increase in

speed, in an apparently linear manner, but at a rate well below that predicted for quadrupeds (which is a behaviour we assume kangaroos would also show at their highest speeds).

One difference between the pattern of locomotion of hopping mice and of kangaroos was that there was no immediate shift to complete hopping at the speeds at which stride frequency and oxygen consumption tended to stabilise initially (3 km h<sup>-1</sup>). More or less continual bipedal hopping was not achieved by the mice until beyond 4.5 km h<sup>-1</sup>, and the animal with consistently high oxygen consumption did not achieve complete hopping, even at 7 km h<sup>-1</sup>. The overall picture for the relationship between type of gait and speed was similar for the two animals with the lower oxygen consumption: between 0.5 and 1.5 km h<sup>-1</sup> the mice mostly trotted, between 1.5 and 2.5 km h<sup>-1</sup> they mostly galloped, and above 2.5 km h<sup>-1</sup> some hopping was apparent, initially in the form of a sequence of four to six hops interspaced with galloping. At 3.0 km h<sup>-1</sup> galloping comprised 65% of the strides and hopping 35%. The amount of hopping increased gradually until it was continuous at 6 km h<sup>-1</sup>. (Preliminary tests with other *N. cervinus* suggest that this is the common pattern.) For the third animal trotting did not change to galloping until ~ 2.5 km h<sup>-1</sup>, and significant hopping was not evident until 6 km h<sup>-1</sup>. Even at 7 km h<sup>-1</sup> hops only comprised 45% of strides. Why this animal should be different from the others was not obvious; initially it was rather recalcitrant, but with training it performed well. Hopping (or saltatorial bipedal locomotion) seems to be associated with a marked shift in the energy costs of locomotion from the patterns established for running quadrupeds<sup>2</sup> and bipeds<sup>3</sup>. This results in a much lower overall cost of locomotion in the small hopping mice and lower cost at moderate speeds in the large kangaroos.

Our data demonstrate some of the advantages of hopping, particularly for a small rodent living in a desert where food is sparse and cover for protection from predators is limited. Although reasons may also be suggested for the selective advantage of hopping for kangaroos<sup>1</sup>, there is still the question why kangaroos are the only large animals with saltatory locomotion and our experiments give some insight here also. At low speeds the *N. cervinus* largely follow the energy predictions of ref. 2 and when they diverge from this pattern they immediately achieve lower locomotory costs. Kangaroos, however, have much higher costs than predicted for quadrupeds at low speeds, and it is not until moderately high speeds (17–18 km h<sup>-1</sup> for an 18-kg animal) that the costs of hopping become less than those predicted.

In an analysis of the mechanical characteristics of very long leaps of kangaroos, Badoux<sup>4</sup> observed that, to develop the necessary acceleration, the feet must exert a force directly proportional to the animal's mass and inversely proportional to the length of leg. Taylor *et al.*<sup>5</sup> reiterated that the work involved in lifting 1 g of tissue a given vertical height is the same for small animals as for large, if the mechanical efficiency of the muscle of both animals is the same. Because both the resting metabolic rate and the relative cost of locomotion decrease with increasing weight, larger animals have to increase their metabolism by a proportionately greater amount than do small animals to lift a given weight of tissue a given height. The energetic implications of this for hopping bipeds are obvious, particularly at low speeds when elastic storage of energy would be low. The pentapedal gait of large kangaroos at slow speeds may reflect a partial answer to this problem, since anatomical specialisations limit the use of quadrupedal locomotion.

Howell<sup>6</sup> has suggested that biped hopping is an extreme form of the gallop. This is possibly illustrated by the data on the mouse with the higher oxygen consumption. While this animal did not commence significant hopping until ~ 6 km h<sup>-1</sup>, stride frequency and oxygen consumption reached

Fig. 2 a, Stride length; b, stride frequency as a function of speed for *N. cervinus* during steady-state locomotion. The values shown in both graphs are the mean values for the three individuals and the horizontal bars indicate the range of values.

their plateaux at the same speed as for the other hopping mice, 2.5–3.0 km h<sup>-1</sup>. Stride frequency tends to stabilise in most animals once they commence galloping<sup>7</sup>. Consequently it may be that a similar but smaller change in oxygen consumption occurs in other species at speeds above the transition from trotting to galloping, but that this is emphasised in species with anatomical specifications such as those for hopping. This needs further investigation since the data with which Taylor *et al.*<sup>2</sup> established a relationship between the energetic costs of locomotion and body weight were mostly collected at speeds below the trot–gallop transition. This was particularly the case for their kangaroo rats (*Dipodomys merriami* and *D. spectabilis*).

This work was supported by a grant from the Australian Research Grants Committee. I thank Professor R. E. MacMillen for advice and D. Fanning and R. McBlain for technical assistance.

## Mutants of *Klebsiella pneumoniae* resistant to several antibiotics

SPONTANEOUS antibiotic-resistant mutants that arise in bacterial populations are usually only resistant to the particular antibiotic used in the culture medium used for their isolation. In the experiments described here, however, mutants of *Klebsiella pneumoniae* resistant to chloramphenicol, sodium nalidixate and trimethoprim, three unrelated antibiotics, were obtained by including any one of the antibiotics in the culture medium. Because these multiply resistant mutants were commonly found in the alimentary tract of animals experimentally infected with antibiotic-sensitive *K. pneumoniae* and then fed on antibiotic-containing diets they may be clinically important.

Mutants resistant to antibiotics other than trimethoprim were obtained by spreading 0.75 ml of a 24-h broth culture containing ~ 5 × 10<sup>8</sup> viable organisms per ml over the surface of a well-dried plate of MacConkey's agar containing antibiotic (20 µg ml<sup>-1</sup>). The plates were incubated at 37 °C for 24 h and colonies that grew on them purified by plating on ordinary MacConkey's agar. Washed broth cultures and Sensitest agar (Oxoid, CM409) containing trimethoprim (3 µg ml<sup>-1</sup>) were used for obtaining mutants resistant to this antibiotic. Antibiotic sensitivity tests were performed by placing disks containing streptomycin (25 µg), tetracycline (30 µg), chloramphenicol (30 µg), ampicillin (25 µg), neomycin (30 µg), spectinomycin (30 µg), rifampicin (50 µg), sodium nalidixate (30 µg), sulphafurazole (50 µg), trimethoprim (1.25 µg) and furazolidone (15 µg) on the surface of plates of Sensitest agar spread with well diluted broth cultures; the plates were incubated at 37 °C for 24 h and read.

When mutants resistant to sodium nalidixate (*nal*<sup>r</sup>), chloramphenicol (*cmp*<sup>r</sup>) and trimethoprim (*tmp*<sup>r</sup>) were isolated from 27 of 32 epidemiologically unrelated strains of *K. pneumoniae* belonging to 20 different capsular types, they were found to be resistant not only to whichever of these three antibiotics were incorporated in the selection

medium but also to the other two; 50–200 colonies grew on each of the plates used. All the colonies on the chloramphenicol and trimethoprim plates that had been inoculated with five of the strains were found by replica plating to be *cmp*<sup>r</sup> *nal*<sup>r</sup> and *tmp*<sup>r</sup>. So were all those on the sodium nalidixate plates inoculated with three of these strains; a few of the 50 or so colonies that grew on each of the sodium nalidixate plates inoculated with the other two strains were *nal*<sup>r</sup> only, the remainder being resistant to the three antibiotics. Disk tests indicated that the sensitivity of these *cmp*<sup>r</sup> *nal*<sup>r</sup> *tmp*<sup>r</sup> mutants to tetracycline, streptomycin, neomycin, spectinomycin, rifampicin, polymyxin, sulphafurazole and furazolidone had not altered appreciably; the strains from which they were derived were resistant to ampicillin. Using very light inocula, six of the multiply resistant mutants were passaged ten times in 10-ml amounts of broth at 37 °C, each passage occupying 24 h; their antibiotic-resistance pattern did not alter as a result. Attempts to transfer the resistance of four of them to *Escherichia coli*, K12 were unsuccessful. The colonial morphology of the mutants was the same as that of their parent strains, and so was the capsular type of all five examined by Dr Ida Ørskov and the virulence for mice by intraperitoneal injection of the only one tested. Like their parent strains, the mutants were prototrophic.

**Table 1** Minimum inhibitory concentration of antibiotics for *K. pneumoniae* mutants and their parent strains

Antibiotic	Median MIC (µg ml <sup>-1</sup> ) for	
	parent strains	mutants
Sodium nalidixate	3	100
Chloramphenicol	3	100
Trimethoprim	0.4	25
Tetracycline	3	12
Sulphafurazole	50	100
Furazolidone	0.8	1.5
Streptomycin	1.5	1.5
Neomycin	1.5	1.5
Spectinomycin	12	12
Rifampicin	25	25
Polymyxin	0.8	0.8

Ten mutant and ten parent strains were examined. The minimum inhibitory concentration (MIC) was determined by inoculating small areas of plates containing twofold falling concentrations of antibiotic in Sensitest agar with approximately 200 viable organisms and then incubating the plates at 37 °C for 24 h. The lowest concentration of antibiotic that prevented growth was recorded as the MIC.

The minimum inhibitory concentrations of sodium nalidixate, chloramphenicol and trimethoprim for the mutants were 25–50 higher than those for their parent strains (Table 1). Those of tetracycline, sulphafurazole and furazolidone, but not of streptomycin, neomycin, spectinomycin, rifampicin and polymyxin, were slightly higher for the mutants than those for their parent strains.

Mutants resistant to streptomycin, spectinomycin and rifampicin were isolated from three *K. pneumoniae* strains; they were resistant only to the antibiotic used in their isolation.

To determine whether a multiply resistant *K. pneumoniae* flora could emerge *in vivo* during the administration of only one antibiotic, groups of 15 1-d-old chicks were given orally 10<sup>8</sup> viable organisms of a spectinomycin-resistant mutant of a *K. pneumoniae* strain and then fed freely on diets containing sodium nalidixate, chloramphenicol or trimethoprim (100 or 500 mg kg<sup>-1</sup>) or no antibiotics for 10 d. Cloacal swabs taken at intervals from the chicks were each smeared over the surface of a MacConkey plate and a Sensitest plate, both containing spectinomycin (20 µg ml<sup>-1</sup>), and a sodium nalidixate disk and a chloramphenicol disk were placed on the MacConkey plate and a trimethoprim disk was placed on the Sensitest plate. The plates

**Table 2** Faecal excretion of antibiotic-resistant organisms by chicks fed diets containing chloramphenicol, trimethoprim or sodium nalidixate after receiving orally a culture of *K. pneumoniae* sensitive to these antibiotics

Antibiotic administered	Time after commencement of administration	No. out of 15 chicks excreting <i>K. pneumoniae</i> organisms that were		
		only the antibiotic administered	resistant to chloramphenicol trimethoprim and sodium nalidixate	all sensitive
Chloramphenicol	4	0(0)	4(13)	11(2)
	8	0(0)	9(10)	4(1)
	17*	0(0)	1(5)	7(3)
Trimethoprim	4	3(8)	7(4)	6(5)
	8	12(11)	7(6)	1(0)
	17*	14(9)	1(1)	1(0)
Sodium nalidixate	4	0(0)	0(0)	15(15)
	8	0(0)	0(0)	13(8)
	4	0(0)	0(0)	15(15)
None	8	0(0)	0(0)	15(15)

Chicks received antibiotic in a concentration of 100 mg kg<sup>-1</sup> and (figures in parentheses) 500 mg kg<sup>-1</sup>.

\*Seven days after the feeding of antibiotic-containing diets ceased.

were incubated at 37 °C for 24 h and those with colonies of *K. pneumoniae* organisms on them that were resistant to sodium nalidixate, chloramphenicol and trimethoprim were recorded. These organisms were found in the faeces of many of the chicks fed diets containing chloramphenicol or trimethoprim (Table 2); from some of them they were the only kind isolated. Organisms of the infecting strain resistant to trimethoprim only were also common in the faeces of most of the chicks in the trimethoprim group. The multiply resistant organisms were also isolated from a few of the chicks in the chloramphenicol and trimethoprim groups 7 d after withdrawing the antibiotic-containing diets; at this time most of the chicks in all the groups had no or very few organisms of the infecting strain in their faeces. No resistant organisms of this strain were found in the faeces of any of the chicks fed diets containing sodium nalidixate or no antibiotics. Surprisingly, on account of the ease with which they can be isolated *in vitro*, no *nal*<sup>r</sup> *E. coli* were found in the faeces of chicks in the sodium nalidixate group.

Antibiotic-resistant mutants of enterobacteria other than *K. pneumoniae* that were available in this laboratory were examined for resistance to antibiotics different from the ones used in their isolation. In addition, those whose parent strains were prototrophic were cultured on a medium consisting of (g l<sup>-1</sup>) K<sub>2</sub>HPO<sub>4</sub> 7; KH<sub>2</sub>PO<sub>4</sub> 3; (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> 1; MgSO<sub>4</sub>·7H<sub>2</sub>O, 0.1; NaCl, 5; glucose, 5; agar, 15 to determine whether they too were prototrophic. The antibiotic that had been used to isolate the mutants from different pathogenic and non-pathogenic strains of *E. coli* of human, bovine, porcine and fowl origin was sodium nalidixate (106), streptomycin (40), ampicillin (14), spectinomycin (10) and rifampicin (1), from different *Salmonella* strains was sodium nalidixate (24), streptomycin (18), ampicillin (1), spectinomycin (3) and rifampicin (5) and from different *Shigella flexneri* and *S. sonnei* strains was sodium nalidixate (8), streptomycin (5), spectinomycin (1) and rifampicin (2). All these 238 mutants were only resistant to the antibiotic used in their isolation and all the 214 with prototrophic parents were also prototrophic.

I thank Miss Margaret Lovell for technical help and Dr J. E. T. Jones for *K. pneumoniae* strains.

## Selective entry of immunoblasts into gut from intestinal lymph

THE observation<sup>1</sup> that the lymphoid blast cells in the thoracic duct lymph of rats homed preferentially to the lamina propria of the small gut after being injected intravenously has received ample confirmation<sup>2-4</sup>. But although the thoracic duct lymph of rodents comes principally from the intestine there must also be a significant contribution from other viscera as well as from the caudal somatic lymph nodes. It follows that the large lymphoid immunoblasts present in thoracic duct lymph may have come from several sources, and it has been shown that their numbers increase after antigens have been injected subcutaneously into the hindquarters<sup>5</sup>. Are the immunoblasts that home to the small gut selected randomly, or do they have some special feature which mediates their extravasation in the gut? Straightforward immunological factors such as the specificity of the immunoblasts or the presence of antigens in the gut do not seem to be of primary importance<sup>6,7</sup>.

Immunoblasts teased from somatic lymph nodes cannot home to the gut nearly as well as those from mesenteric nodes or thoracic duct lymph<sup>2,8</sup> but the performance of immunoblasts which normally enter the lymph from somatic nodes has not been measured. By cannulating appropriate lymph ducts in experimental sheep we have studied the problem directly and our results are reported here.

Yearling sheep were anaesthetised and polyvinyl cannulae inserted into the intestinal lymph duct and an efferent duct of one of the peripheral, somatic lymph nodes (popliteal, prefemoral or prescapular). After the operation the conscious sheep were placed in metabolism cages and the lymph was collected quantitatively into sterile, heparinised, plastic bottles<sup>9-11</sup>. In these relatively young sheep up to 15% of the white cells in the intestinal lymph were immunoblasts, but in the efferent lymph from somatic nodes, immunoblasts accounted for 2% or less of the white cells. For this reason 2 ml of a mixture of suspensions of killed bacteria (*Corynebacterium parvum*, *Brucella abortus* and *Salmonella typhi* O and H, Wellcome Research Laboratories) was injected subcutaneously into the drainage area of the cannulated node so that 4 d later, when the immune response was greatest, 20-40% of the cells in the efferent lymph consisted of immunoblasts<sup>12,13</sup>. An 8-h collection of either intestinal or efferent lymph was then incubated for 1 h at 38 °C with <sup>125</sup>I-iododeoxyuridine (IUDR, Radiochemical Centre, Amersham) at a final concentration

**Table 1** Percentages of injected radioactivity present in tissues of sheep 20 h after injection of autochthonous immunoblasts collected from intestinal lymph or efferent lymph of somatic lymph nodes and labelled *in vitro* with  $^{125}\text{I}$ UdR

Type of labelled cells injected	Immunoblasts from efferent lymph of somatic nodes				Immunoblasts from intestinal lymph				
	1	3	5	7	2	4	6	8	10
Experiment no.									
Small intestine	0.9	0.4	0.8	0.6	35.3	30.5	27.8	27.0	28.4
Spleen	16.0	16.8	21.0	19.0	0.2	1.4	0.3	1.4	0.4
Mesenteric lymph nodes	0.1	0.1	0.2	0.1	1.8	3.4	2.7	2.9	3.4
Somatic lymph nodes	1.3	2.6	0.9	0.8	0.2	1.1	0.3	0.7	0.6

of  $0.1 \mu\text{Ci ml}^{-1}$ . The total number of white cells in the collections varied between  $10^6$  and  $10^{10}$  and included 10–40% immunoblasts; autoradiographs showed later that 70–80% of the latter had labelled nuclei. The labelled cells were then washed once and returned to the sheep by intravenous injection. The sheep was killed 20 h later and selected organs were removed, cut into small pieces and loaded into counting vials so that the gamma emission of each organ could be measured in a scintillation spectrometer. The relevant results from nine such experiments are shown in Table 1.

Clearly immunoblasts generated in somatic nodes did not enter the small gut but tended to localise in the spleen and, incidentally, did not reappear in significant numbers in samples of either lymph or blood. Conversely, immunoblasts generated in the lymphoid tissue associated with the gut avoided the spleen and localised mainly in the small gut; up to a further 10% of the injected cells were recovered in the intestinal lymph during the course of the experiments. The latter observation shows that, as in studies on rats<sup>3,4,6</sup> most radioactivity remained associated with intact immunoblasts throughout the experiment. Unfortunately, it is not practical to prepare representative autoradiographs from the major organs of an adult sheep, and so little can be said about the microanatomical localisation of the labelled cells—we assume that it is generally similar to that found in the rat<sup>3,4</sup>.

It was suggested, on *a priori* grounds, that immunoblasts which enter the gut must be IgA secretors<sup>4</sup> and there is evidence for this view<sup>8,14</sup>. In the experiments reported here we found, by immunodiffusion tests, that detergent extracts of washed cells from intestinal lymph always contained IgA as the major immunoglobulin. Extracts of lymph cells from stimulated somatic nodes contained mainly IgG, with some IgM, but we found no IgA. Furthermore, the immunoblasts from somatic nodes did not acquire the ability to home to gut even when they had been collected and incubated in isologous intestinal lymph plasma, which is rich in IgA<sup>15</sup>.

These findings support the view that one of the intrinsic cellular factors which mediate the extravasation of immunoblasts in the small gut is the production of IgA or a molecule associated closely with it. Certainly the view<sup>3</sup> that lymph-borne immunoblasts from any source may extravasate into the gut is wrong in any general sense.

The Chester Beatty Research Institute receives grants from the Medical Research Council and the Cancer Research Campaign. We thank David Glover for technical assistance and Dr J.-P. Vaerman for antiserum specific for ovine IgA.

## Protection of mice against *Babesia* and *Plasmodium* with BCG

*Babesia* spp. are haemoprotozoans, and some cause diseases of considerable economic importance in cattle. Complete protection against challenge has been recorded only in animals recovered from artificial<sup>1</sup> or natural infections with a virulent strain of the organism. We have achieved the same result with *B. microti* and *B. rodhaini*, two of the species which parasitise mice, by previous infection with *Mycobacterium bovis* strain BCG (Bacillus Calmette-Guérin). Evidence is provided that neither antibody specific for surface antigens of the parasites nor increased phagocytic capacity is responsible for this protection. We suggest that BCG protects by increasing the release of non-antibody soluble mediators of immunity postulated to cause the death of *B. microti* inside red cells<sup>2</sup>. Preliminary observations on protection against *Plasmodium berghei yoelii* and *P. vinckei* are also presented.

Eight female CBA mice 6 weeks old were given  $2 \times 10^7$  live BCG (Glaxo strain) intravenously. Two weeks later  $10^6$  *B. microti* were injected intraperitoneally into these mice and into an equal number of controls. In the mice that received BCG a few parasites were seen in tail blood smears after about a week, but none thereafter during an observation period of more than 100 d. The control group showed the usual primary infection curve for this parasite (Fig. 1a).

Subsequently a group of nine 6-week-old female CBA mice were given  $10^6$  *B. microti* intraperitoneally 28 d after they had received  $2 \times 10^7$  live BCG intravenously. For 155 d no parasites were observed in smears from these mice, even though further challenges of  $2 \times 10^6$ ,  $3 \times 10^6$ ,  $2.5 \times 10^7$  and  $10^6$  organisms were given 14, 25, 50 and 100 d, respectively, after the initial infection. Indeed, absence of recrudescence after splenectomy of three mice on day 40, and failure to transfer infection with the spleens from these animals, suggest that a sterile immunity was achieved.

All of 57 mice, including males, have now been completely protected in eight experiments. Eight of these mice withstood  $7.5 \times 10^8$  organisms. This is a massive dose compared with challenges usually given in protection experiments with blood parasites<sup>3–6</sup> and indicates the strength of

the protection conferred by BCG. The dose used produced a 2% parasitaemia within hours of being given intraperitoneally, but the count did not rise further. As healthy parasites became fewer over the next 2 d the inclusion bodies shown by electron microscopy to be degenerate intraerythrocytic parasites<sup>2</sup> appeared. These were in sufficient numbers to account for at least most of the

original healthy parasites. Thus *B. microti* die inside the red cells of mice protected with BCG.

Indirect fluorescent antibody titres to *B. microti* antigen were negligible in sera from mice given BCG 26 d previously and not challenged with *B. microti*, and also in serum from mice protected with BCG (Table 1). This test detects all antibody specific for surface antigens of the parasite. Furthermore, giving 3 mg silica intravenously (Doröntrop Quartz No. 12,  $<5\ \mu\text{m}$ ) either before or after challenging two groups of six BCG-immunised mice with *B. microti*, which would be expected to decrease antibody production and phagocytic activity, respectively<sup>7</sup>, did not decrease the protection that BCG gave. Thus this protection is unlikely to be due to cross-reacting antibodies, or enhancement of either antibody production or phagocytic activity. In any event the intraerythrocytic degeneration of the parasites precludes their death inside macrophages.

Ten female CBA mice in two experiments were completely protected against *B. rodhaini* (Antwerp Strain), which is invariably fatal in unprotected mice, by giving them live BCG intravenously 3 weeks before challenge (Fig. 1c). When protection of one of these mice lapsed temporarily from day 20 we obtained light microscopical evidence of intraerythrocytic death of *B. rodhaini* also. Again we used  $2 \times 10^7$  BCG and  $10^6$  parasites. This number of organisms killed the four control mice on day 9.

Similarly, in one preliminary experiment we were able to protect four out of four female CBA mice against  $10^6$  *P. berghei yoelii* (Strain 17X) by intravenous injection of  $2 \times 10^7$  live BCG 1 month beforehand (Fig. 1d). Some male CBA mice (two out of four) were less well protected. An appreciable degree of protection, again with light microscopical evidence of intraerythrocytic death of parasites, has also been achieved in eight mice with *P. vinckei* in the same conditions (Fig. 1e). This parasite is normally lethal in mice, and killed the four controls on day 8, but the protected group survived.

Vaccines incorporating killed *Mycobacterium* sp. and parasites, given intradermally, subcutaneously or intramuscularly, have been used against *B. argentine*<sup>3</sup> and *P. knowlesi*<sup>6,8,9</sup>. All except the one containing merozoites<sup>6</sup> were only moderately successful. Killed *Mycobacterium* sp. alone has not been protective, perhaps because it was never given intravenously. Live BCG, on the other hand, has been reported to protect against some protozoa, the success varying with the route of administration. Thus intraperitoneal live BCG has been unable to protect mice against *Trypanosoma cruzi*<sup>10</sup> or *Toxoplasma gondii*<sup>11</sup>. Likewise, live BCG injected into the retrobulbar space of rabbits did not protect the eye from *Toxoplasma gondii*<sup>12</sup>. In contrast, pretreatment with intravenous live BCG reduced the number of circulating *Trypanosoma cruzi* in mice<sup>13</sup> and protected rabbits' eyes from *Toxoplasma gondii*<sup>12</sup>. In neither case, however, was the protection as strong as that which we have observed against *B. microti*, *B. rodhaini*, *P. berghei yoelii* or *P. vinckei*. This may be simply a question of timing and dose of BCG rather than any fundamental difference between the protection afforded against the different protozoa.

BCG provides nonspecific resistance in a wide variety of diseases, both neoplastic<sup>14,15</sup> and infectious<sup>16,17</sup>. In certain

Fig. 1 a, Course of infection of mice given  $2 \times 10^7$  live BCG intravenously, and  $10^6$  *B. microti* 14 d later. — — —, BCG-vaccinated; —, non-vaccinated. b,  $10^6$  *B. microti* given 28 d after  $2 \times 10^7$  live BCG intravenously. conditions BCG can increase antibody production<sup>18</sup> and make macrophages hyperactive<sup>19</sup>. From our evidence it seems unlikely that either of these two mechanisms, or cross-reacting antibodies, can explain the protection observed. The occasional appearance of parasites in smears from all the mice infected intraperitoneally with *B. microti* 14 d after BCG inoculation and in some of those protected against *B. rodhaini* eliminates the possibility that activated peritoneal macrophages<sup>20</sup> prevented the parasites reaching the circulation.

Immunity to *Babesia* is not yet understood. Thymus-derived lymphocytes are necessary for recovery from infection<sup>21,22</sup>, but their role is uncertain. Transfer of large volumes of recovery serum have yielded inconsistent results<sup>4,23-25</sup>; thus it seems unlikely that T lymphocytes merely help in the production of antibody that is free in the serum. Furthermore there is no evidence that T lymphocytes can kill *Babesia* parasites or infected erythrocytes by contact lysis.

**Table 1** Anti-*Babesia* antibody levels

Time serum taken	Titre
26 d after BCG alone	0
12 and 20 d after <i>B. microti</i> (BCG 14 d before <i>B. microti</i> )	1:20
14 d after <i>B. microti</i> (BCG 28 d before <i>B. microti</i> )	1:20
Recovered controls	1:2,560

Mice given BCG, BCG and *B. microti*, and *B. microti* alone. Antibody levels detected by an indirect fluorescent antibody test. Serum from at least six mice pooled for each reading.

Another hypothesis is that T lymphocytes are necessary for the release of a non-antibody mediator of immunity. Indeed, the massive T-cell activation in spleens of mice infected with *P. berghei* yoelii<sup>26</sup> could be explained on this basis, as the authors remarked. There are many such products of activated lymphoid cells which exhibit various activities *in vitro*; some, for instance, cause intracellular death of *Toxoplasma gondii*<sup>27</sup>, and others of *M. tuberculosis*<sup>28</sup>.

Among these mediators are the substances with interferon and migration-inhibition activities present in the serum of BCG-infected mice after stimulation either specifically or with certain unrelated antigens<sup>29</sup>. As well as protecting mice from *M. tuberculosis*<sup>30</sup>, these substances can inhibit various unrelated organisms *in vitro*<sup>31</sup>. The finding that BCG must be given intravenously for appreciable release of the mediators of this inhibition<sup>30</sup> is consistent with the requirement for this route of administration to protect against certain protozoa<sup>10-13</sup>, and our failure to protect with subcutaneous BCG. Our results are also in keeping with the original proposal by Mackaness<sup>32</sup> that cellular immunity, although specifically induced, may be non-specifically expressed; he also suggested that this could be accomplished by migration inhibition factor<sup>33</sup>. Furthermore, interferon activity has been reported in the serum of mice infected with *P. berghei*<sup>34</sup> and interferon inducers protect mice against this organism<sup>35,36</sup>.

For these reasons, and in view of the intraerythrocytic death of parasites both in normally recovering<sup>2</sup> and BCG-protected mice, we consider that the most likely mechanism of immunity to these two genera of parasites in mice is the release of such a mediator, the output of mediator(s) being increased, and thus protection augmented, by previous infection with BCG.

The duration and details of the nature of this protection remain to be established. Nevertheless, in addition to giving a greater understanding of the basic mechanism of immunity involved, this approach may lead to a practical method of stimulating immunity against these two genera

of blood parasites. Further, its nonspecificity promises activity against a range of species and strains.

## Contact-induced spreading is a new phenomenon depending on cell-cell contact

THERE is firm evidence that the characteristic changes of cell behaviour *in vitro* described as contact inhibition of locomotion<sup>1</sup>, contact inhibition of extension<sup>2</sup> and contact inhibition of phagocytosis<sup>3</sup> occur as a direct result of cell-cell contact. In addition it has been suggested<sup>4</sup> that the inhibition of both pinocytosis<sup>5</sup> and blebbing<sup>6</sup>, in those regions of the margins of cells in contact with other cells, may also be a direct result of cell-cell contact. These examples may well be part of a general class of cell-contact-dependent phenomena which could play an important role in cellular interactions. I report here another contact-dependent reaction which takes place between chick embryo pigmented retina epithelial (PRE) cells in culture. In brief, it can be shown that the degree of polarisation exhibited by these cells and the degree to which they are spread on their substrate is influenced profoundly by whether or not they are in contact with other cells.

Observations<sup>7</sup> of cultured PRE cells moving on a plane substrate have shown that collisions between the cells usually result in the development of stable contacts between the cells, so that islands and sheets of cells are eventually formed from a culture which consisted initially of isolated

single cells. In addition it has been found that, whereas isolated PRE cells lacking contacts with other cells are usually only poorly spread on the substrate and only infrequently display fibroblast-like leading lamellae, those PRE cells incorporated into islands of cells are much more extensively spread and display typical leading lamellae if marginally positioned in an island<sup>7</sup>. My preliminary observations suggested that as a previously isolated and poorly spread cell made contact with another cell or island of cells, it underwent a striking change in morphology and behaviour to resemble the cells of the island it had joined<sup>7</sup>. The investigation reported here confirms this observation and demonstrates that this change in morphology is dependent on cell-cell contact.

A single-cell suspension of 10-d chick embryo PRE cells was prepared and plated out on to collagen-coated coverslips as previously described<sup>8</sup>. The cultures were incubated at 37 °C for 5 h to allow the cells to attach to the substrate before being prepared for photography. A field of cells was selected and photographed at 30-min intervals for periods of up to 6 h. A selection from a representative series of such photographs is shown in Fig. 1.

The characteristic difference in morphology between isolated cells and cells in contact with other cells is clearly seen in Fig. 1a. The isolated cell illustrated is clearly only poorly spread on the substrate and as a result its nucleus is obscured by pigment granules. The general appearance of such isolated cells suggests that they are 'unpolarised' in that they usually lack a fibroblast-like leading lamella and they display vigorous and apparently uncoordinated blebbing activity at their margins. Although the cells are poorly spread they clearly adhere relatively well to the substrate since cell detachment was never observed although all observations were made on inverted cultures. In addition I have found that such cells can withstand vigorous washing

and perfusion without detaching from the substrate (unpublished observations). By contrast to the isolated cells, those incorporated into islands are much more extensively spread on the substrate (Fig. 1a). Cells that are marginally positioned in an island exhibit clear 'polarisation' in that they display typical fibroblast-like leading lamellae from those parts of their margin not in contact with other cells. Blebbing by these well spread cells is only very rarely observed.

The sequence of photographs shown in Fig. 1 demonstrates the striking change in morphology shown by an isolated cell after colliding with an island of cells. The first signs of this change are evident within 30 min of the collision (Fig. 1b). By this time the cell has begun to spread more extensively on the substrate and as a result its nucleus has become less obscured by pigment granules, blebbing has decreased and the first signs of polarisation are evident. Within 90 min of the collision the cell closely resembles the other cells making up the island, blebbing has ceased, the cell is well spread on the substrate and a leading lamella is beginning to develop from the area of its margin not in contact with other cells (Fig. 1c). With further time the cell becomes indistinguishable from its neighbours in the island (Fig. 1d).

**Table 1** Comparison of the area of substrate occupied by single cells and cells in two-cell islands

	Mean cell spread area $\pm$ s.e. ( $\mu\text{m}^2$ )	n	
Single cells	315.4 $\pm$ 27.5	25	
*Two-cell islands	496.2 $\pm$ 38.8	25	$P < 0.001$

\*The area of complete two-cell islands was measured and the mean area occupied by the individual cells was obtained by division.

Five cultures of PRE cells were prepared essentially as described in the legend to Fig. 1, but the original cell suspension was adjusted to  $3.2 \times 10^5 \text{ ml}^{-1}$  before being plated out. Medium, substrate, culture vessels, sample size and incubating conditions were as described in the legend to Fig. 1. The cultures were incubated for 24 h and then the coverslips with attached cells were removed, fixed with formol saline and stained with Harris' haematoxylin. The areas of five single cells and five two-cell islands in each of the fixed cultures was measured using the Curtis<sup>10</sup> modification of the Chalkley<sup>11</sup> random array method. Sufficient estimates of each measured area were obtained to ensure that the final estimate had a standard error of 5% or less.

There seems little reason to doubt that this change in the behaviour and morphology of a previously isolated cell is a direct response to contact with other cells. Alternative explanations in terms of adaptation to culture conditions or recovery from cell dissociation procedures are unlikely since the characteristic differences between isolated cells and those in contact with other cells are maintained for several days in culture. Equally it seems unlikely that the observations can be explained in terms of local diffusion gradients surrounding the islands of cells. Isolated PRE cells move only rather slowly and inefficiently<sup>7</sup>; thus an isolated poorly spread cell may lie within 5–10  $\mu\text{m}$  of the edge of an island of well spread cells yet it will display no signs of spreading or polarisation unless it establishes visible (to the light microscope) contact with the island. This observation could be reconciled with an explanation in terms of diffusion gradients only if such gradients were extremely local in effect. Very short range gradients caused by diffusion boundary layer effects have been proposed to influence the division of cells in culture<sup>9</sup>. Such a system seems unlikely to be operating here, however, since it can be shown that the individual cells comprising a two cell island occupy a significantly greater area of the substrate than do single isolated cells (Table 1). In fact the data in Table 1 indicate that a collision between two previously isolated cells results in both cells increasing by approximately 50% the area of the substrate that they occupy individually. It is difficult to

**Fig. 1** Contact-induced spreading of a PRE cell. A single cell suspension was prepared from the pigmented retina of 10-d chick embryos as previously described<sup>8</sup>. The cells were suspended in Ham's F10 supplemented with 10% chick serum at pH 7.6 and the concentration was adjusted to  $4.8 \times 10^5 \text{ ml}^{-1}$ . Samples of 0.2 ml of the suspension were plated out into 9-mm diameter glass rings 1 cm high, attached with sterile silicone grease to collagen-coated coverslips<sup>8</sup>. Cultures were incubated at 37 °C under a gas phase of 5%  $\text{CO}_2$ , 20%  $\text{O}_2$  and 75%  $\text{N}_2$ . After 5 h the glass rings were removed and the coverslips with attached cells were converted to inverted filming slides for photography. Photographs were obtained using a Zeiss photomicroscope fitted with phase contrast optics; the cultures being maintained at 37 °C by an air curtain incubator. a–d, Series of photographs of the same microscope field to illustrate the spreading of a single PRE cell (arrow) after contact with an island of cells. a, After 5 h in culture, arbitrarily defined as 0 time; b, 0 + 30 min; c, 0 + 90 min; d, 0 + 240 min. See text for details. The scale bar represents 10  $\mu\text{m}$ .

see how this response at the single cell contact level could be explained in terms of any diffusion gradient theory.

It seems clear that the marked change in morphology and behaviour shown by isolated PRE cells in response to a collision with an island of cells is dependent on cell contact. Since the most striking aspect of the response is the extensive spreading of the cell I propose that the phenomenon be called contact-induced spreading.

There have been no reports of a reaction similar to contact-induced spreading occurring in fibroblastic cell types but there is at least preliminary evidence to suggest that the phenomenon may not be restricted to PRE cells. Trinkaus<sup>12</sup> noted that while isolated *Fundulus* gastrula cells in culture were normally only poorly spread on the substrate, those incorporated into islands of cells were spread extensively. Additionally, a reaction similar to contact-induced spreading has been observed in cultured chick liver parenchyma cells<sup>13</sup> and cultured limpet haematocytes (T. A. Partridge, personal communication). It is interesting that all these examples are of cells that assume an epithelioid morphology in tissue culture and it seems possible therefore that contact-induced spreading may be a characteristic of cultured epithelial cells.

The mechanism of contact-induced spreading is obscure but it seems clear that it must involve changes in the adhesion of the cell to the substrate since the area of cell-substrate apposition is considerably increased as a result of the reaction. It seems therefore that the development of a cell-cell contact can affect cell-substrate adhesion. A similar conclusion was reached by Trinkaus from his observations of cultured *Fundulus* gastrula cells<sup>12</sup>.

It is likely that contact-induced spreading also involves a change in the locomotory behaviour of the cell since as a result of the reaction a previously unpolarised blebbing cell develops a fibroblast-like leading lamella and, from time-lapse film observations<sup>7</sup>, appears to be attempting to move away from the islands it has joined. It is apparent from Fig 1 that the phenomenon also involves the development of extensive regions of contact, and presumably therefore adhesion, between the previously isolated cell and its neighbours in the island. Although it has been shown that ultrastructural contact specialisations develop between PRE cells within 24 h in culture<sup>7</sup>, it is not known whether or not these develop rapidly enough to play any role in contact-induced spreading.

Contact-induced spreading seems to be another example of the group of cellular interactions dependent on cell-cell contact. Whether or not the various members of this group share common mechanisms remains to be established. The findings reported here, however, again emphasise the importance of cell-cell contacts in regulating the behaviour of cells, at least *in vitro*.

## Chronic suppression of immunoglobulin allotype production in adult congenic mice

MOUSE allotypes refer to the inheritance of antigenic differences on the constant region of immunoglobulin (Ig) heavy chains ( $C_H$ ). As such, allotypes are used as genetic markers to distinguish allelic  $C_H$  genes, the expression of which is codominant in heterozygous mice<sup>1,2</sup>. The expression of a paternal  $C_H$  gene, however, can be suppressed in heterozygote offspring if the mother has previously been made immune to the allotype encoded by the paternal gene<sup>3</sup>. Neonatally induced suppression of this sort is known to lead to (or result in) the generation of allotype-specific suppressor T lymphocytes which directly or indirectly prevent allotype production by B lymphocytes<sup>4-6</sup>. In contrast to this we have shown that allotype suppression can also be initiated in adult mice, that is in BALB/c mice that are congenic for the C57BL allotype (C.B-17 mice)<sup>1</sup>. When X-irradiated C.B-17 mice (550 r.) are injected with thymocytes from BALB/c donors immune to the C57BL allotype, IgG<sub>2a</sub> allotype production in the C.B-17 recipients becomes chronically suppressed<sup>7</sup>. We now report that allotype suppression in C.B-17 mice is mediated by T cells; that production of only the IgG<sub>2a</sub> class allotype (G<sup>2</sup>) is suppressed, presumably as a result of direct interaction between specific T and B cells, and that the capacity of spleen cells to suppress host allotype production can be transferred serially from one C.B-17 mouse to another and as yet without obvious limit.

Mouse 7S Ig allotype determinants of BALB/c (F<sup>19</sup>G<sup>1,6,7,8</sup>H<sup>9,11</sup>), of C.AL-20 a BALB/c congenic strain with the allotype of the AL/N inbred strain (F<sup>19</sup>G<sup>4,6,7,8</sup>H<sup>4</sup>) and of C.B-17 (F<sup>3</sup>G<sup>2</sup>H<sup>9,10</sup>) are denoted here according to the Potter-Lieberman nomenclature where F, G and H refer to the IgG<sub>1</sub>, IgG<sub>2a</sub> and IgG<sub>2b</sub> subclasses, respectively<sup>1</sup>. Anti-allotype immunity was induced in BALB/c, C.AL-20 and C.B-17 donor mice by reciprocal immunisation with each other's Ig in the manner described previously<sup>8</sup>. The recipients in each cell transfer experiment were tested for the presence or absence of different allotypes by means of gel precipitation in micro-Ouchterlony plates.

The kinetics of G<sup>2</sup> suppression in C.B-17 mice that received thymocytes, bone marrow cells or spleen cells from BALB/c mice immune to G<sup>2</sup> are shown in Table 1. After the intravenous injection of  $3 \times 10^6$ - $5 \times 10^6$  thymocytes into X-irradiated C.B-17 recipients (550 r.), G<sup>2</sup> began to disappear as early as 2 weeks later and after 5 weeks was undetectable (groups A and B). Host allotype suppression was chronic and although not shown here, it still persists in C.B-17 recipients 1 yr after cell transfer. The injection of comparable numbers of bone marrow cells (mostly B cells) did not, however, suppress G<sup>2</sup> (groups C and D). Moreover, the exposure of suppressor spleen cells to AKR mouse antiserum specific for T cells (anti- $\theta$  serum) followed by the application of complement (C') abrogated the ability of these cells to suppress G<sup>2</sup> production (groups E and F). Spleen cells treated with anti- $\theta$  serum gave a good proliferative response (<sup>125</sup>I-5'-iododeoxyuridine incorporation) to *E. coli* lipopolysaccharide (Bacto 055-B5), a B-cell mitogen<sup>9</sup>, but unlike the control spleen cells, showed only a marginal proliferative response to phytohaemagglutinin (Gibco), a T-cell mitogen<sup>9</sup> (not shown). These latter results with mitogens were taken as independent evidence for the efficacy and specificity of anti- $\theta$  treatment. We conclude that G<sup>2</sup> suppression is dependent on T-cell immunity.

As Table 2 shows, the antigenic basis for host allotype suppression relates solely to the G<sup>2</sup> globulin. First, the involvement of a non-Ig serum antigen is precluded since spleen cells from BALB/c mice that were made immune to chromatographically pure Fc fragments of C57BL/6 7S

**Table 1** T-cell-dependent suppression of the IgG<sub>2a</sub> allotype (G<sup>2</sup>) in X-irradiated C.B-17 mice after their intravenous injection with BALB/c lymphoid cells immune to G<sup>2</sup>

Group	No. of immune cells injected*		Spleen	No. of recipients showing G <sup>2</sup> /No. injected† (weeks after cell transfer)					
	Thymus	Bone marrow		1	2	3	4	7	20
A	3 × 10 <sup>6</sup>			5/5		5/5	2/5	0/5	0/4
B	5 × 10 <sup>6</sup>			18/18	9/18	3/18	0/18		0/16
C		3 × 10 <sup>6</sup>		6/6		6/6		6/6	6/6
D		5 × 10 <sup>6</sup>		6/6		6/6		6/6	6/6
E			10 × 10 <sup>6</sup>	14/14	2/14	0/14		0/14	
F			10 × 10 <sup>6</sup> (treated with anti-θ serum)	13/13	13/13	13/13		13/13	

\*BALB/c mice were made immune to the IgG<sub>2a</sub> allotype of C57BL mice (G<sup>2</sup>) after five or more intraperitoneal injections of C57BL/6 serum hyperimmune to rabbit red cell ghosts; all BALB/c donors were producing precipitating antibody against G<sup>2</sup> at the time of cell transfer. The AKR mouse anti-θ serum came from Dr J. B. Smith of this institute; exposure of spleen cells to this antiserum was done as follows (group F): 10<sup>7</sup> cells per ml were incubated for 45 min with a 1/16 dilution of antiserum (in phosphate-buffered saline containing 0.1% bovine serum albumin) at 37 °C in a 5% CO<sub>2</sub> atmosphere. After one wash, the cells were resuspended in a 1/10 dilution of guinea pig complement (1 ml of complement per 10<sup>7</sup> cells) and incubated for 30 min more at 37 °C. The cells were then washed three times before being injected into C.B-17 mice. Control spleen suspensions were treated as above except AKR normal mouse serum was substituted for AKR anti-θ serum (group E). The results of groups B, E and F represent two or more separate experiments.

†C.B-17 recipients were X irradiated with 550 r. 1 d before cell transfer in the following conditions: 190 kV; 15 mA; filtration, 1 mm Al and 0.5 mm Cu; dose rate 40–45 r. min<sup>-1</sup>. Recipient sera were reacted with BALB/c anti-G<sup>2</sup> in micro-Ouchterlony plates to test for the presence of G<sup>2</sup> allotype.

Ig were able to suppress G<sup>2</sup> production in C.B-17 mice (group C). Moreover, C.B-17 serum (group B) could substitute for C57BL/6 serum (group A) as an immunogen. C.B-17 serum is not known to be different from that of BALB/c except to contain Ig allotypes of C57BL mice. Second, allotype determinants that characterise the IgG<sub>1</sub> (F<sup>a</sup>) and IgG<sub>2b</sub> (H<sup>a</sup>) subclasses continue to be produced in G<sup>2</sup>-suppressed mice. Evidence of this is deduced from the fact that both anti-F<sup>a</sup>G<sup>2</sup> (groups A–C) and anti-H<sup>a</sup> (group D) gave precipitin bands with serum from G<sup>2</sup>-suppressed C.B-17 mice. It is important to note that the use of C.AL-20 donor mice immune to G<sup>2</sup> was necessary in group D because the IgG<sub>2b</sub> molecules of both BALB/c and C.B-17 mice share the H<sup>a</sup> determinant. With BALB/c mice as donors, it would be impossible to distinguish H<sup>a</sup> production of host cells from that of donor cells. Earlier observations by Jacobson *et al.*<sup>4</sup> are consistent with the above results as Ig-4b (F<sup>a</sup>) was also not suppressed in mice that were suppressed for Ig-1b (G<sup>2</sup>) production by means of neonatal exposure to anti-allotype serum.

From the above, it seems clear that the IgG<sub>1</sub>, IgG<sub>2a</sub> and IgG<sub>2b</sub> subclasses can be produced independently of one another. This could mean that B cells independently differ-

entiate into producers of IgG<sub>1</sub>, IgG<sub>2a</sub> or IgG<sub>2b</sub>, or that C<sub>H</sub> genes for the IgG subclasses are expressed sequentially in differentiating immune cells, in which case the expression of IgG<sub>1</sub> and IgG<sub>2b</sub> must precede that of IgG<sub>2a</sub>. It also seems clear that BALB/c suppressor T cells must have allotype receptors for G<sup>2</sup> (G<sup>2</sup>-suppressor T cells). With G<sup>2</sup> recognition acting as the stimulus, such T cells might proceed to kill G<sup>2</sup>-bearing B cells directly, or alternatively, they might elaborate a suppressive factor which specifically prevents B cells from becoming G<sup>2</sup> producers. A mechanism similar to the latter is perhaps to be favoured in view of recent evidence for T-cell factors that have cooperative<sup>12,13</sup> or suppressive effects<sup>9,14</sup> on specific Ig production.

A more indirect mechanism can be postulated: in this the target of G<sup>2</sup>-suppressor T cells is another T cell that specifically helps B cells produce G<sup>2</sup> (G<sup>2</sup>-helper T cell). This would imply that G<sup>2</sup>-helper T cells carry G<sup>2</sup> determinants on their surface. To suggest any other basis for discrimination seems unwarranted since the specificity of G<sup>2</sup> suppression requires immunity to only the allotype determinants located on the Fc fragment of IgG<sub>2a</sub> molecules (Table 2). We have yet to obtain any evidence for G<sup>2</sup>-helper T cells.

The long term persistence of allotype suppression

**Table 2** Restriction of allotype suppression in X-irradiated C.B-17 mice to the IgG<sub>2a</sub> allotype (G<sup>2</sup>)

Group	Donor mice* (7S Ig allotypes)	Donor mice immunised with†	C.B-17 host allotypes (F <sup>a</sup> G <sup>2</sup> H <sup>a</sup> , <sup>16</sup> ) present 3–5 weeks after intravenous injection of donor spleen cells§ (No. of recipients positive/No. injected)		
			F <sup>a</sup>	G <sup>2</sup>	H <sup>a</sup>
A	BALB/c (F <sup>19</sup> G <sup>1,6,7,8</sup> H <sup>9,11</sup> )	C57BL/6 serum	7/7	0/7

D	C.AL-20 (F <sup>19</sup> G <sup>4,6,7,8</sup> H <sup>a</sup> )	C57BL/6 serum		0/8	8/8

\*C.AL-20 donor mice are BALB/c congenic mice that carry the Ig allotype of the AL/N mouse strain. These mice were given by Dr Michael Potter of the National Cancer Institute. F, G and H denote the IgG<sub>1</sub>, IgG<sub>2a</sub> and IgG<sub>2b</sub> subclasses, respectively; the numbers correspond to individual allotypic determinants (nomenclature of Potter and Lieberman<sup>1</sup>). Mouse IgG<sub>1</sub>, IgG<sub>2a</sub> and IgG<sub>2b</sub> have been alternately denoted by Herzenberg *et al.*<sup>2</sup> as Ig-4, Ig-1 and Ig-3, respectively. Here a lower case letter is used to distinguish allotypes (for example, Ig-1a and Ig-1b) and a second number is used to designate individual allotype determinants (for example, Ig-1.1).

†Donor mice were immunised as described in Table 1 except that the first antigen injection was given in Freund's complete adjuvant. Pápain digestion<sup>10</sup> of C57BL/6 7S Ig gave Fc fragments that were purified over DEAE-cellulose according to the method of Fahey and Askonas<sup>11</sup>.

§C.B-17 recipients were X irradiated with 550 r. 1 d before cell transfer in the conditions described in Table 1. Each recipient was injected intravenously with 20 × 10<sup>6</sup> spleen cells from the respective donor mice. The antisera used to test for the presence of F<sup>a</sup>, G<sup>2</sup> and H<sup>a</sup> in C.B-17 recipients were C.B-17 anti-F<sup>a</sup>G<sup>2</sup>, BALB/c anti-G<sup>2</sup> and C.AL-20 anti-H<sup>a</sup>. The indicated specificity of these antisera was assured after testing them against the Igs of various plasmacytomas which were grown in BALB/c, C.B-17 or C.AL-20 mice.

prompted us to transfer serially the spleens of G<sup>2</sup>-suppressed recipients into other C.B-17 mice. In this way, we intended to evaluate the potential for expansion of T cell-mediated immunity. Of three such experiments attempted, Table 3 shows the results of the one that has been under way for the longest time. Starting with the entire spleen of one BALB/c mouse immune to G<sup>2</sup>, we have suppressed G<sup>2</sup> production in 78 C.B-17 recipients. This corresponds to 91% of all injected recipients and covers four cell transfer generations and a cumulative time span of 46 weeks.

general context, it is interesting to speculate that allotype-specific suppressor T cells may constitute part of a normal regulatory system which controls the production of different Ig allotypes by B cells.

As far as we know this is the first time that chronic allotype suppression has been initiated in adult mice and in mice with a genetic background different from SJL. The abnormalities of Ig regulation in SJL mice<sup>18</sup> have been considered as a possible explanation for the susceptibility of (SJL×BALB/c) F<sub>1</sub> mice to chronic allotype suppression.

Table 3 Propagation of IgG<sub>2a</sub> allotype (G<sup>2</sup>) suppression in X-irradiated C.B-17 mice by serial transfer of spleen cells

TX, thymectomised.

\*The suppression of G<sup>2</sup> in C.B-17 mice was initiated with the spleen of one BALB/c mouse immune to G<sup>2</sup>; the spleen was divided equally as a cell suspension among six C.B-17 recipients (group A). When G<sup>2</sup> suppression occurred, three of these C.B-17 recipients were used as spleen cell donors for serial transfer into other C.B-17 mice. This kind of procedure was repeated over four cell transfer generations, as indicated. All cell transfers were done intravenously.

†Four of the G<sup>2</sup>-suppressed mice in group D (non-TX recipients) were immunised exogenously with six injections of C57BL/6 serum before being used as donors. Normal, unirradiated C.B-17 mice served as controls for the hyperimmunisation. These did not produce precipitating antibody to G<sup>2</sup>, neither did the transfer of their spleens into other C.B-17 mice cause G<sup>2</sup> suppression.

‡All C.B-17 recipients received 550 r. of X irradiation 1 d before cell transfer. Half of the C.B-17 mice in groups C and D were thymectomised 4 weeks before serving as recipients for cell transfer. Recipient sera were reacted with BALB/c anti-G<sup>2</sup> sera in micro-Ouchterlony plates to test for the presence or absence of G<sup>2</sup>.

§Times at which one or more of the injected recipients were found dead.

Two further points should be made: (1) Exogenous immunisation of G<sup>2</sup>-suppressed recipients with hyperimmune serum of C57BL/6 mice boosted the potential of these recipients to suppress G<sup>2</sup> production in other C.B-17 mice (group E); this potential was not yet exhausted at the fourth transfer generation (group F). (2) Thymectomy of prospective C.B-17 recipients delayed the onset of G<sup>2</sup> suppression (groups C and D). The reason for this is unclear.

Two explanations for the extended serial transfer of G<sup>2</sup> suppression in C.B-17 recipients seem reasonable. The first is that G<sup>2</sup>-suppressor T cells of the original donor can be clonally propagated—although with this as the sole explanation, it is difficult to understand why B-cell immunity (antibody responses) cannot be expanded as easily as the present example of T-cell immunity<sup>15</sup>. Therefore, a second explanation inclusive of the idea of clonal expansion is that suppressor T cells directed against G<sup>2</sup> are generated in C.B-17 host mice.

Support for the second explanation comes from the demonstrations<sup>4,16</sup> of G<sup>2</sup> allotype suppression in adult (SJL×BALB/c) F<sub>1</sub> mice that earlier were suppressed neonatally by continued exposure to anti-G<sup>2</sup> antibody. About half of the mice so treated were chronically suppressed beyond 6 months of age; the spleen cells of these mice could suppress G<sup>2</sup> production of normal (SJL×BALB/c) F<sub>1</sub> spleen cells both *in vivo* and *in vitro*<sup>5,6</sup>. This was shown to be due to suppressor T cells which survive indefinitely as a population and apparently derive from the (SJL×BALB/c) F<sub>1</sub> hosts.

If the idea of autosuppressor T cells is applied to our results this suggests that the same genes which enable BALB/c T cells to suppress G<sup>2</sup> production are present in C.B-17 mice. This possibility seems reasonable since BALB/c and C.B-17 mice share the same major histocompatibility (H-2) locus and many immune functions of T cells are under the control of immune response genes that map with the H-2 locus (reviewed in ref. 17). In this

sion<sup>4,6</sup>. But this consideration does not obviously apply to our results because BALB/c and C.B-17 mice do not show Ig irregularities like those in SJL mice. Therefore, the use of BALB/c congenic mice seems to provide a model autoimmune system in which to study the long term effects of constant stimulation and suppression of specific immune cells.

We thank Dr J. B. Smith for help in the anti-θ experiments and Mrs Eva Cunningham for technical assistance. This work was supported by grants from the US Public Health Service and the National Institutes of Health, and by an appropriation from the Commonwealth of Pennsylvania.

## Decreased resistance in some heterozygotes in H-2-linked immune response to polyoma-induced tumour

THE relationship between the major histocompatibility complex (MHC) and immune response (*I*r) genes has been demonstrated in the case of several antigens, including some transplantation antigens<sup>1</sup>. Among these, some tumour-associated transplantation antigens (TATA) are probably included<sup>1</sup>. To date, however, few results are available to document this prediction. In the mouse quantitative transplantations of chemically-induced neoplasms suggest that the H-2-linked *I*r genes of different F<sub>1</sub> hybrids can control their susceptibility to parent-specific tumours<sup>2</sup>. This control, however, is certainly complex (that is, involving more than one gene), possibly because this sort of tumour can have different types of TATA<sup>3</sup>.

Using a better defined antigen, the X1 leukaemia-specific antigen, Sato *et al.*<sup>4</sup> demonstrated that the success of transplantation immunity, induced in specifically immunised mice, is H-2 dependent. Antitumour resistance is dominantly inherited in those F<sub>1</sub> hybrids which have appropriate *I*r gene(s). In the present studies, we found a clearcut H-2 dependence concerning transplantation immunity against another sort of TATA, those of a polyoma-induced tumour. Also, the recent prediction of Willims *et al.*<sup>3</sup>, that some H-2 (or *I*r genes) combinations would lead to suppression of antitumour responsiveness is substantiated by some of our results.

of the A.SW parental strain (H-2<sup>a</sup>) and semisynthetic F<sub>1</sub> hybrids of the following combinations, obtained with congenic resistant partner strains: (A/Sn × A.SW)F<sub>1</sub> (H-2<sup>a</sup>/H-2<sup>a</sup>), (A.BY × A.SW)F<sub>1</sub> (H-2<sup>b</sup>/H-2<sup>a</sup>) and (A.CA × A.SW)F<sub>1</sub> (H-2<sup>i</sup>/H-2<sup>a</sup>). Theoretically, the only traits by which all these mice differ is one half of the H-2 and closely-linked genetic material. Animals of both sexes were used and equally distributed among the groups.

The results of these transplantation assays were observed as tumour incidences (number of mice dying of the tumour/number of injected mice) and by mean survival times (MST) in days (Tables 1 and 2). They are expressed in Fig. 1 as the mean of 1/MST, taking the value of 0 for mice which rejected the tumour graft. This enables the representation of the susceptibility to the tumour, using the information from two different criteria<sup>5</sup>. As both types of immunisation procedures (two independent experiments having been carried out with each of them) gave superimposable results, all the data are combined in Fig. 1.

It can be seen that immunisation considerably diminished susceptibility in the A.SW and (A/Sn × A.SW)F<sub>1</sub> groups, whereas no protective effect was detected in (A.BY × A.SW)F<sub>1</sub> and (A.CA × A.SW)F<sub>1</sub> groups. This confirms that some F<sub>1</sub> hybrids can be less resistant than the parental strain to a parental strain-specific tumour<sup>7-9</sup>, even after immunisation.

This seems somewhat aberrant because the H-2-linked *I*r genes generally are dominantly expressed for the highest response. Different mechanisms can be proposed for explaining the present finding: (1) A cross immunity between the TATA of SEWA and normal transplantation antigens contained in these hybrids which are not immunised against

**Table 1** Susceptibility of mice challenged with 10<sup>3</sup> viable SEWA cells intraperitoneally, after specific protection by amputation of the tumour-bearing leg (pool of two independent experiments)

Strains	H-2	Treatment	Tumour incidence	MST ± s.e. (d)
A.SW	s/s	Non-treated	9/10	47.3 ± 2.0
		Protected	1/9	71
(A.BY × A.SW)F <sub>1</sub>	b/s	Non-treated	2/2	34.0 ± 2.0
		Protected*	3/3	35.6 ± 2.0
(A/Sn × A.SW)F <sub>1</sub>	a/s	Non-treated	14/16	49.3 ± 5.9
		Protected	1/12	53.0
(A.CA × A.SW)F <sub>1</sub>	f/s	Non-treated	10/10	46.1 ± 1.4
		Protected	3/10	41.0 ± 6.2

\*In the first experiment of protection, all mice in this group died of tumour after the amputation of the tumour-bearing leg, in spite of the fact that they were treated according to the same schedule as the mice of the other groups. This further suggests that the mice of this genome are less resistant. Results for mice in this experiment were excluded from the Table.

The SEWA line used was derived from a polyoma-induced osteosarcoma<sup>3</sup>. It was maintained *in vivo* in A.SW mice by intraperitoneal, consecutive passages as an ascitic tumour. Non-treated and specifically immunised animals were injected. Two modes of immunisation were used: (1) Amputation of a tumour-bearing leg, the site of subcutaneous injection of 4 × 10<sup>4</sup> ascitic SEWA cells 15–25 d previously (Table 1). (2) Three weekly subcutaneous injections of 10<sup>6</sup> plaque-forming units (PFU) polyoma virus (small plaque strain) (Table 2). One to three weeks after completion of immunisation, mice (three months old) received an intraperitoneal challenge of 10<sup>3</sup> viable cells. Mice used were

the SEWA tumour could be envisaged. Such common transplantation specificities between TATA and normal allogeneic antigens have already been reported in the case of chemically-induced tumours<sup>8,10</sup>. (2) Also, one example of dominantly expressed non-response of an H-2-linked *I*r gene has been reported<sup>11</sup>. Thus, allowing a good anti-TATA response the H-2<sup>a</sup>/H-2<sup>a</sup> chromosome of the A.SW could be recessive in the H-2<sup>a</sup>/H-2<sup>b</sup> and H-2<sup>a</sup>/H-2<sup>i</sup> heterozygotes. We do not, however, favour *a priori* such an explanation because all other works reported dominance of the response and not of the non-response. The finding reported in ref. 10 seems to be most exceptional.

**Table 2** Susceptibility of mice challenged with 10<sup>3</sup> viable SEWA cells intraperitoneally, after specific protection by three weekly subcutaneous injections of 10<sup>6</sup> PFU polyoma virus (pool of two independent experiments)

Strains	H-2	Treatment	Tumour incidence	MST ± s.e. (d)
A.SW	s/s	Non-treated	10/15	39.6 ± 3.4
		Protected	0/15	—
(A.BY × A.SW)F <sub>1</sub>	b/s	Non-treated	5/5	37.4 ± 1.2
		Protected	9/11	33.1 ± 3.0
(A/Sn × A.SW)F <sub>1</sub>	a/s	Non-treated	9/10	37.8 ± 2.2
		Protected	0/10	—
(A.CA × A.SW)F <sub>1</sub>	f/s	Non-treated	8/8	48.7 ± 0.8
		Protected	8/10	47.0 ± 2.3

Fig. 1 Susceptibility, expressed as 1/MST (arbitrary units) of A.SW, (A.BY x A.SW) $F_1$ , (A/Sn x A.SW) $F_1$  and (A.CA x A.SW) $F_1$  to  $10^3$  SEWA tumour cells. Open column, non-treated mice; Solid columns, mice immunised by two different procedures; error bars are 1 s.e.; figures above bars, pooled tumour incidence of corresponding experimental groups.

(3) That  $H-2^s/H-2^b$  and  $H-2^s/H-2^d$  are less protected against the tumour graft than  $H-2^s/H-2^s$  could be explained, on the basis of a higher response of the heterozygotes, in two ways: (i) The non-protected  $F_1$  hybrids could have a higher anti-TATA reaction giving rise to the production of enhancing antibodies, as already discussed in another situation by Huemer<sup>7</sup>. Further experiments could clarify this point, by transferring the serum of non-protected immunised hybrids to test animals (ii) Recent findings led Prehn to hypothesise that a mild immune reaction, in certain cases, could enhance tumour growth instead of suppressing it<sup>12</sup>. Although this sort of mechanism is difficult to prove in the present examples, it may explain our results.

In conclusion, and whatever the exact mechanism, the results demonstrate that one half of the H-2 and H-2-associated genetic material may detectably influence the intensity of the anti-TATA immune rejection of a polyoma-induced tumour.

We thank Mr M. Liegey for assistance and Mrs C. Lipcey for revision of the English text.

## Sprouting of synapses after partial denervation of frog cardiac ganglion

SYNAPTIC connections in the adult nervous system of several species can be quite flexible and this characteristic has been termed neuronal plasticity. For example, when lesions are made in the axonal pathways of the brains of mature rats, surviving nerve terminals can proliferate and innervate the synaptic sites vacated by the degenerating axons<sup>1,2</sup>. This "sprouting" occurs in the central nervous system<sup>3-4</sup>, autonomic nervous system<sup>5</sup> and peripheral nervous system<sup>6</sup>, and seems to be a characteristic response of nervous tissue to partial denervation. In only a few studies has sprouting been reported not to occur<sup>7-9</sup>. Sprouting of synapses has important implications for the maintenance of neuronal connections and the ability of the nervous system to recover from focal lesions. But several questions need to be answered. For example, are sprouted synapses functional, and if so, do they transmit normally? Is there any specificity in or control over the proliferation of new connections? What initiates and terminates the sprouting? We can now begin to answer these questions. Our studies on the parasympathetic cardiac ganglion of the frog have shown that synaptic sprouting occurs very rapidly after partial denervation. Furthermore, the number of boutons per cell remains constant throughout sprouting and is the same as the number per cell in control ganglia.

The cardiac ganglion in the frog, which lies in the thin, interatrial septum<sup>10</sup>, was dissected from the heart and kept in a shallow recording chamber in frog Ringer (112 mM NaCl, 2 mM KCl, 3 mM HEPES buffer (pH 7.2) and 5 mM  $CaCl_2$ ). The calcium concentration was increased slightly to enhance synaptic transmission<sup>12</sup>. The preganglionic (vagus) nerves were drawn into separate suction electrodes to stimulate right or left vagus nerves independently. Ganglion cells on the left branch of the septum (Fig. 1) were impaled

Fig. 1 Schematic drawing of the interatrial septum in the frog showing the arrangement of stimulating and recording electrodes. The cardiac ganglion cells are scattered along branches of the vagus nerves which traverse the septum. Near the entry to the heart many axons cross between left and right branches. The left and right vagus nerves to the heart were drawn into separate suction electrodes. Ganglion cells along the left vagal branch were impaled and their synaptic input from either (both) vagus nerve(s) was mapped.

**Fig. 2** Intracellular recordings of responses from ganglion cells, evoked by stimulation of the right vagus nerve in a normal ganglion (*a*) and in one in which the right vagus nerve had sprouted to innervate the entire ganglion (*b*). In both instances a large excitatory postsynaptic potential evoked an impulse and outlasted the action potential. In (*b*), the left vagus nerve had been crushed 16 d previously; the left vagus axons had degenerated and the right vagus endings had proliferated to contact all the ganglion cells.

with high resistance micropipettes and excitatory post-synaptic responses to right and left vagal stimulation were photographed. In some frogs, the left vagus nerve was exposed near its exit from the skull and crushed while the animals were anaesthetised with 0.5% tricaine methanesulphonate (Sigma). These operated animals were kept at room temperature in running tap water.

To study the sprouting of synaptic connections in the ganglion after partial denervation, we mapped the vagal innervation of cells on the left branch in normal frogs and operated frogs. In normal frogs, each ganglion cell is usually innervated by only one or sometimes two vagal fibres<sup>2</sup>, and, as might be expected, neurones tend to be innervated by the ipsilateral vagus nerve. Eighty-seven per cent of the cells on the left branch had input(s) from the left vagus nerve and 48% had input(s) from the right vagus nerve (207 cells from 15 ganglia). A small proportion of these cells (34%) had inputs from both nerves. An even smaller fraction (3%) had no inputs.

When the vagal innervation of neurones on the left branch was mapped in the operated frogs, nearly all the cells received input(s) from the intact (right) vagus nerve.

**Fig. 3** Sprouting of preganglionic nerve fibres to the parasympathetic cardiac ganglion in the frog; increase in the percentage of ganglion cells innervated by the right vagus nerve after the left vagus nerve had been crushed *a*, Percentage of neurones from the left branch of the cardiac ganglion which received synaptic input from the contralateral vagus nerve on various days after crushing the ipsilateral vagus nerve. *b*, Percentage of neurones which received synaptic input from the left vagus nerve after the operation. Day zero shows data from 15 unoperated ganglia. Each symbol represents data from one ganglion (20–30 cells impaled in each ganglion) and a solid line has been drawn through the weighted means. Percentages were calculated on the basis of the total number of cells which received any synaptic input.

For example, 10–26 d after the left vagus nerve was crushed, 100% of cells with synaptic inputs was innervated by the right vagus nerve (compare 48% for unoperated frogs). Six per cent had no inputs; this latter figure is similar to that in normal animals and presumably due to damage caused during dissection. Because there was no visible loss of ganglion cells after the operation, we interpret this increased percentage of contralateral innervation as due to a proliferation, or sprouting, of the surviving right vagus nerve.

The “sprouted synapses” are functional, and as far as we could detect, transmit normally (Fig. 2). No abnormal synaptic responses were evoked during or after sprouting. Experiments are in progress to examine synaptic transmission in greater detail to determine whether we can resolve any peculiarities of sprouting synapses.

The time course of sprouting was examined by mapping vagal innervation of different ganglia at several intervals after the operation. Figure 3 shows that as soon as 24 h after crushing of the left vagus nerve, there was a small but significant ( $P < 0.01$ ) increase in innervation by the right vagus nerve. The maximum extent of sprouting was reached about 8 days after the operation; there was no further increase in the proportion of cells innervated by the right vagus nerve.

To study the morphological basis of this phenomenon

**Fig. 4** Histograms of numbers of synapses per cell body before (*c*), during (*b*), and after (*a*) sprouting of preganglionic inputs. Synaptic boutons were counted in whole mounts of ganglia stained with zinc iodide. In *c*, boutons from 73 neurones on the left branches in nine unoperated ganglia were counted. In *b*, boutons were counted from 112 ganglion cells (left branch) from animals in which the left vagus nerve had been crushed 1–8 d previously. In *a*, boutons were counted from 120 neurones (left branch) from animals 9–26 d after the operation. Numbers above each histogram are the mean values.

and determine whether we could correlate the changes in innervation as determined physiologically with any structural changes, we stained synaptic boutons in whole-mount preparations with the zinc-iodide method<sup>10,11</sup> for light microscopy. Although the basis of the zinc iodide method is not well understood, we assume that there is no difference in the ability of sprouted synapses and normal synapses to take up the stain. In normal frogs, the average number of synaptic boutons per cell on the left branch was  $9.1 \pm 4.3$ . When boutons were counted in ganglia after the left vagus nerve had been crushed, and sprouting of the right vagus nerve was complete, there was no change ( $9.0 \pm 3.9$  boutons per cell). Boutons were counted at several intervals after crushing of the left vagus nerve. Figure 4 summarises the measurements and shows that there was no change in the number of boutons per cell during sprouting (1–8 d after the operation) or after its completion (9–26 d after the operation).

These findings indicate that surviving vagal axons respond rapidly to partial denervation of the ganglion by sprouting and form new functional synapses. Furthermore, the morphological studies show that sprouting is a well controlled phenomenon. Thus, the proliferation of synapses does not change the number of boutons from that found on normal cells. These findings are consistent with the hypothesis that sprouting synapses grow to vacant synaptic sites<sup>2</sup> and that each cell has a fixed number of these sites<sup>7</sup>.

## Molecular differentiation in the preimplantation mouse embryo

THE primary observable event of differentiation in the mammalian embryo is the formation of the trophectoderm and the inner cell mass (ICM). Differentiation first becomes evident in the mouse embryo during early blastulation and is clear and apparently irreversible by the 60-cell blastocyst stage. The 45 or so trophectoderm cells surround a blastocoelic cavity containing the ICM, they pump fluid, are phagocytic, are interconnected through junctional complexes and can elicit an implantation response in the uterus<sup>1</sup>. The trophectoderm gives rise to the ectoplacental trophoblast, primary and secondary trophoblastic giant cells and probably also to extra-embryonic ectoderm<sup>1,2</sup>. The cells of the ICM are less evidently differentiated, being rounded, sticky cells somewhat like cleavage stage blastomeres, but having lost the capacity to form trophectoderm<sup>3,4</sup>. The ICM gives rise to embryonic ectoderm, and to both extra-embryonic and embryonic endoderm<sup>1,2,5</sup>. Although

the fully differentiated cells of the blastocyst are distinguishable by structural and functional criteria, adequate markers of differentiation are not available for the morula stage, when the determinative events leading to differentiation are presumed to occur. Thus, attempts to detect blastomeres with a commitment to one or the other differentiated cell type have relied for an index of commitment on the subsequent behaviour of genetically or physically marked blastomeres combined in various spatial relations with other distinguishable blastomeres. This experimental approach is open to criticism. Frequently, many cell divisions must elapse before suitable genetic markers can be detected with sufficient sensitivity, and the procedures involve artificial manipulation and therefore possibly modification of blastomeres to test their potency<sup>2,6</sup>. The detection of a cell marker which is produced *in situ* in the earliest stages of differentiation, and one which is detectable by highly sensitive techniques would circumvent both of these problems. We describe here the detection of tissue specific markers which may prove to fulfil these criteria.

Mouse blastocysts were flushed from the uteri of super-ovulated mice of an inbred strain carrying the *a<sup>c</sup>* gene (extreme non-agouti) which had been mated to *a<sup>c</sup>/a<sup>c</sup>* males 3.5 d previously (detection of vaginal plug indicated day 0). All blastocysts had recently expanded, with zona pellucida intact and with no evidence of trophoblastic giant cell formation. Blastocysts from several females were pooled for each experiment and then divided into three groups: the first group was left intact, the second group was used for microdissection of ICMs and the third for microdissection of trophoblastic vesicles<sup>1</sup>. Dissection of the trophoblastic vesicles involves loss of the polar trophoblast overlying the ICM. Occasionally both trophoblastic vesicles and ICMs were recovered from the same blastocysts. Microdissected fragments were incubated in medium PB1+10% foetal calf serum for 2–3 h, and then checked to determine that only cells in the trophoblastic preparation and not those in the ICM preparation were accumulating fluid. This procedure served to test for any major cross contamination of cell type. The embryos and embryonic fragments were then washed in protein-free medium 16 (ref. 7), and transferred to 100  $\mu$ l of medium 16 containing 10  $\mu$ l of <sup>35</sup>S-L-methionine (New England Nuclear, specific activity 200 Ci mmol<sup>-1</sup>). After incubation for 4 h at 37 °C in a moist atmosphere of 5% CO<sub>2</sub> in air, the blastocysts and fragments were collected into 25  $\mu$ l of lysis buffer containing urea, 2-mercaptoethanol, Ampholines (LKB, pH 5–7 and 3–10) and non-ionic detergent Nonidet P-40.

It was confirmed that the radiolabelled amino acid had been incorporated into proteins by measuring trichloroacetic acid-precipitable counts of aliquots of each sample<sup>8</sup>. Microdissection of embryos did not seem in most experiments to reduce the ability of fragments to incorporate label, when allowance was made for the loss of approximately one third of embryonic tissue during dissection. The relative rate of protein synthesis was comparable with that previously observed in intact blastocysts at the same stage of development<sup>10</sup>. In each of six experiments, a minimum of 8–10 microdissected fragments of each tissue was used.

Labelled proteins were separated by two-dimensional polyacrylamide gel electrophoresis<sup>9</sup>. After separation of proteins by isoelectric focusing on cylindrical gels, proteins were electrophoresed into exponential (8–15%) gradient, sodium dodecyl sulphate (SDS)–polyacrylamide slab gels<sup>8,9</sup>. After electrophoresis, the slab gels were infiltrated with the scintillant PPO<sup>11</sup>, dried under vacuum, placed under X-ray film (Kodak Royal-X-Omat, RP/R54) and stored at –70 °C for 6–10 weeks before developing. Each spot detected on the autoradiographs represented one polypeptide into which label had been incorporated.

Representative two-dimensional protein patterns of intact blastocysts (*a*), cells of the ICM (*b*) and cells of the trophoblast (*c*) are shown in Fig. 1. Patterns were compared for protein spots common to all three preparations (intact embryo, Fig. 1*a*), spots limited to the ICM and intact embryo (indicated by arrows, Fig. 1*b*) and spots limited to the trophoblast and intact embryo (indicated by solid triangles, Fig. 1*c*). No spots were found exclusively in intact embryos. Most polypeptide spots were common to all three types of preparations, as might be expected since they presumably represent proteins required for general cell function. Several 'tissue-specific' spots, however, were seen consistently. The term 'tissue-specific' spots describes those polypeptides which were either not detectable or only very weakly so in one dissected tissue but clearly present in the other. An occasional faint trace of some of the stronger trophoblast-specific spots was detected on some gels of the ICM (Fig. 1*b*), and vice versa (Fig. 1*c*). Such spots might represent a genuine observation but may alternatively be due to cross contamination by a few cells, made visible by the sensitivity of the technique.

Apart from many apparent quantitative differences between individual spots in the patterns obtained from dissected ICM and trophoblast, ICM tissue yielded at least eight consistent tissue-specific spots (arrows, Fig. 1*b*), while trophoblast tissue yielded a number of obvious, major

'tissue-specific' spots (Fig. 1*c*) of which three spots constituted a relatively substantial fraction of the total incorporated material in the tissue (Fig. 1*c*). In addition, at least three other spots were found in ICM dissections but occurred in either of two different positions relative to all other spots in different experiments (asterisks, left of *b* and *c*). One possible explanation for this observation is that at least three polypeptides differ in the tissues from different dissections. Such a difference could result from genetic heterogeneity in the *a*<sup>0</sup> strain blastocyst or perhaps from the chemical modification of polypeptides, such as the addition or deletion of a carbohydrate group. The chemical modification of polypeptides may be a normal feature of development and could be related to the age of the blastocysts or the position of cells within the embryo. Nine other spots (not marked) were detected in the trophoblast only or in the ICM only but were not consistently observed in the microdissections. These polypeptides were only weakly radioactive and may be more clearly defined with prolonged exposures or with preflashing of the X-ray film<sup>11</sup>.

The failure to detect polypeptide spots unique to intact blastocysts implies that the polar trophoblast overlying the ICM probably does not synthesise a unique set of proteins. One spot which was, however, very weak in the gels of intact embryos (Fig. 1*a*) was relatively intense in gels of ICM (arrow 1, Fig. 1*b*) and absent from the gels of the trophoblast (Fig. 1*c*). This observation could be explained by an ICM-trophoblast interaction, in which quantitative rather than qualitative regulation of protein synthesis was involved. In this case interactions between ICM and trophoblast may have functioned to limit rather than induce the synthesis of a particular polypeptide.

These results have identified molecular correlates of the earlier visible events of differentiation in the mouse. The existence of differences at the molecular level is not surprising in view of the overt differentiation at the cellular level<sup>12</sup>. Indeed, the fact that only a relatively minor proportion of the spots identified are 'tissue-specific' might be considered surprising. But we are not detecting all newly synthesised proteins with this technique, since the limits between which both isoelectric focusing and gradient electrophoresis function will exclude many proteins. Other polypeptides will be only weakly radioactive and will require longer exposure to preflashed X-ray film for detection. In addition, some autoradiographic spots may not necessarily represent the direct expression of new gene products but rather, as a normal feature of development,

**Fig. 1** *a*, Separation of protein labelled with <sup>35</sup>S-L-methionine from intact, 3.5-d *a*<sup>0</sup> blastocysts by high resolution, two-dimensional gel electrophoresis. In the first dimension, proteins were separated according to charge by isoelectric focusing (IEF) on 135-mm cylindrical gels. In the second dimension, proteins were separated according to molecular weight on sodium dodecyl sulphate (SDS), exponential-gradient (8–15% acrylamide), polyacrylamide slab gels. For the first dimension, the pH range was determined by cutting a one-dimensional gel (after isoelectric focusing) into 3-mm pieces, mashing the pieces in degassed, distilled water (2 ml), shaking the mixture for approximately 1 h (in tightly sealed vials) and then measuring the pH of the mixtures. Approximate molecular weights ( $\times 10^{-3}$ ) are given on the far right and were determined from gels calibrated for molecular weight as before<sup>9</sup>. The arrow points to a polypeptide which was absent from trophoblast preparations, relatively intense in ICM preparations (arrow, 1, Fig. 1*b*) but only weakly radioactive in the intact embryo. *b*, Representative autoradiograph of protein labelled with <sup>35</sup>S-L-methionine from ICM dissection. Spots limited to this tissue are indicated by arrows. Faint traces of major trophoblast spots are indicated by solid triangles. Approximate molecular weights ( $\times 10^{-3}$ ) are given on the far right. *c*, Representative autoradiograph of protein labelled with <sup>35</sup>S-L-methionine derived from trophoblast dissection. Spots limited to this tissue are indicated by solid triangles with major spots indicated by triangles 1–3. Faint traces of major ICM spots are marked by arrows. Approximate molecular weights ( $\times 10^{-3}$ ) are given on the far right.

the chemical or enzymatic modification of proteins, with a resulting alteration in spot position. Further study is required to define those spots representing new gene products and those spots representing polypeptides which have been modified after translation.

With the above caveats in mind, the detection of the differences described here presents a powerful approach for the analysis of progressively earlier stages of mammalian development to determine the time at which the 'tissue-specific' proteins first appear and the spatial distribution of the cells producing them. With such an approach using intact, non-manipulated and unmarked embryos, it may prove possible to test directly the hypothesis that cell position determines selective gene expression and thus differentiation in preimplantation morulae<sup>13-15</sup>.

## Increased cyclic nucleotide phosphodiesterase activity in leukaemic lymphocytes

THE intracellular concentration of cyclic AMP influences cellular proliferation and maturation in both normal and malignant tissue. For example, the concentration of cyclic AMP—changes during the cell cycle being lowest during mitosis<sup>1</sup>—is inversely related to the rate of cell growth<sup>2</sup>, and is elevated in contact-inhibited cell populations<sup>3,4</sup>. In studies of malignant tissue, the concentration of cyclic AMP is lower in cells transformed *in vitro* by oncogenic viruses than in untransformed cells<sup>3-5</sup>, and is lower in certain tumours grown *in vivo* than in the corresponding normal tissue<sup>6,7</sup>. Furthermore, in malignant cells, exogenous cyclic AMP or agents that increase the intracellular concentration of this cyclic nucleotide decrease the rate of growth<sup>8</sup> and induce morphological and biochemical differentiation<sup>9,10</sup>.

The role of cyclic GMP in cell growth is less clear although it has been demonstrated that its concentration increases in lymphocytes responding to plant mitogens<sup>11</sup> and decreases in fibroblasts transformed by oncogenic viruses<sup>12</sup>.

A decreased concentration of cyclic AMP in malignant cells may be caused by a reduction in the activity of the

enzyme catalysing its synthesis (adenylate cyclase) or an increase in the activity of the enzyme catalysing its hydrolysis (phosphodiesterase). There is evidence that both these enzymes are altered in certain transformed cells. For example, BHK cells<sup>13</sup> and astrocytoma cells<sup>14</sup> transformed by oncogenic viruses have lower activities of adenylate cyclase than do untransformed cells. Other types of transformed cells and certain solid tumours did not, however, always exhibit lower activities of adenylate cyclase (for reviews see refs 15 and 16).

Most studies of phosphodiesterase showed that enzyme activity was lower in malignant cells than in normal cells (for review see ref. 17). Other studies showed no change in phosphodiesterase activity in malignant cells<sup>18</sup>, and still others<sup>19</sup> have shown that although hepatomas have a decreased total activity of phosphodiesterase, the activity of the low  $K_m$  form of the enzyme was increased.

We now report that certain leukaemic lymphocytes have markedly increased activities of both cyclic AMP phosphodiesterase and cyclic GMP phosphodiesterase compared with those of normal lymphocytes. This increased capacity to hydrolyse the cyclic nucleotides may provide an explanation for the abnormal growth of these cells.

Female mice (20-25 g, Jackson Laboratories, Bar Harbor, Maine) were given free access to food and water. Lymphocytic leukaemia cell lines, L5178Y and L1210 (Little, Cambridge, Massachusetts) were grown in the ascites fluid of the peritoneal cavity of C<sub>3</sub>H<sub>2</sub>F<sub>1</sub> mice. Activities of cyclic AMP

**Fig. 1** Cyclic nucleotide phosphodiesterase activity of normal and leukaemic lymphocytes. Normal lymphocytes (open bars) were prepared from the lymph nodes of three strains of mice: DBA/2, the strain in which the tumours originated; C<sub>3</sub>H<sub>2</sub>F<sub>1</sub> (CDF), the strain that serves as host for the tumour; and Swiss Webster (SW), a widely used inbred strain. Lymph nodes were minced in Krebs-Henseleit buffer, pH 8.0. Cells were freed from the stroma in a Dull No. 24 homogeniser using a loose fitting Teflon pestle. Cell suspensions were purified by passage through a plastic column fitted with 40 × 7 mm of loosely-packed siliconised glass wool. Cells were washed twice in buffer and collected by centrifuging at 480g for 10 min. Cells were sonicated for 15 s at 100 W in 50 mM glycylglycine buffer, pH 8.0. Leukaemic lymphocytes, L5178Y and L1210 (hatched bars), were collected 6 d after transplantation into CDF mice by injecting 2 ml Krebs-Henseleit buffer intraperitoneally and aspirating the cell suspension. Cells were prepared in the same manner as were the normal lymphocytes. Using these techniques, both preparations contained more than 95% lymphocytes; 99% of the cells were viable as evidenced by their ability to exclude Trypan blue. Cells were sonicated for 15 s, at 100 W, which was long enough to disrupt more than 90% of the cells without appreciable loss of phosphodiesterase activity. Cyclic nucleotide phosphodiesterase was measured in the whole sonicate using either cyclic AMP (250 μM) or cyclic GMP (100 μM) as substrate. Each tube contained a 50 mM glycylglycine buffer (pH 8.0) containing 0.1 mM CaCl<sub>2</sub> and an enzyme cycling system described in detail elsewhere<sup>19,20</sup>. Protein was measured by the method of Lowry *et al.*<sup>28</sup>. Activity of both cyclic nucleotide phosphodiesterases (on a protein basis) was significantly greater in the leukaemic lymphocytes than in the normal lymphocytes ( $P < 0.005$ ). When the activity was based on the number of cells, the difference in activity between the normal and leukaemic cells was two to three times greater than when the activity was based on protein. Bars represent mean ± s.e. of at least five enzyme preparations. *a*, Cyclic AMP phosphodiesterase; *b*, Cyclic GMP phosphodiesterase.

**Table 1** Kinetic analysis of cyclic nucleotide phosphodiesterases of normal and leukaemic lymphocytes

Cell Source	Cyclic AMP phosphodiesterase		Cyclic GMP phosphodiesterase	
	$V_{\max}$	$K_m$ ( $\mu\text{M}$ )	$V_{\max}$	$K_m$ ( $\mu\text{M}$ )
Normal

DBA/2	11 $\pm$ 1	67 $\pm$ 7	7.6 $\pm$ 1.6	40 $\pm$ 4
C <sub>3</sub> D <sub>2</sub> F <sub>1</sub>	22 $\pm$ 6	102 $\pm$ 14	9.6 $\pm$ 1.2	32 $\pm$ 5
Leukaemic				
L1210	224 $\pm$ 20	159 $\pm$ 29	124 $\pm$ 28	60 $\pm$ 7
L5178Y	141 $\pm$ 31	113 $\pm$ 18	225 $\pm$ 48	52 $\pm$ 9

Normal and leukaemic lymphocytes were prepared as in Fig. 1. Cells were sonicated and centrifuged at 100,000*g* for 60 min. The activity of cyclic AMP and cyclic GMP phosphodiesterase was measured in the supernatant fraction.  $V_{\max}$  and  $K_m$  were calculated according to the procedure of Hofstee<sup>30</sup> at substrate concentrations from 15–250  $\mu\text{M}$  cyclic AMP and 12.5–100  $\mu\text{M}$  cyclic GMP.  $V_{\max}$  for both cyclic nucleotide phosphodiesterases was significantly greater in the leukaemic cell preparations than in any of the normal cell preparations ( $P < 0.005$  for all preparations except for Swiss Webster cyclic GMP phosphodiesterase where  $P < 0.01$ ). Each value represents the mean  $\pm$  s.e. for three to five enzyme preparations. Enzyme activity is expressed as nmol cyclic nucleotide hydrolysed per mg protein per min.

phosphodiesterase<sup>19</sup> and cyclic GMP phosphodiesterase<sup>20</sup> were determined as described previously. The rate of hydrolysis of the cyclic nucleotides in these assays was linear with respect to the time of incubation and concentration of tissue. The effect of tissue on the standard curves was determined and, if necessary, appropriate corrections were made. All experiments were designed to study the enzymes from freshly prepared normal and leukaemic lymphocyte preparations on the same day in identical assay conditions.

Figure 1 compares the specific activities of cyclic AMP phosphodiesterase and cyclic GMP phosphodiesterase in whole sonicates of leukaemic and normal lymphocytes. As can be seen, the phosphodiesterase activity in the leukaemic lymphocytes was 5–10-fold greater than that of any of the other three normal lymphocyte preparations studied. To determine if this increase in phosphodiesterase activity of the leukaemic cell preparations was confined to a specific subcellular element in these cells, we studied the phosphodiesterase activity in various subcellular fractions as well as in the 100,000*g* supernatant fluid. Leukaemic cells exhibited a greater phosphodiesterase activity in all subcellular fractions studied.

A kinetic analysis of the 100,000*g* supernatant fraction of the lymphocyte preparations is shown in Table 1. The activity of phosphodiesterase was determined at substrate concentrations from 1 to 250  $\mu\text{M}$  for cyclic AMP and from 0.8 to 100  $\mu\text{M}$  for cyclic GMP. At all substrate concentrations, the phosphodiesterase from leukaemic cells hydrolysed cyclic AMP and cyclic GMP at a greater rate than did the phosphodiesterase of normal lymphocytes. The calculated maximum velocities ( $V_{\max}$ ) for both the cyclic nucleotide phosphodiesterases from either the L1210 or L5178Y leukaemic lymphocytes was markedly greater than the  $V_{\max}$  of any normal lymphocyte preparation.

This increased reaction velocity could not be attributed

to an increased apparent affinity of the enzyme from the leukaemic cell for its substrate since preparations from normal lymphocytes showed similar or even lower apparent Michaelis constants ( $K_m$  values) than did the preparations from the leukaemic cell lines. At concentrations of cyclic AMP from 15 to 250  $\mu\text{M}$  or at concentrations of cyclic GMP from 12.5 to 100  $\mu\text{M}$ , each phosphodiesterase exhibited a single  $K_m$  value. At lower substrate concentrations, complex kinetic behaviour made accurate assessment of other  $K_m$  values impractical. The complex kinetics observed may indicate the presence of a mixture of isoenzymes in these cells as has been found in most tissues<sup>21,22</sup> including single cell lines<sup>23</sup>.

Several possibilities may account for the observed increase in phosphodiesterase activity of leukaemic lymphocytes. For example, the difference may be attributable to the different environments in which the cells were grown, as the leukaemic cells were in suspension in the ascites fluid of the peritoneal cavity, whereas the normal lymphocytes were in a solid tissue. To examine this possibility we injected leukaemic lymphocytes subcutaneously into CDF mice. Six days later the solid nodule was dissected, and the cells were freed from stroma by the procedure described for the preparation of normal lymphocytes (see Fig. 1). The phosphodiesterase activity of these cells (73  $\pm$  4 nmol cyclic AMP and 65  $\pm$  5 nmol cyclic GMP hydrolysed per mg protein per min) was not significantly different from that of leukaemic cells grown for 6 d in the ascites fluid of the peritoneal cavity of another group of CDF mice (86  $\pm$  5 nmol cyclic AMP and 59  $\pm$  3 nmol cyclic GMP hydrolysed per mg protein per min) indicating that the greater phosphodiesterase activity in leukaemic lymphocytes was probably not caused by the physical environment of the cells.

We next examined the possibility that the increased activity of phosphodiesterase in leukaemic cells could be attributed to the presence in these cells of a heat-stable, calcium-dependent, protein activator of phosphodiesterase which has been found previously in almost all other tissues<sup>24,25</sup>. We assayed for the presence of this activator in leukaemic cells according to the method of Cheung<sup>25</sup>. These cells did contain an activator of phosphodiesterase as evidenced by its ability to increase the activity of phosphodiesterase from mouse cerebrum fivefold (Table 2). It had no effect, however, on the phosphodiesterase from leukaemic lymphocytes. This suggested either that the phosphodiesterase from leukaemic lymphocytes could not be activated or that it was already maximally activated. To examine this latter possibility we measured the phosphodiesterase activity in the presence of the calcium chelator, EGTA. As can be seen (Table 2) EGTA produced a 75% inhibition of phosphodiesterase in brain (suggesting that this enzyme was already partially activated) but had no

**Table 2** Effects of phosphodiesterase activator from leukaemic lymphocytes on the cyclic AMP phosphodiesterase activity of cerebrum and leukaemic lymphocytes

Phosphodiesterase source	Cyclic AMP phosphodiesterase		
	Control	Activator	EGTA
Cerebrum	56 $\pm$ 4	217 $\pm$ 11*	16 $\pm$ 1*
Leukaemic lymphocytes	61 $\pm$ 3	59 $\pm$ 6	68 $\pm$ 3

Activator of phosphodiesterase was prepared from leukaemic lymphocytes according to Cheung<sup>25</sup>. Activity of phosphodiesterase was determined in whole sonicates of cerebrum of DBA/2 mice and L1210 leukaemic lymphocytes in the presence of 0.1 mM Ca<sup>2+</sup> and 3 mM Mg<sup>2+</sup> in the absence and presence of activator (25  $\mu\text{l}$ ) or EGTA (1 mM) using 250  $\mu\text{M}$  cyclic AMP as substrate. Activity is expressed as nmol cyclic AMP hydrolysed per mg protein per min. Each value represents the mean of four determinations  $\pm$  s.e.

\* $P < 0.001$  compared with control values.

effect on the phosphodiesterase of the leukaemic lymphocytes. In addition, when portions of enzyme preparations from normal lymphocytes were added to the enzyme from leukaemic cells, the phosphodiesterase activity was additive, suggesting that no inhibitor of phosphodiesterase was present in the normal cells. Thus, the greater activity of phosphodiesterase in leukaemic lymphocytes apparently was not caused by the presence of a phosphodiesterase more responsive to the endogenous activator or by a phosphodiesterase in a highly activated state, but rather was attributable to a greater quantity of the enzyme in the leukaemic cells.

Based on the present findings and on the evidence that cyclic AMP inhibits the rate of growth of these leukaemic lymphocytes<sup>26,27</sup>, one may speculate that the abnormal proliferation of these cells may be explained by an increase in the activity of the enzyme that catalyses the hydrolysis of cyclic AMP. The significance and interpretation of the high activity of cyclic GMP phosphodiesterase in leukaemic lymphocytes must await studies on the role of cyclic GMP in these cells. Further, since cyclic AMP phosphodiesterase exists in multiple forms<sup>21-23</sup>, which can be selectively inhibited by drugs<sup>28</sup>, it may be possible to inhibit specifically the predominant forms of the enzyme in these malignant cells. This might cause an elevation in the concentration of cyclic AMP, and consequently a reduction in the growth rate of the abnormal cells, leaving normal cells unaltered.

These studies on the multiple forms of phosphodiesterase as well as studies which are designed to show whether other qualitative differences exist between the phosphodiesterases of normal and leukaemic lymphocytes are currently in progress. It would be particularly instructive to determine, for example, if the increased activity is attributable to a single enzyme which hydrolyses both cyclic AMP and cyclic GMP or to a specific increase in an enzyme form with specificity for either of the two cyclic nucleotides.

We thank Mr T. Wallace for assistance. This work was supported by a grant from the US Public Health Service.

## Spectrophotometric evidence for the presence of phytochrome in the envelope membranes of barley etioplasts

PHYTOCHROME is a chromoprotein photoreceptor, existing in two photoconvertible forms (Pr and Pfr), and is responsible for various metabolic and developmental responses of higher plants to light<sup>1</sup>. The location of phytochrome in plant cells and its mechanism of action are matters of debate. Many physiological responses to light have been adduced as evidence for phytochrome either being a component of certain cellular membranes, or acting on them, bringing about rapid changes in cell metabolism which lead to developmental changes<sup>2</sup>. There have been claims that phytochrome, in the Pfr form only, binds specifically to as yet uncharacterised membranous fractions<sup>3-6</sup> and the data have formed the basis for allosteric models of the action of phytochrome<sup>3-7</sup>. Further progress requires a demonstration of the precise location of phytochrome with relation to a well characterised membrane where it is known to direct a process *in vitro*. We demonstrated<sup>8,9</sup> the specific association of a proportion of total cellular phytochrome with etioplasts isolated from 6-d-old etiolated barley leaves. Etioplast phytochrome, as a result of its interconversions, was shown to regulate, *in vitro*, the efflux of endogenous etioplast gibberellins across the envelope membranes into the surrounding medium. Confirmatory results have been obtained with etiolated wheat leaves<sup>10,11</sup>. Although phytochrome was detected spectrophotometrically in the purified etioplast preparations from barley, no data were obtained

Fig. 1 Protocol for the separation of etioplast envelopes. Procedure as in ref. 10 modified by the use of 25 mM MOPS buffer (described in Table 1) as the isolation medium. The period of lysis at 0 °C was extended to 15 min.

Etioplasts were isolated in 25 mM *N*-morpholino-3-propanesulphonic acid (MOPS) buffer containing 3 mM EDTA (disodium salt), 300 mM sucrose, 14 mM 2-mercaptoethanol and adjusted to a final pH of 7.5. Aliquots of (1) the crude homogenate, (2) the first crude plastid pellet, and (3) supernatant after a 1-min spin at 6,000g, (4) the washed plastid pellet and supernatant (5), after a second similar centrifugation, and (6) the final purified etioplasts, were taken for analysis. Samples of various volume were made up to 3 ml for dual wavelength measurement in a Perkin Elmer 156 digital double wavelength spectrophotometer. Measurement was made over a 1-cm path length using calcium carbonate as a light scattering agent. Actinic radiations lasting 30 s were of 660 nm and 730 nm. Measuring beams were also of these wavelengths.

for the suborganellar location of the photoreceptor or for the amount present in the etioplasts. We report here that although only a small proportion of the total phytochrome is associated with etioplasts, it seems to be concentrated in the envelope membranes. These data support the view that phytochrome is located in specific cellular membranes where it regulates transmembrane transport<sup>12</sup>.

Etioplasts were isolated and purified by a modification<sup>8,9</sup> of the Sephadex column technique developed by Wellburn<sup>13</sup>. As we have described previously<sup>8,9</sup>, this method yields etioplasts which are intact and very pure as judged by

electron microscopic and biochemical criteria. Samples for protein<sup>14</sup> and phytochrome<sup>8,9</sup> measurements were taken at each separation stage.

The data from five separate preparations are presented in Table 1, showing high reproducibility. The amount of phytochrome per mg protein of the purified etioplasts was between a quarter and a third that of the crude homogenate. According to Pratt and Coleman<sup>15</sup>, however, a large proportion of the phytochrome of etiolated tissues is in a free, soluble state in the cytoplasm and not associated with specific structures. Approximately 90% of the total homogenate phytochrome remained in the supernatant after the first centrifugation, although unknown amounts may have been associated with organelles or plastid fragments of a lower pelletability than intact etioplasts. Table 1 shows that the purified etioplasts accounted for about 2% of the homogenate protein and 0.6% of the total homogenate phytochrome. Although the actual proportion of phytochrome associated with the etioplasts is small, the number of possible phenomena which it may control there makes it far from insignificant<sup>1</sup>.

To determine the suborganellar location of etioplast phytochrome, purified etioplasts were fractionated into envelope, prolamellar and supernatant fractions according to the method of Mackender and Leech<sup>16</sup> modified as shown in Fig. 1. The prolamellar and envelope fractions contained the expected components revealed by electron microscopy, although biochemical characterisation has not been carried out. Measurements of protein and phytochrome in each fraction for two experiments are presented in Table 2. In both cases, although the protein contents of the 3,000g pellet (that is, the prolamellar fraction) and the 20,000g supernatant were roughly twice that of the 20,000g pellet

**Table 2** Measurement of phytochrome after the fractionation of etioplasts

Fraction	Protein (mg)	$\Delta (\Delta A)$ 660/730 nm	$\Delta (\Delta A)$ per mg protein	Mean $\Delta (\Delta A)$ per mg protein
Intact etioplasts	1.590	0.00200	0.00125	0.00167
	1.320	0.00270	0.00210	
3,000g pellet	1.115	0.00000	0.00000	0.00000
	1.115	0.00000	0.00000	
3,000g supernatant	1.080	0.00215	0.00199	0.00199
	1.000	0.00200	0.00200	
20,000g pellet	0.500	0.00120	0.00240	0.00241
	0.660	0.00160	0.00242	
20,000g supernatant	0.900	0.00000	0.00000	0.00000
	1.000	0.00000	0.00000	

Dual wavelength spectrophotometry was carried out on aliquots of samples made up to 3 ml.

(that is, the envelope fraction), phytochrome was only detectable in the latter. Approximately 77% of the initial etioplast phytochrome was recovered in the 20,000g pellet which in terms of protein content constitutes a 1.44-fold enrichment of phytochrome. The remaining phytochrome was lost or rendered undetectable.

Although definitive proof will depend on rigorous chemical and biochemical characterisation of the subetioplast fractions, these data strongly suggest that all etioplast phytochrome is located in the etioplast envelope. It seems unlikely that its presence there results from nonspecific adsorption, since our earlier work has shown that phytochrome exerts rapid control over transport of gibberellins across the etioplast envelope *in vitro*<sup>8,9</sup>. The pelletable phytochrome investigated by many other workers<sup>7</sup> seems to bind to membranous material only in the Pfr form; etioplast phytochrome, on the other hand, exists as Pr in or on the etioplast envelope. The characteristics of etioplast phytochrome, therefore, are not easily reconcilable with the concept of phytochrome existing as soluble Pr in the cytoplasm and moving to specific binding sites on membranes only when photoconverted to Pfr, as proposed in the allosteric models of phytochrome action<sup>7</sup>. The data are more consistent with our hypothesis<sup>8,9,12</sup> that phytochrome is a normal component of the membrane where it acts as a permease, or transport factor, to regulate the movement of one or more critical metabolites between compartments.

## Regulation of RuDP carboxylase/oxygenase activity and its relationship to plant photorespiration

RIBULOSE 1,5-diphosphate carboxylase/oxygenase (fraction 1 protein), the most abundant protein in nature, is a key photosynthetic enzyme catalysing the addition of CO<sub>2</sub> to ribulose 1,5-diphosphate (RuDP) to form two molecules of phosphoglyceric acid (PGA). The enzyme also has a competitive oxygenase function catalysing the splitting of RuDP by O<sub>2</sub> to form one molecule of PGA and one molecule of phosphoglycolate<sup>1–3</sup>. The latter function of this enzyme has been suggested to be the primary source of phosphoglycolate, the principal substrate for photorespiration<sup>5</sup>.

Fraction 1 protein consists of eight large and eight small subunits<sup>6</sup>. The large subunits are both encoded and synthesised within the chloroplast<sup>7,8</sup> and seem to function as

the catalytic sites for the carboxylase/oxygenase functions of this enzyme<sup>9</sup>. In contrast, the small subunits are both encoded and synthesised outside the chloroplast and their function is unresolved<sup>10</sup>. In this report, we present evidence that the small subunits regulate the carboxylase/oxygenase activity of fraction 1 protein<sup>9</sup> and that the oxygenase function of this enzyme is probably not the principal source of phosphoglycolate *in vivo*<sup>5</sup>.

We prepared crystallised fraction 1 protein<sup>11</sup> from green, wild-type (*su/su*) tobacco leaves (cv John Williams Broadleaf) and from the heterozygous, dominant, yellow mutant (*Su/su*) of this line. Mature leaves were obtained from green and yellow progeny derived by selfing the heterozygous yellow plant. Two important features of the yellow plants are that they result from a nuclear mutation<sup>12</sup> and that yellow plants have a two to threefold higher rate of photorespiration than the wild-type sibling<sup>13,14</sup>.

The polypeptide patterns of the fraction 1 protein isolated from the wild type and yellow mutant sibling leaves are shown in Fig. 1. Both proteins had identical isoelectric focusing patterns consisting of three large and two small subunit polypeptides. Thus, we found no detectable (by this technique) structural change of the small subunit between the wild and mutant proteins. As Table 1 shows, however, RuDP carboxylase/oxygenase activities are markedly different. Carboxylase/oxygenase activities of the fraction 1 protein from the mutant were about 50% lower than those obtained with the wild-type enzyme. It should be noted that intermediate levels of activity were observed with a mixture (1:1) of the two enzymes.

A lack of any detectable difference in the small subunit structure between the wild type and its mutant was not entirely unexpected. First, no intraspecific variations in fraction 1 protein have been observed on isoelectric focusing gels in 8 M urea<sup>7</sup>. Second, changes in amino acid composition or sequence without a change in overall net charge of the polypeptides would not be detected by this method.

Fig. 1 Polypeptide composition of fraction 1 protein from wild type (W) and yellow mutant (M) of John Williams Broadleaf, a cultivar of *N. tabacum*. The crystalline fraction 1 proteins were s-carboxymethylated before applying to a prefocused 4.5% polyacrylamide slab gel containing 1% ampholine (pH 5–7) and 8 M urea. Isoelectric focusing was performed as described previously<sup>15</sup>.

**Table 1** RuDP-carboxylase/oxygenase activities of crystallised fraction 1 protein from John Williams Broadleaf wild type (*su/su*) and yellow mutant (*Su/su*) leaves

Experiment	Fraction 1 protein	Carboxylase activity* (c.p.m. $\times 10^2$ per mg protein)	Relative carboxylase activity (%)	Oxygenase activity† (nmol O <sub>2</sub> per mg protein per min)	Relative oxygenase activity (%)
1	Wild type ( <i>su/su</i> )	414.3	100	25.8	100
	Mutant ( <i>Su/su</i> )	236.5	57	10.1	39
	Mixture ( <i>su/su</i> : <i>Su/su</i> ) (1:1 mixture)	317.2	76	17.0	66
	Wild type ( <i>su/su</i> )	425.0	100	28.3	100
2	Mutant ( <i>Su/su</i> )	242.0	56	11.4	40

Experiments 1 and 2 were done with crystalline fraction 1 protein obtained from separate progeny.

\*RuDP carboxylase activity was determined by the  $\text{H}^{14}\text{CO}_3^-$  fixation assay<sup>16</sup>.

†RuDP oxygenase activity was measured polarographically<sup>17</sup>.

Recent results indicate that serological methods can distinguish differences in fraction 1 protein polypeptide composition not resolved by the isoelectric focusing technique (J. C. Gray, personal communication).

The difference in carboxylase and oxygenase activity observed for crystallised fraction 1 protein from the wild type and yellow mutant variety of tobacco was highly reproducible (Table 1). It should be noted that the yellow plant is a nuclear mutant and that it is the small subunit of fraction 1 protein which is nuclear encoded<sup>7</sup>. The difference in activities cannot be attributed to changes in the large subunits (which are maternally encoded) since the proteins were prepared from progeny derived from one parent. Any maternal influence should be expressed equally in all siblings. Thus, our results suggest that the small subunit modifies or regulates enzymatic activity of this protein. How this is accomplished remains to be established.

A surprising outcome of these experiments was the apparent lack of complete correlation between the specific carboxylase/oxygenase activities of the isolated fraction 1 proteins and the respective physiological responses of the plant. For example, the yellow mutant, grown under moderate intensities of light and normal atmospheric levels of  $\text{CO}_2$ , characteristically has a higher photorespiratory rate (~threefold) and a lower net rate of photosynthesis, compared with the wild type<sup>13,14</sup>. We note from the data in Table 1 that (1) the carboxylase and oxygenase activities of fraction 1 protein seem to be tightly coupled functions; (2) the carboxylase activities of the isolated enzymes and the respective photosynthetic yields of the parent plants are correlated, and (3) the oxygenase activities of the isolated fraction 1 proteins and the respective photorespiratory rates of the parent plants are not correlated. Based on these data, we suggest that the small subunit regulates the oxygenase and carboxylase function of fraction 1 protein concomitantly rather than independently. Lorimer and Andrews<sup>18</sup> earlier proposed on theoretical grounds that the two functions of this enzyme could not be separated. Our results also support the proposal that RuDP-oxygenase is not the sole source of phosphoglycolate<sup>3</sup>.

This work was supported by grants from the US National Science Foundation and from the University of Maryland. We thank Dr G. W. Schaeffer for tobacco leaves and Ms P. Fox for technical assistance.

## Increase in serum haptoglobin stimulated by prostaglandins

SERUM haptoglobin is decreased in haemolytic anaemias and severe hepatic dysfunction such as cirrhosis, and increased in many pathological states, especially inflammatory and malignant neoplastic disorders<sup>1</sup>. Serum haptoglobin can be increased markedly in experimental animals by various inflammatory agents such as turpentine, carrageenan or proteolytic enzymes<sup>2</sup>. Others, such as histamine and 5-hydroxytryptamine, produce a very slight increase<sup>3</sup>. I have now found that various prostaglandins ( $\text{PGE}_1$ ,  $\text{PGE}_2$ ,  $\text{PGF}_{2\alpha}$  and  $\text{PGA}_2$ ) can increase serum haptoglobin as much as do turpentine and carrageenan.

Willis<sup>4</sup> showed that PGEs are increased in inflammatory exudate, and Hammerström *et al.*<sup>5</sup> found increased  $\text{PGE}_2$  in fibroblasts transformed by polyoma virus. In my experiments  $\text{PGE}_1$  (as little as  $1 \mu\text{g kg}^{-1}$ ) produced more than a fivefold increase of serum haptoglobin in rabbits;  $2 \mu\text{g kg}^{-1}$  produced more than a tenfold increase 24 h after injection (Fig. 1a). A larger dose produced a more marked response. Repeated injection produced a prolonged increase, as in pathological states (Fig. 1b). This response differs from that observed in response to turpentine, which had the same effect when injected repeatedly as when injected once<sup>2</sup>.

The effect of PG was inhibited by previous administration of cycloheximide, 5-fluorouracil or ethionine (Fig. 1c), which suggests that PG stimulates the synthesis of haptoglobin in the liver. On the other hand, the action of turpentine was not inhibited by these agents (Fig. 1c), suggesting that turpentine releases stored haptoglobin in the liver. Only previous treatment with carbon tetrachloride inhibited the action of turpentine<sup>6,7</sup>. Carbon tetrachloride seems to block the passage of haptoglobin from the hepatic pool into the circulation<sup>8</sup>.  $\text{PGE}_1$  increases the

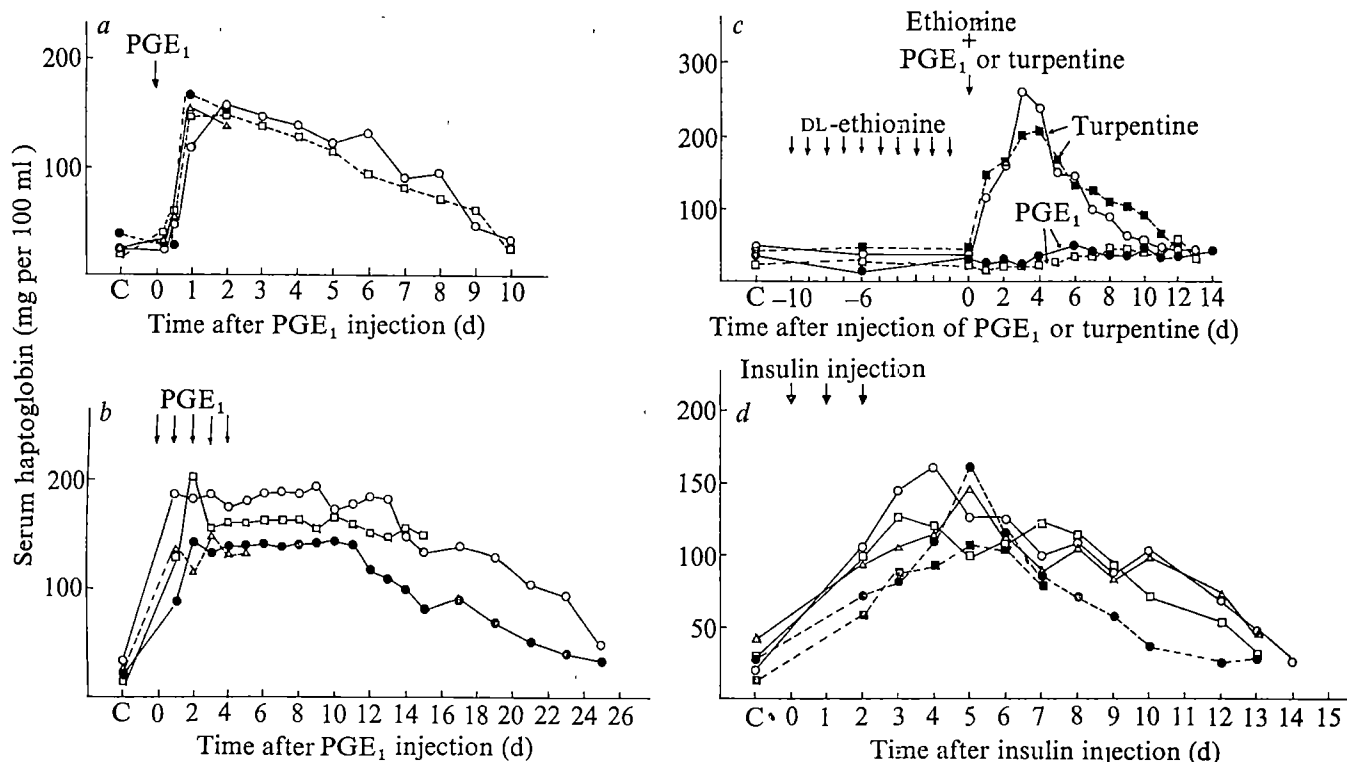

Fig. 1 *a*, Effect of intravenous PGE<sub>1</sub> (2 μg kg<sup>-1</sup>) on serum haptoglobin level in four rabbits. PGE<sub>1</sub> (5 mg) was dissolved in 0.5 ml of 95% ethanol, and mixed with 4.5 ml of 0.02% Na<sub>2</sub>CO<sub>3</sub> solution. The stock PGE<sub>1</sub> solution (1 mg ml<sup>-1</sup>) was divided into samples of 0.05 ml (50 μg of PGE<sub>1</sub>) to vials, and kept frozen until use. The stock PGE<sub>1</sub> solution was diluted with 0.15 M NaCl immediately before use. Serum haptoglobin was measured by paper electrophoresis<sup>13</sup>. Maximum haptoglobin was reached after 24 h and returned to control level after 10 d. The pattern is very similar to that observed after injection of turpentine. PGE<sub>1</sub> (30 μg kg<sup>-1</sup>) increased rabbit serum haptoglobin as much as 300 mg per 100 ml of serum. When PGE<sub>1</sub> was administered subcutaneously, the effect was much less prominent. A similar effect was obtained with PGE<sub>2</sub>, PGF<sub>2α</sub> or PGA<sub>2</sub> but with less marked effect. *b*, Effect of prolonged administration of PGE<sub>1</sub> (2 μg kg<sup>-1</sup> for 5 d) on serum haptoglobin in four rabbits. *c*, Effect of DL-ethionine (10 mg kg<sup>-1</sup>) on PGE<sub>1</sub> and action of turpentine on serum haptoglobin. Ethionine was administered intraperitoneally to four rabbits for 10 d. On the eleventh day PGE<sub>1</sub> (30 μg kg<sup>-1</sup>) was injected with ethionine into two rabbits. The remaining two rabbits were injected with 1 ml of turpentine subcutaneously at the dorsolumbar region. Cycloheximide (2 mg kg<sup>-1</sup>) was injected for 5 d and 5-fluorouracil (10 mg kg<sup>-1</sup>) was injected intraperitoneally. *d*, Effect of insulin (0.5 U kg<sup>-1</sup> d<sup>-1</sup>), administered intramuscularly for 3 d.

content of cyclic AMP in the liver, whereas PGF<sub>2α</sub> and PGA<sub>1</sub> have no effect<sup>9,10</sup>. Insulin, which causes a decrease of cyclic AMP in the liver<sup>11</sup>, also increased serum haptoglobin quite strikingly in my experiments (Fig. 1*d*). Thus PG may stimulate haptoglobin synthesis directly in the liver, or act in some other way not involving cyclic AMP.

Whereas the biological actions of PGs differ according to the type of PG and tissue involved<sup>12</sup>, the fact that serum haptoglobin was increased by every PG tested, irrespective of structure, is interesting. In any case, serum haptoglobin level provides a convenient marker for various actions of PG *in vivo* as long as the function of the liver is intact. The biological significance of increased haptoglobin in the serum remains to be elucidated.

I thank Dr John Pike (Upjohn) for PGs.

## Exclusively inhibitory action of iontophoretic acetylcholine on single neurones of feline thalamus

In most regions of the mammalian brain only a small percentage of the neurones located with multi-barrelled micropipettes are inhibited by iontophoretic acetylcholine (ACh). Indeed, the much more frequent occurrence of cells excited by rather small doses of acetylcholine (see ref. 7 for review), together with the finding that both the inhibitory and excitatory actions of ACh are often antagonised by the same pharmacological agents, has led to the suggestion that the inhibitory action of ACh is mediated indirectly through the excitation of neighbouring cholinceptive interneurons whose inhibitory transmitter is a substance other than ACh<sup>2,3</sup>. Several workers<sup>4-8</sup> have tried to overcome this difficulty by working in the most superficial layers of the cerebral cortex where a strong inhibitory action of ACh predominates and ACh excitation has seldom been reported. We wish to draw attention to the possibility that the nucleus reticularis of the cat thalamus may well prove to be an appropriate area in which to study the depressant action of ACh on central mammalian neurones since almost every cell encountered proved to be inhibited by a short, low amplitude pulse of ACh.

Four cats anaesthetised with a mixture of halothane (0.5%), nitrous oxide (65%) and oxygen were placed in a stereotaxic frame and burr holes prepared in both sides of the skull at the appropriate stereotaxic coordinates. Through each burr hole a single track was made using a freshly filled five barrelled micropipette which contained one barrel filled with 4 M NaCl for single unit recording, another with 1 M NaCl for current and current balancing controls and two drug barrels containing 1M AChCl and 1 M sodium glutamate. In this preliminary study no other drugs or putative inhibitory transmitters were present in the microelectrodes. The coordinates of the electrodes were AP9.5 and L7.0 or 8.0 and recording began at H7.0 and continued until H0.0 (ref. 9). After a single microelectrode track had been made on each side of the brain the animals were more deeply anaesthetised with pentobarbitone, killed by perfusion fixation, and the brains prepared for histological analysis.

In Fig. 1*b* five microelectrode tracks, made in four cats on the stereotaxic coordinates AP9.5 and L7.0 or 8.0, are represented schematically by vertical lines to show the depth of the neurones which were either inhibited (●) or excited (×) by small iontophoretic applications of ACh as the microelectrodes transversed first the nucleus reticularis and then entered the ventrobasal complex of the thalamus. Track 1, which lay within the thickness of a single histological section and from which the line drawn in Fig. 1*a* was traced, penetrated only the nucleus reticularis and located only cells inhibited by ACh. All other tracks lay slightly more medial to track 1 and penetrated both the nucleus reticularis and the ventral basal complex of the thalamus. Tracks 4 and 5 are from the same cat. In track 4 the results suggest that the electrode re-entered the nucleus reticularis at the lower limit of its descent and again located cells inhibited by ACh. During the withdrawal of this electrode through the nucleus reticularis three more

cells inhibited by ACh (○) were found. During a subsequent descent of the same electrode on the right side of the cat (track 5), the depth distribution of cells inhibited and excited by ACh was almost identical to that seen in track 4. This experiment eliminates the possibility that the change from ACh-evoked inhibition to excitation reflects a progressive deterioration in either the health of the animal, or the effectiveness of the microelectrode and its contents. The oscillographs in Fig. 2 illustrate the changes in single unit activity of two neurones located in track 4 during iontophoretic applications of ACh. The first cell located in the nucleus reticularis at the approximate stereotaxic coordinate H4.41 shows the typical spontaneous activity of all cells located in this region and was strongly inhibited by ACh. The second neurone which lay approximately 2.43 mm deeper than the nucleus reticularis shows the typical excitation evoked by iontophoretic ACh applied to a majority of neurones in the ventrobasal thalamus<sup>10</sup>. The ACh-evoked inhibition could not be mimicked by the passage of larger amounts of positive current through the NaCl barrel of the microelectrode and was only marginally reduced in intensity when the current through the ACh barrel was balanced by passing a negative current of equal magnitude through the NaCl barrel. Of 74 cells found to be inhibited in the five tracks shown schematically in Fig. 1*a* (cells less than 50  $\mu$ m apart and showing the same response to ACh are represented by a single symbol) 17 were inhibited when the retaining current on the ACh barrel (25 nA) was reduced and 57 more by currents of less than 40 nA ( $33 \pm 3$  nA).

In addition, the inhibition evoked by the release of ACh by relatively low current applications had a shorter latency of onset than the excitations evoked by either the same or larger currents from the same microelectrode during its descent through the deeper nuclei of the thalamus. The observations that the onset of ACh-evoked inhibition is of

Fig. 1 Schematic drawings to show how cells located within the nucleus reticularis were inhibited by iontophoretic ACh and those lying deeper in the ventrobasal complex of the thalamus excited. *a*, From the histological section which contained the microelectrode track represented by line 1 in *b* shows line L8.00 down which this particular microelectrode passed. The five vertical lines in *b* schematically show the depth distribution of the cells which were either inhibited (●) or excited (×) as microelectrodes penetrated or were withdrawn (○) from the brain of four cats along the coordinates AP9.5 and L7.0 (2 and 3) or 8.0 (1, 4 and 5). Tracks 4 and 5 are from the left and right side of the same cat. The depths of the cells along each track were read from the micrometer of the micro-manipulator drive and no attempt has been made to correct these values so that they correspond with the coordinates taken from the atlas of Snider and Niemer<sup>9</sup> and arbitrarily assigned to the line drawing.

**Fig. 2** Oscillographic records to show the inhibition and excitation of neurones in the nucleus reticularis and ventrobasal complex of the thalamus located in the same microelectrode track. *A*, From a cell located at the stereotaxic coordinate H4.41 showing: *a-c*, dose-related inhibitions evoked by progressively smaller doses of ACh released by currents from 55–15 nA; *d*, effect of withdrawing 25 nA of the 25 nA backing current; *e*, lack of effect of 60 nA positive current passed through NaCl barrel; *f*, effect of balancing the 55 nA passed through the ACh barrel by –55 nA passed through the NaCl barrel. *B*, Records *a* and *b* show excitation of a neurone located 2.43 mm deeper in the track by similar doses of ACh. Note that the delay between the onset of the ACh application and the ACh-evoked excitation in *B* was greater than that which occurred in *A* between the onset of the ACh pulse and the ACh-evoked inhibition.

shorter latency than ACh-evoked excitation are in keeping with the view of Krnjević<sup>1</sup>, who has suggested that ACh-evoked excitation in the cerebral cortex is often preceded by a period of inhibition. Since in the nucleus reticularis ACh-evoked inhibition has a shorter latency than the excitation evoked by larger currents in the ventrobasal complex, it is difficult to believe that ACh-evoked inhibition could be mediated by the excitation of an intervening cholinergic interneurone. The possibility that the inhibitory action of ACh might be mediated by a presynaptic mechanism was eliminated in part by showing ACh to be an equally effective inhibitor of cells when firing was enhanced by glutamic acid.

The finding that the action of ACh in the thalamus is excitatory in one region and inhibitory in another could be of great functional significance. For instance it now seems possible that a single cholinergic pathway could excite neurones of the ventrobasal complex and inhibit neurones of the nucleus reticularis. This 'push-pull' arrangement is in keeping with the neurophysiological data of Schlag and Wazak<sup>21</sup> and Massion and Rispal-Padel<sup>22</sup>, which has led to the suggestion that the firing of the neurones of the ventrobasal complex is modulated by inhibitory interneurones whose cell bodies lie within the nucleus reticularis. This idea is contrary, however, to Jasper's<sup>13</sup> original hypothesis which supposed that the nucleus reticularis was the 'final relay' nucleus of the ascending excitatory pathway involved in 'cortical arousal'. Moreover, modern anatomical studies of the thalamus have not been able to confirm the presence of a pathway from the nucleus reticularis to the cortex and indeed show the

majority of the neurones of this nucleus to project to the ventrobasal complex of the thalamus<sup>14–16</sup>. Thus Jasper's original view<sup>13</sup> that the nucleus reticularis is intimately involved in cortical arousal can only be retained by assuming that the neurones of the nucleus reticularis are inhibited by the ascending cholinergic pathway and thus bring about cortical arousal indirectly through disinhibition of the neurones of the more medial nuclei of the thalamus. Interestingly enough, similar physiological findings<sup>17,18</sup> have led Krnjević<sup>1</sup> to suggest that the ACh-inhibited cells in the upper layers of the cerebral cortex bring about disinhibition of ACh-excited neurones lying much deeper in the cerebral cortex. An analogous situation exists in the nervous system of *Aplysia*, in which the firing of a single cholinergic neurone has been shown to excite one cell and inhibit another<sup>19,20</sup>.

## Formation of oestradiol-17 $\beta$ from oestrone sulphate by sheep foetal pituitary *in vitro*

OESTROGENS are synthesised in large amounts by the placenta in several species including man and domestic animals. They occur in the foetal circulation as inactive sulphoconjugates<sup>1</sup> formed by a detoxifying mechanism that protects the foetus from the detrimental effects of high levels of these potent hormones. In the adult sheep, oestradiol-17 $\beta$  exerts feedback effects on gonadotrophin secretion by the adenohypophysis, as in other mammals<sup>2</sup>. In the foetal lamb the pituitary and adrenal are essential in the onset of parturition for hypophysectomy results in the prolongation of gestation, and the infusion of adrenocorticotrophic hormone (ACTH) or glucocorticoids induce delivery<sup>3</sup>. The factors that regulate the activity of the foetal adenohypophysis in late pregnancy are unknown.

A study of the steroid metabolising capacity of the foetal and maternal adenohypophysis and hypothalamus has revealed that oestrone sulphate, present in foetal circulation, can act as a prohormone since it is readily converted *in vitro* into the more biologically active oestrogens, oestrone and oestradiol-17 $\beta$ , especially in the foetal adenohypophysis.

Ewes were anaesthetised with fluothane and foetuses were removed by Caesarean section. After exsanguination under anaesthesia the maternal and foetal adenohypophysis, hypothalamus and a portion of the frontal cortex were removed and weighed. Tissue was minced and incubated in 2 ml of buffer (0.02 M Tris-HCl, 0.32 M sucrose, 0.001 M

MgCl<sub>2</sub> and 0.005 M NADPH, pH 7.4) at 37 °C for 2 h in 95% oxygen, 5% carbon dioxide. Incubations contained 1  $\mu$ Ci of either 6,7-<sup>3</sup>H-oestrone sulphate (2.13 nmol, 470 mCi mmol<sup>-1</sup>) or 6,7-<sup>3</sup>H-oestrone (0.022 nmol, 45 Ci mmol<sup>-1</sup>). After incubation labelled oestrogens were isolated by phenolic extraction, solvent partition and thin-layer chromatography and their radiochemical purity was established by recrystallisation to constant specific activity.

<sup>3</sup>H-oestrone sulphate was hydrolysed to oestrone and converted to oestradiol-17 $\beta$  in all tissues studied (Tables 1 and 2). The arylsulphatase enzymatic activity was about three times greater in the adenohypophysis of the foetus than in that of the ewe ( $P < 0.02$ ). The activity in the hypothalamus and the frontal cortex of both foetus and ewe was low, being similar to that observed in the maternal adenohypophysis. In all tissues, labelled oestrone and oestradiol-17 $\beta$  formed from oestrone sulphate accounted for the total radioactivity recovered in the phenolic fraction. There was no evidence of sulphotransferase activity in any of the tissues studied when <sup>3</sup>H-oestrone was used as substrate.

The quantity of unconjugated oestrogens produced from <sup>3</sup>H-oestrone sulphate by the adenohypophysis *in vitro* was substantial. This was exemplified by an experiment at parturition in which foetal pituitary tissue incubated with <sup>3</sup>H-oestrone sulphate (423 ng per ml medium) yielded the equivalent of 284 ng oestrone and 12.6 ng oestradiol-17 $\beta$  from one pituitary during 2 h of incubation. There was no change in the level of arylsulphatase activity of the foetal adenohypophysis during the second half of gestation or at the time of the sharp increase in plasma conjugated oestrone sulphate that occurred shortly before parturition<sup>4</sup>.

The formation of oestradiol-17 $\beta$  from <sup>3</sup>H-oestrone sulphate demonstrated the presence of 17 $\beta$ -oxidoreductase activity. When foetal and maternal tissues were incubated with <sup>3</sup>H-oestrone instead of <sup>3</sup>H-oestrone sulphate the activity of the foetal adenohypophysis was found to be approximately seven times that of the maternal adenohypophysis ( $P < 0.005$ , Fig. 1). In the hypothalamus and frontal cortex of the foetal lamb and ewe, 17 $\beta$ -oxidoreductase activity was low and similar to that in the maternal pituitary.

The enzymatic capacity of the maternal hypothalamus and adenohypophysis to hydrolyse and convert oestrone sulphate to oestrone and oestradiol-17 $\beta$  confirms results in anaestrous sheep, and has been implicated in the mechanisms by which pituitary function is regulated<sup>5</sup>. Arylsulphatase and 17 $\beta$ -oxidoreductase activities in the central nervous system and adenohypophysis of the foetal lamb have not been previously reported. These enzymes may lead

to the local formation of appreciable amounts of oestrogens from conjugated compounds, such as oestrone sulphate, known to be present in the foetal circulation at a concentration of 2–4 ng ml $^{-1}$  in late pregnancy. Shortly before delivery the plasma concentration of oestrone sulphate in

the foetus increases to even higher levels (up to 39 ng ml $^{-1}$  (ref. 4)), and this change, together with the capacity of the foetal adenohypophysis to produce oestradiol-17 $\beta$ , may contribute to the cascade of endocrine events associated with the onset of parturition.

Other workers have postulated that oestrogens formed by aromatisation in the central nervous system and adenohypophysis of the adult rabbit and developing human foetus may be concerned in sexual differentiation, indicated by the higher conversion of androstenedione to oestrone in the male than in the female<sup>6</sup>. In the sheep we have found no evidence of aromatisation in similar tissues during the second half of pregnancy, and there was no significant sex difference in the arylsulphatase or 17 $\beta$ -oxidoreductase activities. It should be noted, however, that sexual differentiation in the sheep occurs during the first third of the 145-d gestation period<sup>7</sup>. The local formation of oestrogens from oestrogen sulphoconjugated compounds seems to comprise an alternative pathway for the production of these potential regulatory hormones within the central nervous system and adenohypophysis.

## Enzyme induction in mammalian cells defective in 28S ribosomal RNA formation

SYNTHESIS of ribosomal RNA and its transfer to the cytoplasm have been implicated repeatedly in the processing and transport

of informational RNA and the regulation of enzyme activities<sup>1-4</sup>. We have studied the involvement of rRNA in the RNA synthesis-dependent induction of the microsomal enzyme, aryl hydrocarbon hydroxylase<sup>5</sup>; the activity of this mixed-function oxygenase in mammalian tissues and in cells in culture increases many-fold after a few hours exposure to a polycyclic hydrocarbon<sup>6-10</sup>. The induction process requires *de novo* protein synthesis and DNA-dependent RNA synthesis<sup>5,9,11</sup> and can be influenced by post-transcriptional regulatory mechanisms<sup>9,12</sup>.

Our observations suggested that the induction-specific RNA is a heterogeneous, informational RNA which is transferred to and functions in the cytoplasm independently of concomitant rRNA synthesis and transfer<sup>5</sup>. These observations were based on the use of the inhibitors actinomycin D and cycloheximide, both of which may interfere with several aspects of the regulation of aryl hydrocarbon hydroxylase activity<sup>5,9,11,12</sup>. To avoid the ambiguities associated with the use of the inhibitors, we have now examined the possible role of newly formed rRNA in the induction process using a mutant cell line of BHK cells which is temperature-sensitive for the production of 28S rRNA<sup>13</sup>.

Mutant BHK-422E cells were obtained from Dr Claudio Basilico and cultured in medium composed of Eagles' minimal essential medium, 5% foetal bovine serum, 10% tryptose broth (Difco), penicillin, streptomycin, tylosin and gentamycin. They were grown at either 34 or 39 °C for 24 h before rRNA synthesis was examined. <sup>3</sup>H-uridine was added during a subsequent 2-h incubation and cytoplasmic RNA was extracted and analysed by electrophoresis in polyacrylamide-Agarose mixed gels. In cells grown at the permissive temperature (34 °C), two electrophoretic peaks appeared which corresponded to the 18S and 28S ribosomal RNA (Fig. 1). The amount of newly synthesised 28S RNA was about equal to that of 18S rRNA in cells grown at 34 °C. With longer labelling periods, the radioactivity in the 28S peak increased until it reached twice the amount in the 18S RNA peak (data not shown). At 39 °C, the synthesis and transport of the 18S RNA seemed to be unimpaired, but little newly formed 28S RNA was found in the cytoplasm. Radioactivity in the 28S region was only about 5% of the 18S rRNA in the same cells grown at 39 °C. Similar results were obtained by Toniolo *et al.*<sup>13</sup> after 20 h observation. The reduced appearance of 28S rRNA

Fig. 1 Electrophoretic analysis of cytoplasmic RNA labelled during growth at 34 and 39 °C. Cultures were kept at 34 or 39 °C for 24 h and incubated for another 2 h in the presence of <sup>3</sup>H-uridine (1.0 µCi per ml medium, New England Nuclear). Cells were treated with 0.5% Triton X-100 in phosphate buffer (pH 7.4) containing 1.5 mM MgCl<sub>2</sub>. After 20 min, nuclei were centrifuged to a pellet, and the cytoplasmic and nuclear fractions were extracted three times with phenol. A sample of the aqueous phase was added directly to the gel slot and electrophoresed for 90 min in mixed polyacrylamide-Agarose gels<sup>14</sup>. Values represent c.p.m. per slice.

Fig. 2 Induction of aryl hydrocarbon hydroxylase in BHK-422E cells at 34 and 39 °C. Benz(a)anthracene (3 µg per ml medium) was added to cultures after 24 h of incubation at 34 and 39 °C. Cultures were further incubated at the two temperatures and at various times cells from two plates each were pooled. Aryl hydrocarbon hydroxylase activity was assayed by the procedure of Nebert and Gelboin<sup>7</sup> with minor modifications<sup>5</sup>. The incubation period was 60 min. A 2.0 ml sample of the organic layer was extracted into 1 ml of 1 N NaOH. One unit of aryl hydrocarbon hydroxylase catalyses in 1 min the formation of phenolic product with the fluorescence equivalent of 1 fmol of 3-hydroxybenzo(a)pyrene. Protein concentrations were determined by the method of Lowry *et al.*<sup>18</sup> with ribonuclease A as standard. Values represent the mean and range of duplicate determinations in the absence (----) and in the presence (—) of benz(a)anthracene. ▲, 39 °C; ●, 34 °C.

in the cytoplasm has been attributed to a defect in the processing of precursor 32S rRNA<sup>13</sup>. Electrophoretic analysis of nuclear fractions showed considerable radioactivity in the region of 32S RNA in extracts from cultures incubated at both 39 and 34 °C, but as in the case of cytoplasm, virtually no radioactivity appeared in the 28S region of cultures incubated at 39 °C (data not shown).

The time course of aryl hydrocarbon hydroxylase induction was then examined in the mutant BHK cells at temperatures permissive and non-permissive for 28S rRNA synthesis (Fig. 2). Cultures were set at the respective temperatures 24 h before addition of the inducer, benz(a)anthracene. Hydroxylase activity increased nearly linearly for 10 h at both temperatures. Constitutive hydroxylase activity and inducibility were higher at 39 than at 34 °C. The higher levels of hydroxylase activities at the non-permissive temperature might be an expression of a generally greater metabolic activity at the higher temperature.

The results suggest that aryl hydrocarbon hydroxylase induction occurs in the absence of *de novo* formation of 28S RNA. The ability of the mutant BHK cells to form 28S RNA is lost exponentially with a half time of less than 5 h in cells shifted from 34 to 39 °C (ref. 13). In view of the 24 h preincubation period at 39 °C and the relatively short half life of rRNA

**Table 1** Aryl hydrocarbon hydroxylase induction in BHK-422E cells during treatment with actinomycin D and cycloheximide

Group	Treatment*	Incubation period (h)†	Aryl hydrocarbon hydroxylase (U per mg protein)‡
1	Control medium	8	3.9±0.1
2	BA	8	40.3±1.0
3	BA+act D, 2 µg	8	6.5±0.3
4	BA+act D, 4 µg	8	8.3±0.3
5	BA+cycloheximide	8	2.3±0.1
6	BA+cycloheximide followed by BA+act D	3 5	145.3±5.0
7	BA+cycloheximide+act D followed by BA+act D	3 5	19.1±0.5

\*Cultures were treated with benz(a)anthracene (BA), 3 µg in 3 µl of dimethylsulphoxide (DMSO) per ml medium (BA, groups 2–7) or with 3 µl of DMSO (control medium, group 1). Cycloheximide was used at 10 µg ml<sup>-1</sup> (groups 5–7), actinomycin D (act D) at 1 µg ml<sup>-1</sup> (groups 6–8).

†Cultures of groups 6 and 7 were treated for an initial period of 3 h. The medium was then changed and cultures were treated for a further 5 h as indicated.

‡Mean and range of duplicate determinations.

in the nucleus<sup>14,15</sup>, it seems unlikely that significant amounts of unlabelled 28S rRNA are transferred to the cytoplasm. It is also unlikely that the small residual 28S rRNA production at 39 °C (Fig. 1 and ref. 13) has significance in the enzyme induction. This would imply that either 28S rRNA is produced in excess over that needed for translation of essential proteins at the permissive temperature, or that a specific induction-related 28S rRNA is preserved at the non-permissive temperature.

The requirement for RNA synthesis during aryl hydrocarbon hydroxylase induction in the mutant BHK cells at 39 °C is shown in Table 1: actinomycin D (2 or 4 µg ml<sup>-1</sup> medium) inhibited the increase in enzyme activity during 8 h (compare groups 1–4); after a block of protein synthesis in the presence of the inducer which then is followed by release of protein synthesis and a block of RNA synthesis, the enzyme activity increased more than 30-fold (group 6). This enhanced induction is largely suppressed when actinomycin D is present during the initial block of protein synthesis (group 7). The phenomenon of enhanced induction after a temporary block of protein synthesis is discussed elsewhere<sup>9,16</sup>. The results indicate that aryl hydrocarbon hydroxylase induction in BHK-422E cells at 39 °C, as in other cells in culture at 37 °C (refs 5, 9, 11 and 12), depends on a transient *de novo* RNA synthesis which may be independent of concomitant protein synthesis.

Enzyme induction in the virtual absence of 28S rRNA formation is interesting in two aspects. First, it has been suggested that the rate of rRNA synthesis, maturation and transfer have a role in adaptive changes of enzyme activities during cellular growth, differentiation and hormone action<sup>1,2</sup>. This is not supported by the results presented here, although rRNA requirements may differ between the highly selective, substrate-mediated induction of the hydroxylase and the broader regulatory processes affected by hormones. Second, rRNA synthesis and transfer have been implicated in the control of mRNA synthesis and expression<sup>3,4</sup>. Induction of aryl hydrocarbon hydroxylase clearly requires the synthesis of a specific RNA<sup>5,9,11</sup>. The effects of preferential inhibition of rRNA synthesis<sup>5</sup> or of heterogeneous RNA synthesis<sup>17</sup> during induction suggested the involvement of an RNA of the heterogeneous informational type. In agreement with earlier observations<sup>5</sup>, the results indicate that this induction-specific RNA is synthesised and transferred to the cytoplasm independently of concomitant 28S RNA formation and transfer. The results do not exclude the possibility that a nucleolar function is essential in the flow of information from the nucleus to the cytoplasm as postulated by Harris *et al.*<sup>3,4</sup>, but the processing and transfer of 28S RNA now can be eliminated from consideration in the search for this function.

## Compact form of DNA induced by spermidine

RECENT studies have revealed that the packaging of DNA into phage heads is an ordered sequence of structural and biochemical events rather than a simple, spontaneous self-assembly of component molecules. In the assembly of T7 for example<sup>1</sup>, heads containing the products of genes 8–10 and 14–16 are apparently formed first. Gene 9 protein is removed from the heads before or during the incorporation of DNA. At least two other gene products which play no direct structural role are required for the maturation of the heads. A somewhat similar situation exists for phage λ, which has been shown to require ATP for the *in vitro* packaging of DNA into preformed heads (petite λ)<sup>2</sup>.

Apart from the mechanistic description of the specific processes of DNA packaging, there is the important question of whether these processes are facilitated by a thermodynamic driving force toward the compaction of DNA. Packaging *in vitro* DNA (that is, DNA in 0.2 M ionic strength with a small amount of buffer) without some generalised driving force would be so disadvantageous thermodynamically that it does not seem to be a feasible process. For example, T7 DNA may be represented by an effective ellipsoid<sup>3</sup> with a volume of ~10<sup>12</sup> Å<sup>3</sup> (ref. 3). This is roughly 10,000 times the volume of the T7 phage head. A compression of this magnitude would result in a considerable opposing pressure. In addition to this essentially entropic force, there would also be the work required to bring the negatively charged segments of DNA into close proximity to one another and the energy required to bend or fold the stiff DNA chains into a compact structure. If packaging were to take place with all of these opposing forces in full operation, not only would a great deal of free energy be required for the process, but the phage would be 'spring-loaded' to an increasing degree during the packaging and would expel the DNA spontaneously if there were any relaxation in the packaging mechanism. If by contrast phage particles are formed in an ambience in which these forces are overcome or strongly diminished, the agents responsible for the packaging would have the simpler role of selecting a proper mechanistic pathway for a process which is essentially spontaneous.

The notion that the free energy of the compacted form is lowered by its interaction with polyamines<sup>4</sup>,  $Mg^{2+}$ , (ref. 5) cationic polypeptides<sup>6</sup>, or other reagents has been in the literature for some time. Lerman *et al.*<sup>7</sup> have shown that another possible way of favouring the collapse of DNA is by raising the free energy of the expanded form. This is accomplished by the addition of high polymers which interact unfavourably with DNA. The condensed form is simultaneously stabilised by the presence of high salt concentrations. DNA condensed in this manner ( $\psi$  DNA) has also been studied by Evdokimov *et al.*<sup>8</sup> and by Laemmli *et al.*<sup>9</sup> and it seems to be well established that this treatment in sufficiently dilute solution converts single molecules of DNA into compact, dense particles.

It was our desire to see if the same effect could be achieved using materials which are known to exist in host bacterial cells, in particular, the polyamines. This idea is relatively old—for example an early investigation by Kaiser *et al.*<sup>4</sup> indicated that DNA in the presence of spermine is converted to a form which is protected from shear. The reason that the notion has not been pursued further presumably lies in the difficulty of studying such systems<sup>10</sup>. In terms of polymer theory<sup>11</sup>, conditions are required in which segmental attraction is strong (Flory-Fox parameter  $\alpha < 1$ ) and these are precisely the conditions which are well known to cause aggregation and precipitation. The preventative against this is very low concentration. Lerman's group<sup>12</sup> was able to demonstrate monomolecular collapse by the sedimentation of radioactive DNA which was converted into the  $\psi$  form in extremely dilute solution. In general, a physical method of observing the collapse is difficult to find since most techniques become inoperative at the dilutions required.

The technique selected for this investigation is streaming linear dichroism. A brief description of the apparatus has been published<sup>13</sup> and the details will be published soon<sup>14</sup>. The

procedure is the same as for streaming birefringence except that linear dichroism (LD) at 254 nm is used for finding the angle of isocline,  $\chi$ . The strong absorptive properties at 254 nm combined with stress modulation and lock-in amplification provides great sensitivity for the measurement of both  $\chi$  and the magnitude of the LD. Moreover, stream orientation is extremely sensitive to molecular dimensions. With this technique it is possible to make measurements on DNA where aggregation can be largely forestalled.

The effect of spermidine concentration on the orientational properties of DNA is shown in Fig. 1 which plots the isocline angle against gradient. In the conditions of the experiment (0.001 M NaCl, 0.001 M Na cacodylate, pH 6.6), there is an abrupt change in properties at about  $4.6 \times 10^{-5}$  M spermidine.

Fig. 2 Variation of isocline angle of T7 DNA with spermidine concentration at extreme values of gradient: a,  $74.2 \text{ s}^{-1}$ ; b,  $742 \text{ s}^{-1}$ . Conditions as in Fig. 1. DNA  $A_{260} = 0.1$ .

These results are indicative of a drastic cooperative change in size and shape. The effect is brought out more clearly in Fig. 2 which plots the angle of isocline against spermidine concentration for two fixed velocity gradients. The lower curves of Fig. 1 are typical for a long flexible molecule which is being simultaneously stretched and oriented by the hydrodynamic field. The upper curves are typical for a molecule of much smaller dimensions with a low degree of orientation in the hydrodynamic gradient. If the molecules were compacted into spheres, there would be no orientation and the LD would vanish. Most of the experiments in Figs 1 and 2 were carried out at a moderately low DNA concentration ( $A = 0.1$  in a 1-cm cell). In these conditions, accurate measurements may be made throughout the transition but control experiments with the ultracentrifuge indicate heterogeneity, presumably the result of aggregation. To demonstrate that aggregation is not a necessary part of the phenomenon, experiments were carried out in highly dilute solutions ( $A = 0.006$ ). These solutions showed evidence of aggregation only after a number of hours. A typical experiment on the effect of spermidine on such dilute solutions is shown in Fig. 1 ( $\Delta$ ). Data on the collapsed form are less accurate because of the combination of low concentration and low LD, although the disappearance of native extended DNA is clear cut.

**Fig. 3** Electron micrograph of spermidine-collapsed T7 DNA. Carbon-coated copper grids were coated with a monolayer of cytochrome *c* and glow-discharged. Grids were then floated for 10 min on a DNA-spermidine solution, touched to filter paper, floated on 1% uranyl acetate solution and blotted dry. Micrographs were obtained with a Phillips EM300 microscope.

Once the conditions for molecular collapse were established in the LD experiments, a number of ancillary experiments were performed to throw light on the structure of the collapsed form. Figure 3 shows an electron micrograph of a representative particle of DNA ( $A = 0.006$ ) in the presence of  $10^{-4}$  M spermidine in the same conditions of salt and pH as noted for Fig. 1. We consider the general size and shape of these particles to be more significant than the specific morphology since the latter is sensitive to sample preparation. For example, with uranyl acetate staining approximately 90% of the DNA molecules have the morphology of Fig. 3, whereas with unstained, shadowed preparations the molecules have approximately the same size and shape but only 10% have a central cavity. Note that Richards *et al.*<sup>15</sup> have reported the presence of hollow disks in electron micrographs of ruptured T7 phage.

Circular dichroism studies on the collapsed form yielded curves which differ only in negligible details from the B-form curves which are obtained before collapse. This is in contrast to the CD of the  $\psi$  form of DNA which is drastically different from the B form, and to the CD spectra of whole phages T5 and T7 which are distorted from the B form. This distortion has been attributed to the presence of C form DNA<sup>16</sup>.

Studies of the helix-coil transition of the collapsed DNA-spermidine complex show that the transition is shifted to a higher temperature and is considerably sharper than that of unperturbed DNA.

Experiments with other polyamines revealed that DNA is also collapsed by spermine at significantly lower concentrations than those required for spermidine. A description of these studies plus a more complete interpretation of the LD and electron micrograph experiments will be reported later.

We thank Dr D. Chatteraj for electron micrographs. This research was supported by grants from the NIH and the NSF.

## Evidence for a major conformational change of coat protein in assembly of fl bacteriophage

RECENT structural studies<sup>1,2</sup> indicate that the DNA of filamentous bacteriophages is enclosed in a sheath of  $\alpha$ -helical coat protein. In the course of phage biosynthesis this protein is tightly bound to the membrane of the host (*Escherichia coli*)<sup>3,4</sup>. We present here the results of circular dichroism (CD) studies strongly suggesting that the protein has a quite different conformation in its membrane-bound state, so that a major conformational change must accompany incorporation into the virus.

Methods for the preparation of fl and for the purification of coat protein have been described previously<sup>5</sup>. Accurate concentration measurements are necessary for the quantitation of CD spectra. These were made spectrophotometrically, using the following  $A$  values, based on dry weight determinations: for whole virus,  $A_{260} = 3.78$  or  $A_{268} = 3.95$ ; for purified coat protein,  $A_{260} = 1.65$ . The values given apply to a solution containing 1 mg ml<sup>-1</sup> and a light path of 1 cm. In the experiments using phosphatidylcholine vesicles, where light scattering interfered with spectrophotometric measurements, coat protein containing radioactive tyrosine and lysine was used, specific activity was determined relative to absorbance in the intact phage, and concentration in the vesicles was obtained on the basis of radioactive counts. CD spectra were measured using a Cary 60 spectropolarimeter with CD attachment.

Figure 1 shows the CD spectrum in the peptide absorption region for intact virus and for virus dissociated by 30 mM deoxycholate<sup>6</sup>, but without separation of the components. The possible contribution from DNA to these spectra must be small, both because the DNA content of the virus is small and because the magnitude of the CD spectrum of DNA is low in this spectral range, regardless of conformation<sup>6-8</sup>. The difference between the curves of Fig. 1 must therefore arise predominantly from a conformational change of the viral protein, more than 98% of which is the viral coat protein.

Mean residue ellipticities of the viral protein obtained from Fig. 1 (assuming that DNA makes no contribution at all) are shown in Fig. 2. A protein content of 88.5% (determined in this laboratory, but agreeing with previous measurements<sup>9</sup>) was used, together with a mean residue molecular weight of 105, calculated from the amino acid composition of the protein. Fig. 2 also shows the CD spectra of chromatographically purified coat protein in 30 mM deoxycholate, of coat protein precipitated by removal of deoxycholate by ultrafiltration and redissolved in 30 mM deoxycholate, and of coat protein similarly precipitated and redissolved in 5 mM oleyl lysophosphatidyl-

Fig. 1 Circular dichroism (per kg virus) of intact virus in 0.1 M NaCl (a) and after dissociation by 30 mM deoxycholate (b).

choline. (Spectra similar to curves *d* and *e* were obtained in two other detergents as well and in two other micelle-forming lysolipids.) Figure 2 also shows the CD spectrum of coat protein incorporated into egg yolk phosphatidylcholine vesicles. Phage in  $\text{CHCl}_3$ -saturated aqueous solution (where the CD spectrum is identical to that of intact phage) was deposited on the walls of a conical centrifuge tube by evaporation of solvent with dry  $\text{N}_2$ . Egg yolk phosphatidylcholine dissolved in  $\text{CHCl}_3$  was deposited in the same way. Aqueous buffer was added and vesicles were formed by sonication as described by Huang<sup>10</sup> and chromatographed on Sepharose 4B. The coat protein (radioactively labelled) was found to have been separated from viral DNA and eluted with the phospholipid vesicles. The molar ratio of lipid phosphorus to protein in the combined peak was 80. The protein was accessible to proteolytic enzymes, proving that it was not simply trapped in the vesicles during sonication.

The CD spectrum for the coat protein in the intact virus is unlike any known spectrum for a protein or polypeptide in simple aqueous solutions<sup>11,12</sup>: the peak wavelengths are appropriate for an  $\alpha$ -helical chain, but the unequal intensities of the bands at 208 and 222 nm are not. Similar unequal intensities, however, have been frequently observed for proteins in particulate suspension<sup>13,14</sup> and they have been theoretically explained on the basis of bunching of the absorbing chromophores into a small space, leading to local concentrations far in excess of the average concentra-

tion of the protein or polypeptide in the solution as a whole<sup>13</sup>. It is entirely appropriate to observe this effect in the virus, in which over 2,000 protein molecules are contained in a single particle. Since the effect leads to a diminution of intensity, always more pronounced at 208 than at 222 nm, the observed spectrum clearly falls within the range expected for proteins or polypeptides with an  $\alpha$ -helical content of 100% (refs 11–13). Our result is thus consistent with the X-ray data cited earlier. It also agrees with previous estimates based on optical parameters<sup>15,16</sup>.

The CD spectra of amphiphile-solubilised protein are all similar and differ greatly from the spectrum in the intact virus. The helical content is less than 50%. No increase in negative CD is observed below 210 nm, indicating<sup>11</sup> that no significant portion of the protein has been converted to a structureless random coil. Part of the non-helical portion of the structure could be in the  $\beta$ -conformation or some twisted variant thereof. If so, it is likely that the hydrophobic amino acid residues (residues 21–39)<sup>17</sup> are involved and this might explain why the coat protein is always in a dimeric state in those detergents in which molecular weight measurements have made<sup>5</sup>, since  $\beta$  structures require interchain hydrogen bonds for stabilisation. Estimates of the location of probable helical segments were made for us

Fig. 2 Mean residue ellipticity of coat protein. *a*, In intact virus, from Fig. 1 assuming no contribution from DNA; *b*, in deoxycholate micelles (30 mM), from Fig. 1 with same assumption; *c*, purified protein in 30 mM deoxycholate; *d*, purified protein redissolved in 30 mM deoxycholate after precipitation; *e*, purified protein in oleyl lysophosphatidylcholine micelles (5 mM) after precipitation; *f*, purified protein in egg yolk phosphatidylcholine vesicles, prepared as described in the text.

by Drs Chou and Fasman and by Drs Krigbaum and Knutton, using the methods they have described previously<sup>18,19</sup>. Both groups predict helical segments near both chain termini and assign a probable  $\beta$ -pleated structure to residues 26–37 and 27–36, respectively. (The fd coat protein sequence<sup>17</sup> was used for this analysis, but we have found fd and fl to be identical in amino acid composition and the pattern of proteolytic fragments<sup>20</sup>.)

If we make the reasonable assumption that the similar spectra observed in detergent micelles, phospholipid micelles and phospholipid vesicles also represent the state of the coat protein when bound to the membrane in the host bacterium, and take into account the proteolytic digestion data presented previously<sup>20</sup>, we are led to the conclusion that the membrane-bound state has the central portion of the coat protein polypeptide inserted into the hydrophobic core of the membrane, very likely in a  $\beta$  conformation. A major structural change must thus occur when the protein is removed from the membrane and incorporated into newly-assembled phage particles.

We thank Dr Jacqueline A. Reynolds for assistance. This work was supported by grants from the NIH, US Public Health Service.

## Hyper-repressible operator-type mutant in sulphate permease gene of *Aspergillus nidulans*

SINCE the pioneering work on regulation of the *lac* operon in *Escherichia coli*<sup>1</sup> a great number of operator mutations have been described. In eukaryotic organisms, however, only a few mutations affecting *cis*-acting regulatory element (some of which can be formally interpreted as operator mutants) have been reported<sup>2–6</sup>. The term 'operator' in the case of eukaryotes is used in an operational sense as it is not known whether it describes a molecular organisation similar to that found in bacteria. This report describes a mutant of *Aspergillus nidulans* altered at a site closely linked to the *sB* gene for sulphate permease<sup>7</sup>. This mutation causes a hypersensitivity of this gene to repression by sulphur amino acids.

Sulphate permease in *A. nidulans* is completely repressed if the mycelium is grown in the presence of cysteine, homocysteine or methionine. Toxicity of chromate, a substrate to the sulphate permease, is therefore easily reversed by the addition of methionine to the growth medium. More than 100 mutants resistant to chromate have been isolated in *A. nidulans*<sup>8</sup>, all of which were allelic, both in heterokaryons and diploids, to the previously known mutant *sB3*, indicating that the mutations affect sulphate permease<sup>8</sup>. One of these mutants, *sB<sub>90</sub>*, was particularly interesting as, unlike other mutants, it showed a normal growth rate on minimal medium. Chromate (1 mM) inhibited growth of this mutant but 0.03 mM L-methionine was sufficient to reverse chromate toxicity, whereas 5 mM L-methionine was necessary in the case of the wild type. This suggested that the mutant takes up less chromate than the wild type because of altered specificity of sulphate permease or its hypersensitivity to repression. Table 1 supports the second alternative. When the mutant and the wild type were grown in sulphur-free medium (there was enough sulphur in the conidia used for inoculation to ensure growth for 12–16 h), the rate of sulphate uptake in both strains was very similar (see also Table 2).  $K_m$  for sulphate was  $5.0 \times 10^{-5}$  M and  $4.0 \times 10^{-5}$  M, respectively, for wild-type and *sB<sub>90</sub>* strains. A similar inhibition of sulphate uptake by chromate in both strains was observed:  $K_i = 3.3 \times 10^{-5}$  M for wild type and  $K_i = 3.4 \times 10^{-5}$  M for the mutant *sB<sub>90</sub>*. These data indicate that the mutation *sB<sub>90</sub>* does not alter the sulphate permease itself, but rather the regulation of its synthesis. On the other hand, in more than 700 progeny examined from the cross *sB<sub>90</sub> × sB3* no wild-type segregants (which would be chromate-sensitive) were found. The *sB<sub>90</sub>* site must therefore be situated within or very close to the *sB* locus. The simplest hypothesis would be that *sB<sub>90</sub>* affects a regulatory site involved in the repression of sulphate permease, so that its affinity to a regulatory molecule is increased.

Table 1 Effect of L-methionine in growth medium on level of sulphate permease in *sB<sub>90</sub>* and wild-type strains

Strains	Sulphate uptake (nmol per min per mg dry weight)		MM—S
	Control MM—S	MM—S + 0.3 mM L-methionine*	MM—S + meth
<i>sB<sub>90</sub></i>	5.95	0.47	12.7
Wild type	7.62	2.38	3.2

Mycelia were grown and sulphate uptake assayed as described previously<sup>10</sup>. MM—S, minimal medium without sulphur source.

\* Minimal concentration that enables strain *sB<sub>90</sub>* to grow on 1 mM chromate (Table 2).

To test this hypothesis we used a recessive regulatory mutant *suAmeth* in which several enzymes of methionine synthesis including sulphate permease are constitutive<sup>9</sup>. The character of this mutation strongly suggests that this gene is responsible for the synthesis of a repressor-like molecule involved in a negative control system. Due to the constitutive formation of sulphate permease the strain *suAmeth* is extremely sensitive to chromate even in the presence of a high concentration of methionine (Table 2). If the *sB<sub>90</sub>* mutation causes an increased affinity to the regulatory molecule one would expect to find the mutation *suAmeth* epistatic to *sB<sub>90</sub>*, as without active repressor the latter mutation cannot be manifested. This was the case. As shown in Table 2 the double mutant *sB<sub>90</sub>suAmeth* is equally sensitive to chromate as is *suAmeth* alone. As expected, strain *sB3suAmeth* displays the phenotype of *sB3* because even constitutive synthesis of impaired sulphate permease does not lead to an increased chromate uptake. Experiments on sulphate uptake (Table 3) confirm the results of growth tests. Strain *sB<sub>90</sub>suAmeth* shows a constitutive synthesis of sulphate permease. Thus, the introduction of the *suAmeth* mutation to strain *sB<sub>90</sub>* results in the changeover from hyper-repressibility to constitutive synthesis

**Table 2** Effect of *suAmeth* mutation on growth of *sB3* and *sB<sub>90</sub>* strains on L-methionine (10 mM) and various concentration of chromate

Chromate (mM)	Wide type	<i>sB3</i>	<i>sB<sub>90</sub></i>	Strains		
				<i>suAmeth</i>	<i>sB3suAmeth</i>	<i>sB<sub>90</sub>suAmeth</i>
0.03	+	+	+	+	+	+
0.05	+	+	+	±	+	±
0.06	+	+	+	—	+	—
1.00	+	+	+	—	+	—
1.50	±	+	+	—	+	—
2.00	—	+	+	—	+	—

Growth tests on solid medium (24 h at 37 °C) were carried out as described previously<sup>8</sup>. Growth symbols: +, normal growth; ±, weak growth; —, no growth.

**Table 3** Sulphate uptake by *sB3*, *sB<sub>90</sub>*, *suAmeth* and double mutant strains grown with and without L-methionine

Strain	Sulphate uptake (nmol per min per mg dry weight)	
	MM—S	MM—S + L-methionine (10 mM)
Wild type	10.65	0.00
<i>sB3</i>	0.00	0.00
<i>sB<sub>90</sub></i>	10.18	0.00
<i>suAmeth</i>	11.57	8.33
<i>sB3suAmeth</i>	0.00	0.00
<i>sB<sub>90</sub>suAmeth</i>	12.00	10.13

Culture conditions and sulphate uptake assays were as described previously<sup>10</sup>. Djenkolic acid was added to the *sB3* and *sB3suAmeth* cultures as a sulphur source. It does not cause repression of sulphate permease in the wild type.

**Table 4** Activity of ATP sulphurylase and homocysteine synthase in *sB3*, *sB<sub>90</sub>*, *suAmeth* and double mutant strains

Strain	Activity (nmol per min per mg protein)	
	ATP sulphurylase	Homocysteine synthase
Wild type	71.8	35.6
<i>sB3</i>	69.3	32.8
<i>sB<sub>90</sub></i>	72.4	48.5
<i>suAmeth</i>	116.8	120.0
<i>sB3suAmeth</i>	152.0	138.5
<i>sB<sub>90</sub>suAmeth</i>	130.0	154.5

Mycelia for enzyme assays grown, extracted and assayed as described previously<sup>10</sup>.

of the sulphate permease; these data confirm both the operator-type nature of the *sB<sub>90</sub>* mutation and the regulatory role of the *suAmeth* gene product.

One of the most characteristic features of an operator mutation is that it is *cis*-acting. The interpretation of a *cis-trans* test is straightforward in the case of an operator-constitutive mutant which is dominant, but not in the case of a recessive mutant like *sB<sub>90</sub>*. Diploid *sB<sub>90</sub>/sB<sup>+</sup>* was sensitive to chromate indicating the recessive character of the mutation.

We have tested two other enzymes that are controlled by the *suAmeth* gene<sup>9</sup>—ATP sulphurylase and homocysteine synthase (Table 4). No significant differences in the level of these enzymes were observed between *sB3*, *sB<sub>90</sub>* and wild-type strains. Both enzymes were derepressed in the *sB3suAmeth* and *sB<sub>90</sub>suAmeth* strains. This is additional evidence that the mutation *sB<sub>90</sub>* affects only the regulation of sulphate permease.

All operator or operator-type mutants described so far in fungi have been selected as having increased activity over that of the wild type, at least in some growth conditions. Recognition of *cis*-acting regulatory mutations in control regions adjacent to structural genes which lead to reduced activity are much more difficult to recognise as they cannot be readily distinguished from mutations within structural genes themselves. The *sB<sub>90</sub>* mutation, however, is a clear indication that such mutations do exist.

## α and β Chains of the major haemoglobin and a note on the minor component of *Tarsius*

THE position of *Tarsius* (the tarsier) in the evolution of the primates has long been controversial. Gadow<sup>1</sup> placed it in a separate suborder, but Pocock<sup>2</sup> allied it with the monkeys, apes and man in the Haplorhini, assigning the lemurs, lorisooids and tree shrews to the Strepsirhini. This was accepted by Hill<sup>3</sup> but Simpson<sup>4</sup> divided the primates into two suborders, Anthropoidea and Prosimii, placing *Tarsius* in the latter together with lemurs, lorisooids and tree shrews, though as a separate infraorder. The problem arises

because of resemblances between *Tarsius* and the anthropoids. These include the absence of a rhinarium, a retinal structure similar to the anthropoid fovea and a haemochorial placenta, compared with the epitheliochorial form of prosimians, *Tarsius* is often regarded as a 'living fossil', implying that little evolution has taken place since its divergence from the other primates. The problem may be solved with the aid of data on the primary structure of mammalian proteins<sup>6</sup>: there is sufficient evidence about haemoglobin, for example, to construct a hypothetical ancestral primate sequence<sup>5-7</sup>. Using two samples of blood from *T. bancanus* collected during the past 3 yr, we have determined the  $\alpha$  and  $\beta$  Hb chain sequences and found that, at the molecular level, *Tarsius* is not a 'living fossil' and that the most parsimonious globin trees cluster *Tarsius* with the anthropoids and not the prosimians, lending support to the Haplorhini-Strepsirhini classification<sup>2,3</sup>.

Both our samples had two haemoglobins on starch-gel electrophoresis at pH 8.6 (Tris-EDTA-borate)<sup>8</sup>; the major and minor components had mobilities identical with those of human HbA ( $\alpha_2\beta_2$ ) and HbA<sub>2</sub> ( $\alpha_2\delta_2$ ) respectively. The two components were separated by ion exchange chromatography on DEAE-Sephadex<sup>9</sup> and absorbances at 540 nm of the pooled fractions showed the minor component to be 18% of the total haemoglobin in each case. The major component was used for sequence studies. Globin was prepared by acid-acetone precipitation<sup>10</sup> and the chains were separated<sup>11</sup>. The amino acid sequences of the  $\alpha$  and  $\beta$  chains were determined after tryptic digestion of the aminoethylated chains. The evidence for the sequences will be given in more detail elsewhere.

The amino acid sequence of the tarsier  $\alpha$  chain differed from the human  $\alpha$  chain in eleven positions and the  $\beta$  chain had fifteen differences from the corresponding human chain. Adequate evidence was obtained for both sequences except for two short regions which are based on amino acid compositions and homology with other globin chains. These are residues 129-136 of the  $\alpha$  chain (from a chymotryptic peptide) and residues 67-75 of the  $\beta$  chain, the sequence of which was postulated after amino acid analysis of two thermolytic peptides.

The available data on primate  $\alpha$  and  $\beta$  chains<sup>12-21</sup> is summarised in Tables 1 and 2 respectively. Only residues that are variable among primates are shown together with the hypothetical primate and anthropoid ancestral residues constructed by Goodman *et al.*<sup>7</sup> using the parsimony principle. The construction of these ancestral residues was not biased by the data for the tarsier. Only sequences for which there is a reasonable amount of evidence have been considered.

There are several changes from the ancestral sequence in both chains which, among primates, are unique to the tarsier ( $\alpha$  15, 53, 68, 73, 129;  $\beta$  6, 19, 21, 52, 58, 69, 73, 75) and certainly do not give the impression that tarsier is a

Fig. 1 Parsimony tree requiring 664 nucleotide replacements for 20 taxa on using a combined  $\alpha$ - and  $\beta$ -globin alignment. Link lengths are the numbers of nucleotide replacements between adjacent ancestral and descendant sequences; italicised numbers are link lengths corrected for superimposed replacements by the augmentation algorithm of Moore and Goodman<sup>6,7</sup>. The ordinate scale, in millions of years, is inferred from fossil evidence on ancestral splitting times of the taxa represented by the sequences. The taxa are: AMP (amphibian, represented by newt  $\alpha$  and frog  $\beta$ ), CHI (chicken), ECH (echidna), KANG (kangaroo), DOG (dog), MOU (mouse), R-MAC (rhesus macaque), J-MAC (Japanese macaque), CER (*Cercopithecus*), LAN (langur or *Presbytis*), HUM (human), ATE (*Ateles*), CEB (*Cebus*), TAR (*Tarsius*), SLO (slow loris or *Nycticebus*), RAB (rabbit), HOR (horse), PIG (pig), SHE (sheep), and BOV (bovine). The  $\alpha$ - and  $\beta$ -globin sequences from these animals are referenced in Beard and Goodman<sup>26</sup>.

'living fossil' at the molecular level. Most of the residues at which the tarsier sequences are unique among primates do not have a defined functional role<sup>22,23</sup>. One change in the  $\alpha$  chain, a Val instead of Leu at position 129 (H12), or position 136 (H19), is at the  $\alpha$ -haem contact. In the  $\beta$  chain, position 75 (E19) is internal and helps stabilise the tertiary structure. The Met found in tarsier has also been found in sheep  $\beta$  chain.

The original aim of the work on tarsier haemoglobin was to acquire sequence information relevant to the animal's phylogenetic position. If the ancestral primate sequence is correct it may be possible, by examining the known sequences, to find changes common only to tarsier and prosimians or to tarsier and the anthropoids. But if tarsier diverged from the anthropoid branch very soon after the prosimians, there may not have been time for substitutions to occur which would be inherited by both lineages. For the discussion which follows only those globins listed in Tables 1 and 2 have been considered.

Table 1 Variable residues in primate  $\alpha$ -globin chains

Residue no.	8	12	15	19	21	23	53	57	67	68	71	73	78	111	113	116	129
Primate ancestor*	Thr	Ala	Gly	Gly	Ala	Asp	Ala	Ala	Thr	Asn	Ala	Val	Ser	Ser	His	Asp	Leu
Anthropoid ancestor*	—	—	—	—	—	—	—	Gly	—	—	—	—	Asn	Ala	—	—	—
<i>Nycticebus</i>	—	—	Glu	Ser	—	—	—	—	—	—	Ser	—	—	Cys	—	—	—
<i>Tarsius</i>	—	—	Asp	—	—	—	Ser	Gly	—	Thr	Gly	Ile	Asn	Cys	—	—	Val
<i>Ateles</i>	Ser	—	—	—	—	—	—	Gly	—	—	—	—	Asn	Ala	—	—	—
<i>Cebus</i>	—	Thr	—	—	—	—	—	Gly	Ser	—	—	—	Asn	Ala	—	—	—
<i>Cercopithecus</i>	Ser	—	—	—	—	Glu	—	Gly	—	Leu	Gly	—	His	Ala	Leu	Glu	—
<i>M. mulatta</i>	Ser	—	—	—	—	Glu	—	Gly	—	Leu	Gly	—	Asn	Ala	Leu	Glu	—
<i>M. fuscata</i>	Ser	—	—	—	—	Glu	—	Gly	—	Leu	Gly	—	Asn	Ala	Leu	Glu	—
<i>Presbytis</i>	—	—	—	—	Gly	Glu	—	Gly	—	—	—	—	His	Ala	Leu	Glu	—
<i>Homo</i>	—	—	—	Ala	—	Glu	—	Gly	—	—	—	—	Asn	Ala	Leu	Glu	—

Residues that are variable among primates and differ from the primate ancestor are shown. The sequences considered are those of *Nycticebus coucang*<sup>12</sup>, *Ateles geoffroyi*<sup>13</sup>, *Cebus apella*<sup>14</sup>, *Cercopithecus aethiops*<sup>15</sup>, *Macaca mulatta*<sup>16</sup>, *Macaca fuscata*<sup>17</sup>, *Presbytis entellus*<sup>18</sup>, and human (*Homo*)<sup>19,20</sup>  $\alpha$  globins.

\* From the parsimony construction of Goodman *et al.*<sup>7</sup> (provided by Professor M. Goodman); these constructions also include the following alternative parsimony solutions at positions 23 (primate Glu, anthropoid Glu) and 111 (Ala, Ala). With these alternatives, however, inclusion of the tarsier sequence would add more mutations to the tree than with the solution used above.

Table 2 Variable residues in primate  $\beta$ -globin chains

Residue no.	5	6	9	13	19	21	22	33	43	50	52	56	58	69	73	75	76	87	104	112	121	125	126	128	139

Residues which are variable among primates and differ from the primate ancestor are shown. The sequences considered are those of *Nycticebus coucang*<sup>9</sup>, *Ateles geoffroyi*<sup>13,21</sup>, *Cebus apella*<sup>14</sup>, *Cercopithecus aethiops*<sup>15</sup>, *Macaca mulatta*<sup>16</sup>, *Macaca fuscata*<sup>17</sup>, *Presbytis entellus*<sup>18</sup>, and human (*Homo*)<sup>19</sup>  $\beta$  globins.

\* From the parsimony construction of Goodman *et al.*<sup>7</sup> (provided by Professor M. Goodman); these constructions also include the following alternative parsimony solutions at positions 9 (primate Ala, anthropoid Ala); 50 (Ser, Ser), 52 (Asn, Asp), 69 (Ala, Gly), 87 (Lys, Gln), 112 (Ile, Cys and Val, Cys). With any of these alternatives, however, inclusion of the tarsier sequence would add more mutations to the tree than the solution used except at  $\beta$  9 and  $\beta$  87 where the alternatives could be used equally well as the anthropoid ancestors.

Unfortunately this selection only includes one prosimian, *Nycticebus*, although several anthropoids are known. Sequences have been reported (as unpublished data<sup>24,25</sup>) for certain other prosimians but adequate evidence has not been published.

In the  $\alpha$  chains shown in Table 1 there have been several changes from the ancestral sequence which could provide useful information. There is one residue which only *Tarsius* and *Nycticebus* have in common among the primates, that is Cys at position 111 instead of the ancestral Ser. At position 15 there is also evidence for a common ancestor of *Tarsius* and *Nycticebus*. On the other hand, there are two positions at which *Nycticebus* retains the ancestral sequence while tarsier and most of the anthropoids share a common change (57—Ala to Gly; 78—Ser to Asn). Both are single-base changes.

If one considers the  $\beta$  globins in Table 2, there is one position (22) at which tarsier and *Nycticebus* share a common change from the ancestral sequence. Also at positions 52 and 69, fewer mutations need have occurred if they shared a common ancestor after diverging from the anthropoids. At position 112, however, a Cys is present in tarsier and the anthropoids instead of the ancestral Phe, while *Nycticebus* has a Val residue at this position. Also at positions 50 and 76 *Nycticebus* has retained the ancestral sequence while tarsier and several anthropoids have acquired the same change. Thus, with respect to both  $\alpha$  and  $\beta$ -chain data, the hypothetical ancestral residues constructed independently of tarsier fail to indicate whether *Tarsius* is closer phylogenetically to Anthropoidea or to Prosimii.

Since the tarsier sequence might contain information needed for a closer approximation to the ancestral sequence, Beard and Goodman<sup>26</sup> included it in a combined  $\alpha$ - and  $\beta$ -globin alignment and used a branch-swapping procedure<sup>7</sup> to search extensively for the most parsimonious tree. In the several equally parsimonious alternatives found, tarsier was always closer to the Anthropoidea than to the slow loris, which supports the inclusion of the tarsier in a subdivision of the primates, Haplorhini<sup>2,3</sup>. Of these trees, that in Fig. 1 conforms closely to traditional evidence on the phylogeny of placental mammals. But more prosimian species need to be included to test adequately the conclusion and only two additional mutations would be added to the path length of the tree if tarsier and slow loris still shared a common ancestor (as prosimians) after the divergence of the Anthropoidea from prosimian primates. On the other hand, six additional mutations would be added if the positions of tarsier and slow loris were reversed. Moreover, if the representation of tarsier's phylogenetic position in Fig. 1 is correct, it is notable that the ancestral haplorhine node is closer to the ancestral anthropoid node than to the ancestral primate node. It should be noted that tarsier diverges more from the haplorhine ancestor than do most of the Anthropoidea. This clearly supports the

impression (see above) that at the molecular level, the tarsier is no 'living fossil'.

Finally, we wish to add a note on the minor component of tarsier haemoglobin. Minor components with a  $\delta$  chain instead of a  $\beta$  chain exist in man, the apes and New World monkeys but not Old World monkeys. Following the observation of a minor haemoglobin in tarsier with A<sub>2</sub>-like mobility<sup>8</sup> it has been suggested that a  $\beta$  protodelta duplication occurred in a tarsoid-like line ancestral to both *Tarsius* and Anthropoidea<sup>27</sup>.

The  $\delta$  chains in New World monkeys, apes and man all have Arg and Asn in positions 116 and 117 respectively instead of His at both these sites which occurs in the  $\beta$  chains. Gly, however, is present at position 5 in both chains of the New World monkeys (except for *Cebus* which was Ala in the  $\beta$  chain) whereas Pro is present in both chains of apes and man. These latter data suggest that more than one gene duplication has occurred<sup>21,28</sup>.

Starch gel electrophoresis (in 6 M urea) indicated that the tarsier haemoglobins differed in their non- $\alpha$  chains. The amino acid compositions of those tryptic peptides containing the sites important in deciphering the origin of the  $\delta$  chains of primates (positions 116, 117 and 5) were identical in both haemoglobins of tarsier. There is, therefore, no direct evidence that the  $\beta$ -like chain of the minor haemoglobin of *Tarsius* is orthologous with either man-ape or New World monkey  $\delta$  chain. It should also be noted that the 'minor' component of tarsier is present in relatively high concentration (18% of total). In other species the concentration of minor component is between 0.5% and 6% (ref 21). It would be interesting to examine the haemolysates of other tarsier blood samples and look at the frequency of occurrence of a minor component in all species of tarsier. Two major haemoglobins have been observed in several prosimians<sup>8,29</sup>.

We thank Dr June Rollinson and Dr C Niemitz for the blood, and Mr E. Crutcher and Mrs D. M. Fisher for technical assistance. We thank Professor M. Goodman for helpful comments. Dr J. Bridgen provided a sequenator analysis of residues 1–20 of the  $\beta$  chains which agreed with the results described. The Medical Research Council gave financial support.

## Thymine hydroperoxide as a mediator in ionising radiation mutagenesis

We describe the mutagenic action of chemically synthesised *cis*-5,6-dihydroxy-6-hydroperoxy-5-hydroxythymine (6-TOOH)<sup>1</sup> on transforming DNA of *Haemophilus influenzae*<sup>2,3</sup>, and suggest a mechanism by which ionising radiation induces mutations *in vivo*.

Fig. 1 Effect of 6-TOOH concentration on the induction of mutations in DNA. Weighed quantities of synthetic 6-TOOH<sup>1</sup> were mixed with solutions of *H. influenzae* DNA (10 µg ml<sup>-1</sup>) carrying the marker high resistance to streptomycin (2,000 µg ml<sup>-1</sup>). The solvent was 0.08 M Tris buffer, pH 7.8-0.04 M NaCl and 0.25 mM CuSO<sub>4</sub>. Samples from the reaction mixture, held at 25 °C, were removed at intervals diluted and assayed with competent *H. influenzae*<sup>3</sup> for markers carrying resistance of 8 µg ml<sup>-1</sup> of kanamycin and for the surviving streptomycin resistance. The mutation frequency is the ratio of the fraction of mutants (*M*) to the fraction of implicit marker (*S*); (*M*<sub>t</sub>/*M*<sub>0</sub>)/(*S*<sub>t</sub>/*S*<sub>0</sub>) where the values at time *t* are compared with that initially (0) present. The initial mutation frequency is unity and not zero as it might appear in the drawing. 6-TOOH concentration was: ○, 11.3 mM; ●, 22.6 mM; ■, 45 mM.

Since Muller<sup>4</sup> discovered radiation mutagenesis no molecular mechanism to explain it has been established. Irradiation of aqueous solutions of biological materials in the presence of air generates various peroxides, including hydrogen peroxide, pyrimidine hydroperoxides<sup>5-7</sup> and lipohydroperoxides<sup>8-10</sup>. Other organic peroxides<sup>11-15</sup> have been found to be mutagenic but they have not been identified in irradiated cells. Hydrogen peroxide is only weakly mutagenic for bacteria<sup>16</sup> and not at all for transforming DNA<sup>15</sup>. The mutagenic potential of lipohydroperoxides has been indicated but not established<sup>17</sup>. Thymine hydroperoxide was reported to be mutagenic for *Escherichia coli*<sup>18</sup>, but this did not get support<sup>19</sup> and later reviews<sup>20,21</sup> did not mention it. Our work began with the finding that 6-TOOH, the agent used by earlier workers<sup>18</sup>, was mutagenic for *H. influenzae*. But a mechanism of action is not easily traced in an *in vivo* system, so the relatively uncomplicated transforming DNA freed of other cellular components was chosen for study. Tris-buffered solutions of purified *H. influenzae* transforming DNA<sup>3</sup> were exposed to 6-TOOH in the presence of a transition metal ion. Changes in the transforming DNA<sup>3</sup> leading to mutations were recognised as new resistance to either of two antibiotics which the DNA conferred on competent *H. influenzae* that are normally sensitive to the antibiotics. Before treatment with hydroperoxide, the transforming

Table 1 Effect of metal ions on mutagenic action of 6-TOOH

Metal ion	Δ Mutation frequency per min
Cu <sup>2+</sup>	1.3
Co <sup>2+</sup>	0.35
Mn <sup>2+</sup>	0.1-0.3
Fe <sup>2+</sup>	0.2
Zn <sup>2+</sup>	0.2
None	0.08
Ca <sup>2+</sup>	0.08
Mg <sup>2+</sup>	0.08
Cu <sup>2+</sup> + 10 <sup>-3</sup> MEDTA	<0.02

The conditions of this comparison were those described in Fig. 1 except that the nature of the metal ion was varied. The initial concentrations of 6-TOOH was 22.6 mM and the metal ion was 0.25 mM in all instances.

DNA conferred resistance to streptomycin, a property which was followed to evaluate the destructive action of the hydroperoxide of genetic markers. Knowledge of this destructive action is necessary if the mutation frequency is to be calculated.

The mutagenic action of 6-TOOH in the presence of Cu<sup>2+</sup> is shown in the data plotted in Fig. 1. The frequency of colonies resistant to kanamycin increased linearly with time of exposure to 6-TOOH and the rate was roughly proportional to the hydroperoxide concentration. A comparable increase in frequency of resistance to novobiocin was also found. In very similar experiments, the effect of different transition metal ions on 6-TOOH mutagenesis was determined. The results are shown in Table 1. Clearly among the metal ions examined, Cu<sup>2+</sup> is much more effective than Co<sup>2+</sup>, Mn<sup>2+</sup>, Fe<sup>2+</sup> or Zn<sup>2+</sup> and two non-transition metal ions Ca<sup>2+</sup> and Mg<sup>2+</sup> which showed no mutagenic action. The level of metal ion represents that which was introduced and not the level of free ionic form during the reaction. The latter was almost certainly lower, for metal ions readily complex with constituents of the system to form weakly dissociated units. The dependence of 6-TOOH mutagenesis on the concentration of metal ion is seen in the results in Fig. 2. The rate of mutagenesis seems to be roughly a direct function of the Cu<sup>2+</sup> concentration. When EDTA was added, mutagenesis by the 6-TOOH was completely blocked. The weak, but definite, mutagenesis observed when no metal ion was added may

Fig. 2 Effect of copper ion concentration on the generation of mutations in DNA by 6-TOOH. The conditions were the same as described in Fig. 1 except that the 6-TOOH concentration was held at 45 mM and the  $\text{Cu}^{2+}$  was varied. ○, No added  $\text{Cu}^{2+}$ ; ■, 0.1 mM  $\text{Cu}^{2+}$ ; □, 0.25 mM  $\text{Cu}^{2+}$ ; ▲, 0.25 mM  $\text{Cu}^{2+}$  + 1 mM EDTA.

have been due to trace quantities of metal ions introduced with the DNA or the inorganic salts. Taken altogether, these results suggest that 6-TOOH in cooperation with certain metal ions, produces changes in transforming DNA that lead to mutations, although a detailed mechanism remains to be established. The involvement of transition metal ions and peroxides, which had been recognised earlier<sup>15,19</sup>, probably means that free radicals are involved<sup>22,23</sup>. Comparable mutagenic action of 6-TOOH on denatured and native transforming DNA seems to eliminate consideration of the denaturing effect of  $\text{Cu}^{2+}$  on DNA<sup>24,26</sup>. In the absence of metal ion, 6-TOOH produced changes in bases guanine, cytosine, and thymine<sup>27</sup>.

Pyrimidine hydroperoxides formed in DNA would be in close proximity to other bases and so might be highly mutagenic as a result of interaction, but neither these *in situ* hydroperoxides nor their glycol products of reaction would be planar and probably could not pair with other bases<sup>28</sup>. Excision of the pyrimidine hydroperoxides from DNA<sup>29,30</sup> *in vivo* would not be expected to reduce their mutagenic action below the level shown in the study reported here.

Hydrogen peroxide in the presence of  $\text{Cu}^{2+}$  failed to produce mutations in *Haemophilus* transforming DNA, which indicates that  $\text{H}_2\text{O}_2$  is not an active intermediate responsible for the mutagenic action of 6-TOOH. This was supported by the finding that catalase, which destroys  $\text{H}_2\text{O}_2$ , did not reduce the mutagenic power of 6-TOOH. Absolute increases in the mutant frequency in early samples of 6-TOOH mutagenesis of transforming DNA disposes of the argument that increases in the mutant frequency may be due to a selective advantage caused by a higher resistance of the mutants to the lethal action of the hydroperoxide. Studies (to be published) of the action of 6-TOOH on Ames' histidine mutants of *Salmonella typhimurium*<sup>31</sup> indicate that the type mutants produced by this agent are substitution rather than frameshift. In this respect, the action of 6-TOOH is similar to that of alkylating agents<sup>28</sup>.

Based on our results, the following mechanism for *in vivo* radiation mutagenesis is proposed, as a working hypothesis. Ionising radiation produces hydroperoxides of pyrimidines or their derivatives in the DNA or metabolic pool of cells. These hydroperoxides interact with transition metal ions forming free radicals which react with and modify neighbouring or other bases of the cell's genome. Some of these modified bases cause base mispairing during replication leading to what are generally regarded as mutations.

## Clocklike behaviour of biological clocks

In a recent review article<sup>1</sup>, Winfree discussed a number of mechanisms that have been proposed to explain the dynamical nature of circadian clocks. The statement, "limit cycle excluded experimentally", appears as the heading of a section which proceeds to propose alternative mechanisms. Although the statements in the text qualify the experimental conclusions as excluding only a certain type of limit cycle, the rather sweeping statement in the heading is the one which is more likely to impress the mathematically unsophisticated reader. For this reason, we would like to emphasise some of the alternative mechanisms.

The data on which this argument is based result from two-pulse experiments<sup>2</sup>. After a relatively weak light pulse which perturbs the system, a second, much stronger one is applied. Because the *Drosophila pseudoobscura* eclosion rhythm can be monitored only for ten cycles or less, the second pulse follows the first by no more than 48 h: two cycles. It is found that the closer the first pulse brings the system to the hypothesised singularity, the flatter is the resulting, second-pulse resetting curve. The important point is that this flattening could be explained by a contraction in the net amplitude displayed during the two recovery cycles.

Winfree suggests two hypotheses to explain such a reduction. (1) A limit cycle process is not operative; rather, a single master oscillator displays conservative dynamics thereby allowing permanent amplitude reduction. (2) A limit cycle process is operative in a population of essentially uncoupled oscillators whose combined action gates the observed rhythm. Dephasing within the population will reduce the net amplitude displayed. Our aim is to suggest that other possibilities exist between these two extremes.

With regard to the first, Winfree has shown that recovery to the limit cycle most probably does not occur within two cycles. He proceeds, however, as though recovery never occurs, to exclude the possibility of a limit cycle model. It is easy to demonstrate that the two-pulse experiment data are compatible with a slowly recovering model. Figure 1 shows a phase plane plot

produced by computer simulation of one of the earlier models<sup>3,4</sup>. This particular plot shows the trajectory of a system starting very near the singularity. Strong pulses given to the system within the first two recovery cycles would result in flatter resetting curves the closer the initial pulse approaches the singularity. (Roughly speaking, the range of the resetting curve corresponds to the projection of a "cycle" on the  $S$  axis.) Similar responses can result from any system satisfying a set of rather general conditions<sup>5</sup>.

Fig. 1 CALCOMP plot of a trajectory starting near the singularity for the system described by differential equations:

$$\begin{aligned} dr/dt &= r - 0.8s - 0.3s^2 + 0.5 & r \geq 0 \\ ds/dt &= r - 0.8s \end{aligned}$$

This has been proposed as a model for circadian clocks<sup>3,4</sup>. Strong light pulses move  $r$  to zero so that the resetting zone, when the system is on the limit cycle, is  $AD$ . Two days away from the postulated initial condition, not far from the singularity, will be small,  $BC$ .

The gradual recovery from the singularity to the limit cycle is actually a property shared by many of the proposed models of circadian rhythms as well as other bio-oscillators<sup>5-8</sup>. Higgins has published a number of phase plots similar to our Fig. 1 (ref. 8). Wever has also described similar phenomena<sup>9</sup>. Quick recovery (that is recovery within a day) to the limit cycle has been the feature of some of the earliest models only and it was the result of an

attempt to simulate the effects of strong pulses.

Many other interesting possibilities occur if one uses models involving populations of coupled oscillators. Such models are quite popular<sup>4,9-11</sup> and have been successful in simulating phenomena such as frequency doubling (rhythm splitting)<sup>4,9-11</sup>. In a population of strongly coupled oscillators, each of which in isolation quickly recovers its limit cycle, a return to the original trajectory may be slowed by resynchronisation among the various units. Consider in addition, a population of units with a stable limit cycle surrounding both an antilimit cycle and stable singularity. If the units are not exactly identical, they will form a "cloud" along the limit cycle. Then the first pulse may send some units into the singularity's region of attraction while leaving others in the region of attraction of the limit cycle. Coupling between units would prohibit a quick return to the respective limit sets (cycle or singularity). Thus an intermediate trajectory will be followed, possibly with a split in the population in which one group resides near the singularity, the other near the limit cycle. A second strong pulse would drive both groups towards the limit cycle where mutual synchronisation would reform the original cloud. The closer the initial push to the singularity, the more units approach that point, and, in the limit, all units reside there indefinitely. In that case, a perfectly flat resetting curve results after the second pulse. (Amplitude was abolished.)

The number of models simulating two-pulse experiment results is certainly quite large and the choice among them may have to be made on the basis of other factors. We prefer limit cycle models (possibly involving strongly coupled oscillators) because they seem compatible not only with the data described in the literature on circadian rhythms<sup>4,11</sup> (including the two-pulse experiments), but also with other systems such as the metabolic oscillations in yeast, where behaviour similar to that of *D. pseudoobscura* is observed<sup>12,13</sup>. The yeasts are known to mutually synchronise within a cycle<sup>14</sup> and apparently are governed by limit cycle dynamics<sup>5,15</sup>. Furthermore, dynamical systems displaying conservative oscillations are structurally un-

stable in the extreme<sup>16</sup> and isoperiodic only in the most unusual conditions<sup>4,17</sup>.

In conclusion, we would like to emphasise that Winfree's elegant experiments have revealed certain aspects of the dynamic behaviour of the circadian regulator of the *Drosophila* eclosion rhythm and represent a prime example of the use of mathematical models for understanding the nature of biological mechanisms. It is only unfortunate that the paper chose to emphasise especially in its title and section titles only two of the many hypotheses still available. Furthermore, most of these hypotheses are very "clocklike" as long as the term "clock" is used to mean a general time-keeping mechanism.

WINFREE REPLIES—There seem to be three issues, all resolvable. First, Aldridge and Pavlidis<sup>4</sup> rightly observe that my experiments<sup>2</sup> exclude only "quickly recovering" limit cycle models, by virtue of showing no change in a measure of the amplitude of a circadian oscillator during 48 h after each of 30 different adjustments of that amplitude. "No change" means roughly "less than  $\pm 10\%$ ". They rightly object that my adjective "quickly recovering", used everywhere else, was deleted from a section heading which then read "limit cycle excluded experimentally"—whereas a very slow recovery of amplitude remains unexcluded, as does a very slow decay of amplitude.

On the other hand, according to my data, the spiralling of trajectories in

the descriptive metaphor of their Fig. 1 is definitely too fast: almost all trajectories strike arc AD within 48 h, ensuring complete recovery to a standard cycle, contrary to observations.

Second, Aldridge and Pavlidis agree that my experiments suggest a long-lasting heterogeneity of state among two-to-many similar circadian mechanisms with each animal. I chose to emphasise phase incoherence and that this could derive from relative independence of these autonomous (possibly cellular) mechanisms. Assuming such independence and persistent incoherence in a population, the metaphor of Fig. 1 (among others) is perfectly compatible with the emphasised peculiarities of the circadian rhythm of *Drosophila*. This was intended to be the main point of my "Unclocklike . . ." paper in *Nature*<sup>4</sup>. Aldridge and Pavlidis chose to emphasise an alternative possibility, that some oscillators in the population are switched off, the others remaining synchronous. This model abandons Fig. 1 for a more complicated drawing with two limit cycles (one unstable) and supposes rapidly synchronising interactions among cells. I agree that this is a sensible alternative, which I overlooked. When a histological assay of circadian state becomes available, the two models—one predicting phase heterogeneity and independence, one predicting amplitude heterogeneity and coupling—should be clearly discriminable.

The third point is terminological. It is usual for familiar words, adopted into a specialised area, to change their connotation as perspectives change and scholars make more refined distinctions. As adopted in the 1950s "clock" connoted little more than adaptive stability of period. But by the mid-1960s much of the literature makes sense only if a more restrictive implicit connotation is recognised, namely what is distinguished in the cell-cycle literature<sup>4</sup> as a "simple clock". This is a mechanism which, like a commercial clock or a music box, unlike a dynamical oscillator, can change only its phase, having no states off a unique causal cycle. In pointing to the singularity and to amplitude lability as two "unclocklike" features of the circadian mechanism, I have adhered to this more restrictive usage, distinguishing "clocks" from "dynamical oscillators". In contrast, Aldridge and Pavlidis apparently use "clock" to mean "dynamical oscillator" as opposed to such alternative periodic mechanisms as a sequential state machine with one fixed cycle. Thus the "clocklike" features of their paper<sup>4</sup> are the same as the "unclocklike" features of mine<sup>3</sup>! I notice that Pittendrigh has simply abandoned the word in entitling a

current preprint ". . . circadian pacemakers".

I am delighted to have this critical exchange, and wish there were a lot more of it in the circadian literature.

## Structure of the galactic magnetic field

RECENTLY Somogyi<sup>1</sup> has presented arguments indicating that the power spectrum of the turbulent galactic magnetic field is of the form  $k^{-\alpha}$ , where  $k$  is the wave-number and  $\alpha = 1.0-1.8$  depending on the model of cosmic-ray transport assumed. This spectrum is relevant for scales of 0.001-1 pc, and was obtained by noting the dependence of the cosmic-ray anisotropy and pathlength on energy. I wish to show that a similar conclusion follows from a related but independent argument based solely on the average cosmic-ray pathlength and observed properties of the large scale galactic magnetic field<sup>2</sup>.

Consider a simple one-dimensional model for the diffusion of cosmic rays perpendicular to the plane of the Galaxy, with constant diffusion coefficient  $K_1$  and free escape at the boundaries  $z = +L$  and  $z = -L$ . For observers near the galactic disk ( $z = 0$ ) it is straightforward to show that the mean path  $\lambda$  is given by

$$\lambda = nm_{\text{HC}}\langle t \rangle = (5/12)nm_{\text{HC}}L^2/K_1 \quad (1)$$

where  $n$  is the interstellar density of hydrogen,  $m_{\text{H}}$  is the mass of a hydrogen atom,  $c$  is the speed of light, and  $\langle t \rangle$  is the average cosmic-ray lifetime<sup>2,3</sup>. From equation (1), one may infer a value of  $K_1$ , given the other parameters, and for those listed in Table 1, the value of  $K_1$  varies from  $1.2 \times 10^{26}$ - $1.2 \times 10^{28}$  cm<sup>2</sup> s<sup>-1</sup>, with a nominal value of  $\sim 10^{27}$  cm<sup>2</sup> s<sup>-1</sup>. This value corresponds to the 'observed' value of the cosmic-ray diffusion coefficient for those particles (with energies  $\sim 5$  GeV per nucleon) which are responsible for spallation.

Next consider the derivation of the diffusion coefficient from the properties of the random interstellar magnetic field. Using standard diffusion theory<sup>4,5</sup>, in the limit that the gyroradius  $r_g$  of the particle is much smaller than the magnetic-field correlation length  $l_0$ , one obtains<sup>2,6</sup>

$$K_1 = F(\alpha)cl_0(r_g/l_0)^{2-\alpha} \quad (2)$$

Here  $F(\alpha)$  is a factor of order unity<sup>2</sup>, and it has been assumed that the magnetic-field power spectrum is flat for wave

numbers  $k < (l_0)^{-1}$ , and is proportional to  $k^{-\alpha}$  for larger wave numbers. Jokipii and Lerche<sup>7</sup> give  $l_0 = 150$  pc, and find an average interstellar field of  $3 \times 10^{-6}$  gauss, so for  $\sim 5$  GeV per nucleon particles,  $r_g/l_0 \sim 1.4 \times 10^{-8}$ . Because this ratio is so small,  $K_1$  as determined from equation

Table 1 Adopted parameters

Parameter	Nominal value	Range
$n$	$1 \text{ cm}^{-3}$	0.2–2
$L$	$1.5 \times 10^3 \text{ pc}$	1.0–3.0
$\lambda$	$5 \text{ g cm}^{-2}$	3–8
$l_0$	$1.5 \times 10^2 \text{ pc}$	0.5–2.0
$B_0$	$3 \times 10^{-6} \text{ gauss}$	2–5

(2) is very sensitive to the exponent  $\alpha$  of the magnetic-field power spectrum. The values calculated from equation (2) are given in Table 2 for several values of  $\alpha$ . The uncertainties given in Table 2 are obtained by varying the parameters through the range shown in Table 1. Comparing the 'observed' result from equation (1) with the entries in the table, one concludes that

$$\alpha = 1.5 \pm 0.2 \quad (3)$$

if the simple diffusive model of cosmic-ray transport is appropriate. The uncertainty quoted in equation (3) is the worst-case limit; the statistical uncertainty would be much less.

This value of the power spectral index ( $\alpha \sim 1.5$ ) of the galactic magnetic

Table 2 Calculated diffusion coefficients

$\alpha$	$K_1 (\text{cm}^2 \text{ s}^{-1})$
1.2	$(5.3 \pm 3.0) \times 10^{24}$
1.4	$(1.5 \pm 0.8) \times 10^{26}$
1.5	$(1.0 \pm 0.5) \times 10^{27}$
1.6	$(6.9 \pm 4.0) \times 10^{27}$
1.8	$(4.6 \pm 3.0) \times 10^{29}$

field is the same as the exponent of the interplanetary field and close to the Kolmogorov value of 5/3. The argument here includes the assumption of one continuous power law from the correlation scale of the fluctuations (150 pc) all the way down to the resonant wavelength for 5 GeV per nucleon particles ( $2 \times 10^{-8}$  pc). For comparison, Somogyi obtains  $\alpha = 1.7 \pm 0.1$  in the simple diffusion model for cosmic-ray transport with the distance to the boundary of the diffusing region independent of energy. His result is based on the resonant wavelengths for  $10^{12}$ – $10^{15}$  GeV per nucleon particles, or scales of  $4 \times 10^{-4}$ – $0.4$  pc.

Somogyi's result and that of equation (3) can be shown to agree even more

closely if one adopts his model and changes his parameters slightly. If the energy dependence of the cosmic-ray pathlength  $\lambda(E) \sim E^{-\beta}$ , with  $\beta = 0.50 \pm 0.1$ , as recent calculations indicate<sup>8</sup>, rather than  $\beta = 0.2 \pm 0.1$  as adopted by Somogyi, then his results indicate that the size of the confinement volume does not depend on energy, and that  $\alpha = 1.55 \pm 0.1$ , in agreement with equation (3). Since equations (1) to (3) yield  $\beta = 2 - \alpha$ , the calculations in this letter predict  $\beta \sim 0.5$ , in agreement with the conclusions of Juliusson *et al.*<sup>8</sup>.

Thus the method presented here gives the result  $\alpha = 1.5 \pm 0.2$ , and predicts that the cosmic-ray pathlength varies as  $E^{-1}$ . Adopting this dependence of pathlength on energy, as supported by recent observations, one can use Somogyi's results to obtain  $\alpha = 1.55 \pm 0.1$  and to show that the size of the diffusing region is independent of energy. The similarity of these two results, based on quite different assumptions, suggests that cosmic rays may be a useful tool for probing the interstellar magnetic field.

I thank Dr W. R. Webber for calling my attention to Somogyi's paper, and for his hospitality while this letter was being written. This work was supported by the Research Corporation through a Cottrell College Science Grant.

**SOMOGYI REPLIES**—The value of  $\alpha$  as derived by Owens<sup>1</sup> is based on a single point of the function expressed by his equation (2), and Owens assumed that the magnetic power spectrum had the form of a power function with a constant exponent in the range  $2 \times 10^{-8} < k^{-1} < 150$  pc. In my paper<sup>2</sup>, indications are given that the anisotropy and lifetime are power functions of energy, and it is proved that in this case the magnetic power spectrum is a power function at least in the range  $10^{-3} \text{ pc} < k^{-1} < 1 \text{ pc}$  corresponding to the energy range  $10^{12} \text{ eV} < E < 10^{15} \text{ eV}$  of anisotropy measurements with large statistical accuracies. The range of  $k$  as given in my paper<sup>2</sup> is thus an experimentally established one.

It would be difficult to argue which of the two  $\alpha$  values is better established. Both are rather uncertain. I agree with

Owens that their agreement is remarkable, especially if recognising that they are based on different experimental evidences independent of each other.

## How specific are nuclear 'receptors' for thyroid hormones?

TATA has questioned<sup>1</sup> the biological relevance of the binding of  $T_3$  to the nucleus. He presents four main arguments against a physiological role for the  $T_3$  binding components in the nucleus. First, the presence of high-affinity, saturable binding sites for thyroid hormones of similar characteristics in a number of other subcellular fractions. Second, the lack of analogy with steroid hormone receptors. Third, the absence of parallelism between the binding of thyroid hormone analogues to the nucleus and the biological activity. Fourth, the fact that only 15–20% of the intracellular triiodothyronine is located in the nucleus.

We believe that several of Tata's conclusions are invalid.

On the first point. The  $K_a$  of the binding of  $T_3$  by the nucleus has been incorrectly cited from the work of Samuels and Tsai<sup>2</sup> (Tata's ref. 19). The correct value is  $3.3 \times 10^{10} \text{ mol}^{-1}$  ( $K_d = 29 \text{ pmol}$ ) for the nuclei of GH<sub>1</sub> cells. The same high  $K_a$  has been found<sup>3</sup> for the binding of  $T_3$  to the nucleus of human lymphocytes and rat liver and kidney nuclei<sup>4</sup>. The fact that these values are much higher than those reported by Tata for the other subcellular components favours the possibility of a physiological role for this type of binding site within the nucleus.

With the technique used by Tata to measure specific binding (his Fig. 2) it is impossible to show high affinity binding sites in the nucleus, because the tracer concentration used is 60 times the maximal binding capacity in the incubation mixtures (binding capacity  $2.9 \text{ fmol } T_3 \text{ per } 100 \mu\text{g DNA}$ ; see ref. 4).

Concerning the second point, the lack of analogy with steroid hormone receptor binding has been reported by Surks *et al.*<sup>5</sup> (Tata's ref. 17) and Visser *et al.*<sup>6</sup>. Why does this lack of analogy imply that thyroid hormone binding in the nucleus is without physiological relevance? Why should the nuclear binding of chemically different substances proceed along identical lines?

The *in vitro* binding of  $T_3$  to the nucleus diminishes when cytosol is added, because the cytosol competes for the same fixed amount of hormone in the incubation mixtures<sup>4</sup>. But, *in vivo* that is not the case since both cytosol binding proteins and nuclear binding sites are in equilibrium with the same free hormone concentration outside the cell. This implies that the presence of more or less binding sites outside the nucleus probably has no effect on the degree of saturation of the nuclear binding sites with  $T_3$ .

As for the third point, the parallelism between the nuclear binding of thyroid hormone analogues and hormonal activity has been shown by Oppenheimer *et al.*<sup>6</sup> (not cited by Tata). Only Triac may be an exception. The completely different manners of binding of thyroid hormone analogues with cytosol and the nucleus<sup>4,7,8</sup>, which implies a non-parallelism with biological activity, also suggests a physiological role for the  $T_3$  binding components of the nucleus.

Finally Tata's fourth point presents no argument at all. For instance, does the fact that more than 60% of thyroxine in the human body is outside the cells imply that this compound has no intracellular action? On the contrary, it implies that the cell has a constant supply of the hormone, independent of variations in production. Perhaps a large binding capacity of  $T_3$  outside the nucleus serves a similar purpose in the supply of  $T_3$  to the nucleus.

We think that the arguments used by Tata are insufficient to reject the postulate that the binding of thyroid hormones to the nucleus is of physiological importance.

TATA REPLIES—I apologise for the errors (see corrigendum, this page) in

my original article<sup>1</sup>. Nonetheless they do not in any way modify the essence of my arguments and conclusions, which Docter *et al.*<sup>2</sup> have misread.

The absolute value of  $K_a$  for the interaction between the isolated nucleus and thyroid hormone is determined by the experimental conditions and is not relevant to my finding that in identical conditions all the subcellular fractions of rat liver exhibit rather similar  $T_3$ -binding constants and properties. Unless similar experiments comparing nuclei with extranuclear fractions are performed by others, I do not see how  $K_a$  values of the order of  $3 \times 10^{10} \text{ mol}^{-1}$  for isolated nuclei establish 'specificity'. Sterling and Milch have observed<sup>3</sup>  $K_a$  values of  $10^{11} \text{ mol}^{-1}$  for the binding of  $T_3$  to mitochondrial extracts. Unpublished data from my own laboratory reveal that concentrations of  $T_3$  lower than those reported in my article did not appreciably alter the result I reported there<sup>1</sup>. A study based on electron microscope autoradiography has also disclosed an ubiquitous intracellular distribution of thyroxine<sup>4</sup>. I agree with Docter *et al.*

## Matters arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

that it is important to consider the situation *in vivo*, but their reasoning (their second point) can equally well be reversed: that is, the number of  $T_3$ -binding sites within the nucleus may have little effect *in vivo* on the saturation of extranuclear sites.

As regards the parallelism between the relative binding affinities and physiological potencies of different hormone analogues (their third point), it would be desirable to observe it in any binding or receptor system. But such an analogy *per se* is of limited value since it is also observed in binding to inert materials like glass, paper, talc, and so on<sup>5,6</sup>. All of these con-

siderations only highlight the difficulties of extrapolating from the results of interaction between isolated subcellular preparations and hormone 'receptors' *in vivo* of physiological significance.

Finally, as perhaps the first person to have pointed out the importance of the response of the target cell's nucleus to thyroid hormones, I would not like to rule out the possible location of hormone 'receptors' in that organelle. What I have, in fact, emphasised in my article<sup>7</sup> is the necessity for a more critical assessment of the current approaches based on the binding of thyroid hormones to isolated nuclei. As, and when, evidence is presented that such binding is related to a primary biochemical event leading to the physiological action of the hormone, then I shall be only too pleased to acknowledge that I am wrong in suggesting this note of caution and necessity for fresh thinking. Meanwhile, the past 50 years' history of thyroid hormone action has taught me not to be too dogmatic or 'fashionable'.

## Corrigendum

In the article "How specific are nuclear 'receptors' for thyroid hormones" by J. R. Tata (*Nature*, **257**, 18; 1975) the following corrections should be made.

On page 21, lines 22–26, the sentence should read . . . This is in agreement with recent reports from Baxter's laboratory<sup>23,40</sup>, but whether or not the endogenous hormone-receptor complex is directly bound to DNA as concluded by these workers or merely to non-histone protein in intact chromatin, as proposed by others<sup>14,15,20–22</sup>, is difficult to decide . . .

In Table 3 (page 22), the following corrections should be made:

The  $K_a$  ( $M^{-1}$ ) value for rat pituitary tumour cell line nuclei should read  $3.3 \times 10^{10}$ .

The no. of sites for rat liver and kidney cytosol should read 0.53 pmol  $mg^{-1}$  liver and 2.9 pmol  $mg^{-1}$  kidney, respectively.

References 28,29,30 should read 29,30,31.

*The Evolution of IBP.* (International Biological Programme 1.) Edited by E. B. Worthington. Pp. xx+268. (Cambridge University: Cambridge, London, New York and Melbourne, September, 1975.) £10.50. *Food Protein Sources.* (International Biological Programme 4.) Edited by N. W. Pirie. Pp. xx+260. (Cambridge University: Cambridge, London, New York and Melbourne, September 1975.) £7.50.

IN March 1959, shortly after the International Geophysical year ended, Sir Rudolph Peters conceived the idea of its biological equivalent. The idea gained the support of a number of biologists, although each had a different idea of what should be studied. In this way the International Biological Programme (IBP) was born. Through the efforts of the late Professor C. H. Waddington and Professor Guiseppe Montalenti, it had by 1964 grown into a decade long, seven-sided study of production ecology and human biology, entitled "The biological basis of productivity and human welfare." Now, nearly 20 years after its conception, the results are to be gathered in an 'international synthesis', a series of volumes of which Dr Worthington's kaliedoscopic study *The Evolution of IBP* is the first.

Dr Worthington was the scientific director of IBP, and the grasp of all its aspects which he demonstrates in this book, shows why Professor Waddington was so determined he should be appointed to that post. He modestly describes himself as editor of the book, although he is virtually its author and, as such, does an extremely workmanlike job of describing what IBP was. But for all its assiduous and dispassionate detail, Dr Worthington's book is not a history of IBP but a historical gazeteer, circumscribed by its own objectivity.

I suspect this has arisen paradoxically from Dr Worthington's deep involvement with the programme, for those so caught up in events are often the worst historians. Though Dr Worthington avoided producing an apologia for IBP he has not produced a critique either. He has simply chosen to record, rather than interpret, events. It is not that he sees history from the IBP's viewpoint: apart from IBP, he does not seem to see history at all. And so the events that have altered scientists' attitudes while IBP existed—events that must have moulded and been

moulded by IBP—are avoided, or only mentioned coyly. Dr Worthington's book is interesting and readable but IBP still needs its Margaret Gowing.

As does the topic to which Mr Pirie has addressed himself for the past 40 years—the need for increasing world protein production. Mr Pirie has long been the advocate of leaf protein as one method of bridging the world protein 'gap' and he persuaded IBP to stress leaf protein in one of its themes.

## International biological programme

Unfortunately, over the years the protein gap has not so much been bridged as obliterated by systematic reductions in estimates of human protein requirements. Mr Pirie has not appreciated this alteration. Discussing the matter in 1969 he commented on the technical competence and professional integrity of some of those responsible for these estimates suggesting that they were biased by a desire to avoid change and a wish to resist wage demands based on the cost of food.

In this volume he avoids those issues and states simply that "more research is needed to meet the world's.....protein need than.....the equally important need for energy and vitamins". I do not believe it and suspect that Mr Pirie underestimates the inertia of his own ideas.

The definition of a protein source used in this book (at least 15% protein on a dry weight basis) is unfortunate, since it excludes the cereals, which provide over half the protein in most diets. Further complications are introduced by the exclusion of domesticated livestock and the inclusion of coconuts and minor seeds which contain less than 15% protein, but which are "interesting and liable to be overlooked".

The discussion of nutritive value is concentrated on protein value, and is confused by the use of terms like BV, NPU and PER without definition or details of the assay conditions. It is a pity that the IBP committee on units symbols and definitions which produced

the 50 page appendix to Dr Worthington's book omitted these. One suspects that some authors did not even consult IBP's own symposium on the evaluation of protein products.

Parts of the book are good—Sir Kenneth Blaxter on non-domesticated ruminants, for example—but on the whole it is a patchy compendium of some information on some aspects of some foods.

The power of the protein myth is such that its title assures it of a good sale, but I wish that Mr Pirie had devoted his talents and his time to a book on food and not fashion.

Fashion is perhaps the nub of it. It is inconceivable that an IBP started now would give such a high priority to protein. Nor that it would so easily dismiss Margaret Mead's plea for basing its Human Adaptability Programme on the social sciences. But then would a new IBP have such difficulty in getting a programme of production ecology started and funded?

IBP was overtaken by events, as anything started in 1959 had to be. In 1959 there was Eisenhower and Khrushchev. No one had heard of Yuri Gagarin, and very few of James Watson. Ecology was still about beetles.

IBP's operational decade encompassed Biafra and Vietnam. At its end there were famines in the Sahel and Ethiopia. A study of the biological bases of human welfare conceived now would be very different indeed: IBP seems academic, old fashioned and even slightly naïve.

Some of its synthesis volumes—the academic ones—will no doubt be standard texts, as some of its achievements are undeniable. Those like Mr Pirie's that are concerned so directly with human welfare run the risk of being outdated by the time they appear. Whether in the long run they'll be seen as the more significant or noble, remains to be seen.

John Rivers

*Crop Genetic Resources for Today and Tomorrow.* International Biological Programme 2.) Edited by O. H. Frankel and J. G. Hawkes. Pp. xiv+491. (Cambridge University: Cambridge, London, New York and Melbourne, September 1975.) £13.

IN recent years there has been an increasing awareness of the erosion of plant genetic resources due to the extension and intensification of land

use required to meet the demands of the human population for food and for manufactures. The concern that action should be taken to conserve these non-renewable resources has been displayed by a relatively few committed workers, among whom the editors of this book—Sir Otto Frankel and Professor Jack Hawkes—have been prominent. The institutional acceptance of the need for co-ordinated action first resulted in a joint review of the problem by the UN Food and Agriculture Organisation (FAO) and IBP. The outcome of this was the publication, as an IBP Handbook, of *Genetic Resources in Plants—their Exploration and Conservation* (edit. by O. M. Frankel and E. Bennett, Blackwell, 1970).

FAO continued to be active in the field or plant exploration and conservation through an Expert Panel. This led in 1974 to the establishment of an International Board for Plant Genetic Resources (IBPGR) under the auspices of the Consultative Group on International Agricultural Research which, co-ordinated by the World Bank, channels funds from governmental and non-governmental donors into the international research centres. The involvement of the IBPGR in plant exploration and conservation marks the initiation of a new phase in the development of this work and one in which it may be expected that wide scale effort will be backed by adequate resources.

Whatever happens in the new phase, however, it will be necessary for those concerned to draw to a large extent on the philosophies and methodologies developed during earlier work. These are well portrayed in *Crop Genetic Resources for Today and Tomorrow* which shows the point reached at the end both of the decade of the IBP and of joint work between FAO and IBP. The book contains contributions made at a technical conference organised by FAO and IBP, one of the important objectives of which was to produce a book collating a range of relevant subjects and approaches. It achieved this objective very well.

The subjects covered included the nature and basis of genetic variation in plant populations and how the explorer should sample populations and regions. Attention is paid to the ways in which, in crop plants, material collected from the wild or in primitive cultivars can be used to provide agriculturally valuable disease-, insect-, drought-, or frost-resistant parents in breeding programmes. As would be expected there is extensive discussion of the problems of how living plant material can be stored as seed, pollen, tissue or cells in culture, or as sporophytic plant members such as roots,

tubers or woody branches. Another approach to 'storage' is to protect plant populations *in situ*, and this is discussed in terms of population genetics by S. R. Jain. The storage of data relating to conserved plants, and their retrieval, is of crucial importance if the collections are to be used effectively by breeders, possible methods are discussed by D. J. Rogers and others.

This book is principally concerned with genetic conservation for plant-breeding purposes. The collectors and

Larger than life winged figure carrying a buck, probably Persian. Engraved by W. Holt from a relief in the Palace of Ashurnasirpal II at Nimrud. Taken from *Fallow Deer: Their History, Distribution and Biology* by D. and N. Chapman. Pp. 256. (Terence Dalton, Lavenham, Suffolk, UK, 1975.) £7.80. A whole chapter is devoted to Persian fallow deer, a very rare and endangered species.

the conservers are therefore undertaking a service for breeders. It would seem desirable on future occasions when the topic is discussed for consideration to be given to the methods by which genetic variability can be transferred in breeding programmes because this defines the systematic range that interests breeders and the kinds of genetic variation that may be useful.

There would have been increased stimulation in the book if the organisers of the conference had invited a devil's advocate to marshal the arguments against conservation instead of entirely confining themselves to the 'in group'. Good arguments can be advanced against the idea that we can always generate the required genotypes by mutation or by the release of variation following hybridisation but no opportunity was given for their expression. This would perhaps have caused

greater emphasis to be placed on the need to conserve not individual alleles but those complexes of genes that have become coadapted over long periods of selections. This was not ignored but was in my view not given the necessary weight.

I am also surprised that no attention was paid at the conference to the conservation of non-nuclear genes. We knew in 1970 that susceptibility to the 'T' race of *Helminthosporium* which caused serious maize losses in the US was determined cytoplasmically. The susceptibility is now known to be determined by mitochondrial DNA. There are important genes in both the mitochondria and the chloroplast DNA. This is well displayed by S. G. Wildman and his colleagues in relation to variation in the large subunit of Fraction 1 protein which is coded for in chloroplast DNA. In considering the kinds of resources we must conserve, and their selection and evaluation, it will be increasingly necessary in the future to give thought to organelles.

This book should provide a useful primer on crop plant collection, conservation and utilisation at a time when such is badly needed **Ralph Riley**

*Photosynthesis and Productivity in Different Environments.* (International Biological Programme 3.) Edited by J. P. Cooper Pp xxiv+715. (Cambridge University: Cambridge, London, New York and Melbourne, September 1975.) £22.00.

THE main aim of IBP was the international study of the biological basis of productivity and human welfare and it is natural, therefore, that much of the research effort which IBP engendered should have centred on the primary stage of energy conversion, photosynthesis. The informed management of the world's resources and the support of its human population is dependent on a knowledge of this process in which solar energy becomes available for the nutrition of animals and man. Surprisingly little data was available on the productive potential of different natural and seminatural vegetation types until the initiation of the IBP in 1964 and much of the research which has since been conducted has been concerned with the accumulation of such vital information. Participants in this exercise gathered together in Aberystwyth in 1973 to present summaries of their findings and this book is based on a selection of the papers which were read at that Conference.

Perhaps the emphasis should be placed on the summary aspect of this collection of papers. One thing which has resulted from the decade of IBP is the assembly of vast quantities of

measurements of plant growth, taken both in the laboratory and the field, and it is obvious that no single volume could attempt to cover this material in any detail. This book does, however, set the scene for the more detailed reports, which have either preceded it or may now be anticipated. It is therefore aimed at the general biologist and presents a glimpse of the full spectrum of IBP work, but at the same time the fact that many papers contain previously unpublished results will make it appeal to research workers in the immediate field of productivity.

The first two parts of the book (out of a total of seven) are concerned with data accumulated on the primary production of terrestrial and aquatic ecosystems. Some of the individual papers within these parts are very broad, for example about 35 pages each on the productivity of forests, grazing lands and tundra, respectively. Such summaries must have been very difficult to write but more effort to avoid a parochial approach could have been made, especially by Kira, whose paper on forests is illustrated almost entirely by examples from Japan. The paper on grazing lands by Caldwell pays particular attention to the relative importance of the C4 pathway of photosynthesis in these habitats and provides a useful synthesis of this subject.

Although about a third of the earth's surface is technically arid (potential evapotranspiration exceeding precipitation), this is not reflected in the volume of literature relating to these situations. The inclusion of a chapter on primary production in deserts is therefore particularly welcome, especially the section dealing with the contribution of lichens to the energy input of such ecosystems.

If the surface area of the earth occupied by an ecosystem is the grounds for justifying its inclusion in this volume, then the agricultural ecosystems of the world certainly deserve a place. A chapter by Loomis and Gerakis is given over to this subject. They concentrate on crop adaptations and show how the photosynthetic characteristics for which selection has been made in domesticated plants varies with latitude. C4 species being little used in latitudes higher than 40°.

Aquatic ecosystems, both freshwater and marine, are discussed at some length and the contribution to productivity by macrophytes and microphytes is considered. The figure derived for the global production of marine microphytes in these chapters ( $31 \times 10^9$  t carbon  $\text{yr}^{-1}$ ) is in close agreement with previously published figures.

The second half of the book turns from the study of whole ecosystems to more physiological aspects of the behaviour of light in plant canopies, photosynthetic studies of individual

species and the influence of environmental stresses upon photosynthesis and the use which is made of photosynthates.

Perhaps the most important contribution which this book makes is that it brings together reviews, most of which are extensive and well written, on a wide range of subjects from whole ecosystems, through whole plant physiology to subcellular biochemical ones. In doing this it may encourage workers in one field to become more aware of developments in related areas and to apply this knowledge to their own problems. Since the communication of ideas seems to be one of the greatest

Cocoa tree shown in bas relief on a Mayan stone tablet (13 × 1.3 cm) of the Late Classic Period (AD 600–900, from El Tajin, Veracruz, now at Instituto Nacional de Antropología e Historia Jalapa, Veracruz, Mexico. Taken from *Diseases of Cocoa* by C. A. Thorold. Pp. viii + 423. (Clarendon: Oxford, 1975) £11 00.

stumbling blocks to the general advancement of science, this book must be considered a valuable contribution. Indeed, if IBP had achieved no more than the bringing together of ecologists, physiologists and biochemists, then it would still have been worthwhile.

The price of this book precludes a very wide market, outside the better-endowed libraries, and this is unfortunate because many of the contributions would have been very useful to research workers and students alike.

**P. D. Moore**

*Small Mammals: Their Productivity and Population Dynamics.* (International Biological Programme 5.) Edited by F. B. Golley, K. Petrusewicz and L. Ryskowski. Pp. xxv + 451. (Cambridge University: Cambridge, London, New York and Melbourne, September 1975.) £12.

NINE years of collaboration by small mammal biologists from twenty-seven countries led to this volume, number 5

in the IBP series. No-one, least of all the editors and contributors, would claim that all there is to be known about small mammals has been fully researched and documented but this does not mean that the present work has had too short a gestation period. Its birth is timely, its development has been satisfactory and its information content is something on which to reflect. For the first time we are provided, within the covers of one book, with an overview of developments in the global study of small mammals. Theory, practice, results and hypothesis, as related to small mammal productivity and population dynamics, all have their place.

The contributors seem to have experienced difficulty in defining the upper size limits of a small mammal but 5 to 6 kg is among the highest figures quoted; bobcats (*Lynx rufus*) can therefore be considered as representing a large 'small mammal' (chapter 8). Among the small mammals, however, most information derives from rodents and it is not surprising that much of the text is devoted to this group of animals. Needless to say gaps in our knowledge of small mammals are referred to on both a taxonomic (For example, bats) and geographical (For example, the tropics) scale.

The ecological implications of being a small mammal are highlighted in the introduction and the importance of these animals as consumers within natural and man-modified ecosystems is clearly indicated. This theme is returned to later, particularly in chapters 10–13, in which the role of small mammals in arctic, temperate, tropical, and eurasian desert systems is reviewed. It is also referred to in chapter 14, in which control measures for small mammals which are either agricultural pests or disease vectors are stressed.

To study the status and role of a small mammal population within any ecosystem it is not only necessary to have a clear idea of the aims of the study but also some idea of the methods to be used in achieving the objective. The second part of the introduction provides a theoretical treatment of productivity investigations and as such provides a useful background to chapters 2–9. Early chapters cover aspects such as population density estimation and methods of age determination. Demographic patterns are reviewed on a worldwide scale and the role of dispersal in population regulation is discussed. Chapter 6 provides evidence of the value of morpho-physiological indices as predictors of the present and future state of population processes, particularly those concerned with population fluctuations. The three fol-

## Birth of a membrane

*Membrane Biogenesis: Mitochondria, Chloroplasts and Bacteria.* Edited by Alexander Tzagoloff. Pp. xvi+460. (Plenum: New York and London, 1975.) \$27.

THIS collection of articles attempts to review the present state of knowledge and direction of research concerning the mechanisms by which biological membranes are assembled. The various contributors are all expert in their field, and give accounts largely of their own work with only sufficient review material as might be necessary to provide perspective.

About 40% of the book is concerned with yeast or *Neurospora* mitochondria, in articles from the laboratories of H. R. Mahler, A. Goffeau, A. W. Linnane, H. W. Weiss and R. A. Butow. The level of investigation described ranges from the more molecular (Weiss on cytochromes) to the more biological, and of the latter class most are concerned with nuclear-cytoplasmic relationships rather than membrane synthesis *per se*. How far the more biological levels of research will proceed towards a deeper understanding of membrane biogenesis rather

than of mitochondrial genetics is not yet clear, and several of the articles would not be out of place in a volume that was dedicated to some subject quite different from membrane biogenesis. Nevertheless these excellent articles are representative of the field as it is and serve to illustrate the features of control and location that complicate the mechanistic aspects of membrane biogenesis in the mitochondria of eukaryotic cells. It is probably these very complexities which serve to divert workers on eukaryotic cells from some of the central problems of membrane biogenesis, well identified in Tzagoloff's introductory chapter. The same concern with nuclear-cytoplasmic relationships arises in the articles by L. Bogorad, R. J. Ellis and I. Ohad on the biogenesis of chloroplast membranes, which account for 33% of the book.

The remaining 27% of the book consists of articles by M. Inouye, L. Minditch and M. Bayer respectively on the outer, inner and outer-plus-inner cell membranes of *Escherichia coli*. The article by Inouye shows well the penetrating knowledge that can be acquired using molecular and biological approaches with *E. coli*: it could serve as compulsory reading for all who wish to work on membrane biogenesis, for it leads the way in setting up (and achieving) the sort of detailed mechanistic objectives necessary for an understanding of how cells assemble their membranes. Although the outer membrane of *E. coli* may not be very representative of more metabolically active membranes, the inner or cytoplasmic membrane certainly is. Yet there is only one article on the biogenesis of the cytoplasmic membranes of bacteria, and it deals largely with glycerol auxotrophs. The lack of further articles dealing in depth with the use of unsaturated fatty acid auxotrophs of *E. coli* is a notable omission. Also lacking is an account of membrane reconstitution, because a full description of membrane biogenesis will not be claimed until we have a cell-free reconstituted system that makes (or more likely, extends) membranes.

This book should recommend itself mainly to those who research on mitochondria and chloroplasts, but less so in view of its overall emphasis to those who work on bacteria. Teachers of advanced undergraduate courses should also find the book useful for reading selected topics by themselves and their students. As collections of specialist articles go, this book is a good one. Its faults are the usual ones—early obsolescence, and lack of overall balance. Its merits are the excellence and timeliness of the individual articles.

P. B. Garland

## Fossil plants in palaeoecology

*Paleoecology of Terrestrial Plants: Basic Principles and Techniques.* By V. A. Krasilov. Pp. viii+283 (Wiley: New York and London; Israel Program for Scientific Translations: Jerusalem, October 1975.) £11.00.

PALAEOECOLOGY is primarily concerned with the reconstruction of past ecosystems from palaeontological and lithological evidence. It is a vast subject that is practiced by scientists of varying disciplines, including geology, botany, zoology, and archaeology. This book fills an important gap in the palaeoecological literature, as it is the first text devoted to the use of fossil plants in palaeoecology.

After a brief introduction in which basic concepts of ecology and palaeoecology are considered, the book is divided into three major parts. The first deals with the burial, transport, and fossilisation of plant material in a variety of sedimentary environments. The second part considers the reconstruction of plant morphology from fossil remains, the environmental deductions that can be made from morphology, and the evolution of plant form. The third part discusses the reconstruction of past vegetation and environment from both fossil pollen and macrofossil remains using a variety of qualitative and quantitative approaches.

These three parts are comprehensive and thorough, with numerous well-chosen examples drawn from a very broad spectrum of both the pre-Quaternary and Quaternary literature. Much of the information is critically assembled and evaluated, although some of the views are unsubstantiated and, in places, are erroneous. For example, the widely held belief (page 144) that the *Taxodium-Nyssa* communities of the south-east US are Tertiary relics has been shown by pollen analytical work in Florida by W. A. Watts to be wrong.

My major criticism of the book is the excessive and largely unjustified use of unusual and often bizarre technical jargon. Terms such as polymeric ecological hyperspace, anthracophobic communities, palynocoenum, xylocénosis, rhizocenosis, selectogenesis, geitogenesis, endoecogenesis, and cenophyllum make reading both difficult and tiring.

In spite of this criticism, the book can be strongly recommended to all botanically-orientated palaeoecologists whether of Quaternary or pre-Quaternary interests who wish to learn more about the basic principles of their subject.

H. J. B. Birks

Newcomers to small mammalogy will find this book invaluable for it will provide them with a backcloth against which they can develop and pursue new projects. Old hands will undoubtedly be grateful to the editors and contributors for the synthesis of data and ideas that have been developed over the last decade. A book well worth reading in spite of its somewhat high price.

## Select Committee needs a better analysis than this

It is depressing that the House of Commons Select Committee on Science and Technology, in its latest report on research in universities (HC87; HMSO, 75p), should have marred an on-the-whole sensible and careful document by some ill-considered remarks about "a handful of highly favoured scientists" who "may influence the formulation of Science Research Council (SRC) policy". Even though the committee protests that the paper is an interim one, and that it is only asking questions and seeking out topics for further investigation, there is cause for concern that it should have gone into print with an appendix in support of this musing which can by no stretch of the imagination be called well researched.

This appendix argues that a few scientists get a lot of money. The list of 3,000 SRC grants in operation in 1973-74, totalling £53 million, was analysed, and it turns out that the top 2% of recipients get 20% of the funds (in grants of £100,000 or greater), and 10% get 45% of the funds. The mean value of grants issued by the Nuclear Physics Board (which also comprises high energy physics) is ten times that of the Mathematics Board. And people who accumulate more than one grant are more likely to be those who are already in receipt of large grants. (This rather depends on whether you believe that the 13 out of 31 recipients of big grants who receive further grants is a significantly higher fraction than the 307 out of 919 recipients of relatively small grants who land a second grant.)

The report's analysis of the trend with time shows that in 1974 almost no grants were awarded for a period of longer than three years; in earlier years 20% fell into that category. Finally, the mean grant size in nuclear and space science seems to have leapt up very significantly in 1974.

The conclusion is that there is a "concentration of large resources in a handful of outstanding individuals" which "seems to indicate at the very least that SRC policy is as much influenced by the demands of a small core of scientists as from any centralised decisions about what lines of research ought to be pursued". Nuclear physics takes a "disproportionately high percentage" of the budget; the SRC does not seem to be making any long term investments, and the increase in nuclear and space grants "would seem to indicate an increased commitment to expensive projects".

The evidence on which these conclusions or indications are based is so incomplete and selected with such ignorance of how science funding operates that the select committee should disown the report. It represents the worst sort of sociology of science in which actually talking to people is regarded as a poor substitute for computer analysis of a mass of data. Had the compiler of the report spoken to the SRC (which he or she palpably did not) before attempting to guess motives and policies, a much more profound analysis could have been made. As it is, the most glaring nonsense is talked of highly favoured individuals, "36

researchers control 23% of the budget" and so on.

Two things need to be said about this apparently charmed circle of researchers. First, some science is necessarily very expensive and requires major capital investment. To deny such expenditure simply because it is widely different in scale from that for most scientific endeavour is to condemn British science to small-minded egalitarianism. Second, the circle is not small at all. Had the committee investigated who gets the big money, they would have found that there is no room on the SRC grant application form to list co-investigators. In some cases the head of a department or a large facility (such as a radiotelescope) secures all the money under one heading, for administrative convenience, and may have 30 or more staff on the grant, pursuing independent work. In other departments, individuals go for their own grants. Thus talk of funds being concentrated among relatively few researchers is meaningless if the committee's investigations are carried out so superficially as to consign this central issue to an observation in a footnote that "research funds probably reach a wider population".

The analysis of temporal trends is equally badly under-researched. Remarks are made about the SRC's "increased commitment" to expensive projects, on the basis of a growth in the grants to space and nuclear science. This "growth" is based on a comparison between grants awarded before 1974 and still current in that year, and those awarded in 1974. But this is no comparison at all without knowledge of funding policy. If the grant committee awards money for relatively cheap research posts (assistantships and fellowships) on a three-year basis, and large capital expenditure on a one-year basis, every new year will see a carry-over from past years of relatively small sums in continuing grants, but the award of large sums for the one year. The average grant continuing into 1974 in nuclear physics was £428 a month. The average new grant was £4,359 a month. Nine hundred per cent growth or an unimportant indicator of detailed grant-giving policy? The report gives no indication that anyone tried to find out. Clearly no-one read the SRC's last annual report on the question of financial strategy. It is deplorable that such a slipshod job coupled with pure guesswork should pass for an analysis of the SRC's policy.

Science is increasingly suffering from divisiveness these days, as different groups are set against each other. If in the name of egalitarianism this fatally flawed report is accepted and used as the basis for recommendations, the committee will have to bear the responsibility for the further decline in morale among those in big science. And the clear bias against nuclear and space science pervading the report looks more than a little ridiculous when it turns out that 60% of those big grants actually go to fund engineering projects. □

Before Italy's latest government crisis, the then Minister for Research, Sr Mario Pedini, forecast that 1976 would be the turning point for Italian science. **Gillian Boucher** reports.

## Trying to make Italian scientific research useful

TO ACHIEVE one's own ministry must be a cherished hope of many a minister without portfolio. Italy's Minister for the Coordination of Scientific and Technological Research has little real power—he does not, for example, appoint the President of the CNR (National Research Council). But Sr Mario Pedini's prophecy rested on the progress of a bill being examined in Parliament for the creation of a Ministry for Scientific Research. And he spoke for many Italians when he argued for more surveillance over research. Along with the general despair over the way that both education and industry are run there has recently arisen the strong feeling that the solution lies in science—that if only academic pursuits could be programmed to the needs of the country all would be well.

In a brief history of Italian research written for a permanent commission of the Senate, A. Alberigi Quaranta summarises the attitudes which led to the current state of affairs. Italian science, stifled by the Fascists, got off to a bad start after the war. American generosity was largely to blame for this: it disguised the need for industrial innovation and provided the means for many of the brightest young researchers to emigrate. In the 1960s, while pure research was flourishing, at least in patches, the state of applied research remained pitiful. This, the argument goes, stemmed partly from the strong inclination of Italian education and culture towards theory as opposed to application, partly from the attitudes of industry, in particular of the many small firms which had not the resources for research or development, and partly from the lack of guidance on the part of the government.

Against all this there is now a violent reaction. Most of the Ministers of Research of the last ten years have in fact supported some project or other for a ministry. But the issue is now a much hotter one. Parliament has been examining two proposals for a ministry: Sr Pedini's bill, recently approved by the late government, and an extra-governmental one supported by parliamentary Christian Democrats, Communists, Socialists and Liberals.

The latter parliamentary text sees the function of the ministry as co-ordination and political direction of research: these powers, it says, would be withdrawn from the CNR. It pro-

Mario Pedini: prophecy

poses that a National Science Council should be created within the compass of the ministry, and that there should be both a national plan for research and a national fund for implementing it.

The chief difference between this proposal and the government bill lies in the government bill's proposal that the ministry, in addition, should administer research. Public bodies, and any private firm which wants public money for research, would have to present their research programmes to the ministry. The ministry would promote certain research by creating some ill-defined 'research centres'. University research would be coordinated and directed by means of a yearly conference, the composition of which may be decided by the Prime Minister. The CNR would give technical advice to the ministry and would execute its plans. Its president would be appointed by the Prime Minister, on the advice of the Minister for Research; at present the President of the CNR is appointed by the President of the Republic.

An exceedingly optimistic timetable is laid down for the yearly funding of science. Publication of the report of the conference on university research is set for this month. All research proposals will be submitted by March 1 to the ministry, which will judge them according to whether they fulfil a need recognised by the government, and whether they will duplicate

other research. The Minister will report at the end of April on the state of research and the value of the submitted projects, and the Interministerial Committee for Economic Planning (CIPE) will make its final report to the Treasury by May 31.

Reactions to the proposals in academic circles have been mixed. On the one hand many academics want to do something useful for their country, and they welcome the possibility of an end to their frustration at the lack of contact between universities and the outside world. On the other hand there is the fear, far from unjustified in Italy, that anything the government touches will grind to a halt, stalled by bureaucracy. The new enthusiasm for coordinating everything is also worrying. The universities are hardly mentioned in Pedini's bill. The sums for research they receive at present from the Ministry of Education are negligible. Pure research will clearly be in a very unhappy position if its only source of funds is through a ministry whose purpose is to administer science "in relation to the technical, social and economic progress of the country". Answering a query about his intentions for universities, Pedini has said, "Let's start with the ministry, and when it has reached puberty we'll mate them"—which is hardly reassuring.

Certain obvious questions beg themselves. Why a ministry, when a body already exists which funds and co-ordinates science, namely the CNR? Why could the CNR not forge the links between research and development, between university and industry? Part of the answer is that the CNR has tried, and failed. A total of 28,000 million lire were spent between 1964 and 1972 on twenty applied research projects; the CNR's own judgment was that most of these were unsatisfactory. Though the scientific merit of the projects was considered carefully when they were planned, there was no proper investigation of whether development would be economically feasible, or even whether there was any Italian industry in a position to use the results. The CNR, in fact, is not equipped to make decisions about economics and industry: it represents the interests of academics, with 128 of the 140 members of its Scientific Committees academics, and members of these committees also on its Administrative Board.

But the CNR, undeterred by these drawbacks and alarmed by the prospect of a ministry, is having another go at applied research. In 1972, after consulting researchers and the Office for Economic Development, it put forward 78 proposals for research projects with potential economic or social applications. By the beginning of 1975 an initial selection had reduced the number of projects to about 40, grouped into seven themes: energy (eg. solar and geothermal energy, conservation of energy); food (eg. increasing plant productivity, new sources of protein, mechanisation of agriculture, fisheries research); health (eg. preventative medicine, viruses, reproduction, biomedical technology); environment (eg. geodynamics, oceanography, soil conservation); educational theory; advanced technology (eg. telecommunications with centimetre and millimetre waves, power lasers, superconductivity, ceramics, control of air traffic); and cognitive advancement (a ragbag including criminology and astrophysics).

These projects, together with assessments of their feasibility and usefulness, were submitted to the CIPE in April 1975. The CIPE's ruling, published on October 9, was startling. The entire 'Health' programme and almost all of 'Food' were approved. 'Energy' and 'Environment' were heavily lopped; nothing remained, for example, of the projects on solar and geothermal energy. 'Cognitive Advancement' and 'Educational Theory' were rejected, at

least for the present. But most surprising, after all the trumpeting about the economic needs of the country, 'Advanced Technology' was almost completely rejected: only the project on the control of air traffic remains.

It is possible that the government has simply lost faith in the CNR's ability to know what industry needs, and prefers to wait for the Ministry for Research. This might be deduced from the extremely fuzzy explanations the CIPE report gives for its decisions. Perhaps the CIPE is concerned to prevent toes from being trodden on—the National Electricity Board (ENEL), for example, may consider research into new sources of energy its own preserve. It may also be considering the violent public dislike of multinationals, which could see the research on telecommunications, for example, as somehow pandering to the Americans.

In any case about 20,000 million lire have been set aside for the first year's research on those projects which have survived scrutiny. Owing to administrative delays it will not actually be handed out until towards the end of this year. The CNR's 1975 grant of 83,000 million lire is increased this year to 100,000 million lire, which means 3,000 million lire less for other research of the CNR—a blow at any time but especially with inflation.

Will the success of the applied projects make the loss worthwhile? Unfortunately the answer is likely to

be no. The projects suffer from the defect seen in all CNR funding, which is ultimately the fault of the way Italian universities are organised. Substantial amounts of money are divided into too many little sums, with the result that there is much duplication and nobody has the resources for a major piece of work. The practice arises because Italian universities are divided into small faculties, usually with one full professor each, which jealously maintain the barriers between themselves and other faculties. The CNR has naturally never challenged this arrangement, and nothing has changed with the new applied projects: only one quarter of the money is going to CNR institutions, some at least of which are big enough for a more flexible, interdisciplinary approach; most of the rest is destined for hundreds of university faculties.

Given this, and the fact that little thought seems to have been directed at precisely how the results achieved are to be made available to those who might use them, the projects seem likely to cause little more than a ripple in Italian economic or social life. But one thing to be thankful for is that the money is there to do something with. If a large part of it ends up financing the pure research that the academics really want to do, many would say so much the better. But when the Ministry for Research is created, money for pure research may be difficult to come by. □

## CANADA

# Getting the message across

David Spurgeon reports from Ottawa on science and the mass media in Canada

A STUDY on communication of science through the mass media confirms what Canadian scientists, science writers and ordinary readers have known for a long time: that the Canadian media do an inadequate job of making science meaningful to their public. But, surprisingly to some, it also indicates that a far greater public desire exists for science coverage than most media managers seem to realise.

The study, begun in 1973, was published recently by the Canadian

Ministry of State for Science and Technology (MOSST)\*. It indicates, for example, that science writers are willing and anxious to do a better job, but that they are hindered by the out-dated ideas and prejudices of their bosses—those who control what the media transmit to the public. At the same time, it reveals that much of the general public is just as interested in learning about science as about those other human activities that receive preferential treatment by the media; yet because of the attitudes of the media managers, this desire goes unsatisfied. The study shows how great the need is for better science coverage, for it reveals the abysmal ignorance about Canadian science on the part of those

Photo: TTC

Toronto Transit commuters: does the Canadian public at large get the science coverage it wants?

same members of the public who want to know more.

The results contained in the second volume, released to the public last month, are the outcome of three separate surveys made of managing

\*Media Impact, Volume 2, Science, Mass Media and the Public, A Research Study on Science Communication. By Orest Dubas and Lisa Martel (Information Canada; June 1975).

editors of daily newspapers with a circulation of more than 5,000, science writers and the public at large. Volume 1 contained an outline of objectives and methodology and gave an account of past research on science communication in other countries.

The public survey was conducted between March and April 1974 by the private firm, Canadian Facts: 2,000 Canadians, aged 15 and over, were randomly selected for interview. The surveys of managing editors and science writers were conducted by the authors through questionnaires. Editors of 52 of the 81 newspapers polled responded. From 176 writers (only 24 of them employed to write science or medicine full-time for daily newspapers) 113 replies were received.

Some indication of the general level of awareness of science affairs in Canada can be gained from the finding that two out of three people interviewed could not even name a single scientist. Of those who did recall one or more names, less than one in five could name more than two. And when names were mentioned, they were mostly the expected ones: Frederick Banting and Charles Best, co-discoverers of insulin, were mentioned about half the time, and—American claims for the invention of the telephone to the contrary—Alexander Graham Bell was mentioned by another third. Only seven persons among the 2,000 polled could recall the name of Dr Gerhard Herzberg, the physicist who won Canada's only Nobel Prize in the natural sciences almost half a century after Banting. Best and MacLeod were awarded the country's only Nobel Prize in medicine in 1923.

To make things worse, some of those interviewed tended to confuse Canadian scientists with those of other countries, or even with public figures who were not scientists at all. For example, 7% cited names like Albert Einstein, Louis Pasteur, Eve Curie, Charles Darwin, Jonas Salk and Alexander Fleming when asked for names of Canadian scientists. And occasionally they brought up names like Lester Pearson (former prime minister), Mme Jeanne Sauvé (former science minister), Farley Mowat (a writer on nature themes), and Fernand Seguin (a French Canadian science communicator).

When it came to Canadian scientific achievements, 61% failed to name one, 22.8% listed a single achievement, 9.7% mentioned two and 8.1% three or more. The discovery of insulin and the invention of the telephone were remembered as Canada's greatest scientific achievements, and most of the optional "projects" mentioned were really technological or engineering feats, such as the St. Lawrence Seaway or the Mirabel airport. Fewer than a

dozen mentioned the CANDU nuclear power reactor, one of the most successful designs in the world. Many of those who recalled a Canadian scientific achievement did so because they were personally involved in it, or knew somebody who was. Thus insulin, for example, was remembered because a respondent "knew the first people treated", and a heart machine because they "used it on me at the hospital."

Significantly for the purposes of the study, the mass media appear to be the major source of what little public awareness there is of Canadian science. Nearly half the respondents cited the media as their major source of information. Magazines were the main source for science news, and were preferred over newspapers and television. Radio ran a poor third, which was surprising because the State-subsidised Canadian Broadcasting Corporation provides many good science programmes; more than half the respondents, however, said they were not aware of any of the science or public affairs programmes mentioned to them. Despite their evident ignorance of the subject, 82% felt it was important to be kept informed about science, 63% were interested in finding out more about Canadian achievements, and more respondents than not (42.8 to 39.6%) thought the media were providing an adequate coverage of science.

Furthermore, without being told that the interview focused on science, the public sample rated news of science and medicine high compared with news about such other things as sport, entertainment, society, politics and foreign affairs. Medicine and health ranked third in interest after news and education, and pollution and biology rated higher than entertainment. More indicated an interest in research in the physical sciences than in sports. Crime was third last on the list of 23 items of interest, following only after a number of scientific categories. And the public even declared itself willing to give up some coverage of some of the non-scientific categories in order to learn more about science.

To anyone who has written for the public about science for years, in fact, many of the public's responses as indicated by the survey were hard to believe. One obvious weakness of the survey was the breadth of its definition of science: it included not only the natural sciences, life sciences and engineering, but also the social sciences and even the humanities, under which such topics as education, business and economics were listed. And one apparent anomaly was the finding that less than half the interested readers judged science articles in newspapers to be accurately reported. In view of their

obvious ignorance of the subject, how would they know? Three out of five, on the other hand, believed magazine articles (at least those about life sciences) to be well reported, and two out of three felt television reporting was accurate—in fact, television was perceived as the most accurate of the media, despite the fact that few magazines or television stations in Canada employ science specialists.

### The Communicators

The study's survey showed that the science writers—the people initially responsible for communicating news of science—themselves believe that the media cover science inadequately, both in quantity and quality. They, too, judged the poorest medium to be radio (which, outside of the CBC, also employs few science specialists). They felt that one of the most important obstacles they faced in reporting science was the need to cover such a wide range of topics (more than one in three wrote on at least 10 fields of science a year), but they also pointed to the difficulty in keeping stories at once simple and accurate, and the lack of time they had to research their stories. The biggest external obstacle was the traditional reluctance of scientists to communicate with the public.

A profile of the science writers revealed that 69% had a university degree, but that twice as many had training in writing and the liberal arts as in the sciences. About 40% took either supplementary training or university courses in the sciences.

The managing editors survey showed less enthusiasm for science coverage and more complacency about the way it was currently being covered than either the public or the science writers. As the authors of the study summarised it: "Editors' replies (to a section asking if they anticipated changes) were indicative of management views on most papers: that all was well with science coverage." While nearly half the papers surveyed had assigned reporters to cover medicine and health, only 22% (11 papers) had assigned a staff member to cover science. Five of these science reporters were on papers with circulations of more than 75,000. A variety of reasons were offered for not having a full-time science writer. Many editors said they could not afford it or found it cheaper to get the news from the wire services. And 29 of 33 editors who replied said their papers did not have enough staff-written science news to justify a full-time science writer—a neatly circular argument, as one critic put it.

Although both the public and the science writers who were surveyed thought it was a good idea to set up science news in a regular, easily-identi-

fied way, the editors were less enthusiastic. Between 40 and 49% of the public agreed that, when they are specifically looking for science articles in the press, they have difficulty finding them. About 68% of the science writers would like to see a weekly column on science in the press, and 44% preferred a full page weekly devoted to science. Yet among the editors, only 31% believed readers would like to see some sort of regular science feature; 70% felt that science should be presented only as items became available, and only five of 52 editors thought readers would want a full page weekly.

Perhaps some clue can be found in the educational backgrounds of the editors: less than one in three had any science courses at the post-secondary school level, and only 31% had a university degree (compared with 69% of the science writers). Although 20% of the editors reported they had had science or technical writing experience themselves, it ranged from one whose experience was "sporadic" to three with more than 20 years' experience.

The authors of the study draw the following conclusions:

"There is as yet a dilettante, hit-and-miss approach to science coverage in general, and Canadian science in particular. Even the barest informative functions of the press are not met in this area, let alone the interpretive or educative role (which is becoming more important as science affects the readers more and more).

"Often only the highlights of a scientific meeting or the outline of a project—with little relevance to impact on society are presented; in many cases by news services reporters and not by staff writers of the paper... Finally, even if good stories are written, they can still get postponed or not even used—frequently superseded by the most trivial, sensationalized items; or else buried in the paper where only the hardy will ever find them."

However, like good journalists, the authors did at least give something of the other side of the argument. One of the editors quoted, from a paper of approximately 50,000 circulation in the prairie provinces, commented: "The whole tenor of the questionnaire is so unrelated to newsroom practice that answers cannot have any validity. For example, anyone knows that any particular story has 100 facets, and to attempt to departmentalize 'science' in the modern world is meaningless. And while on any one day, no one may edit what you call a 'science' story, the next day 10 people may deal with 15 so-called 'science' stories. Go into the newsrooms and you'll find your answers. First of all, define 'science' news."

## BRITISH STEEL

# Quiet change at BSC

ALTHOUGH the spearhead of the British Steel Corporation's attempts to stem its losses and revitalise itself depend to a great extent on agreement with the trade unions to a reduction in the total labour force (some 220,000 people at present), a step forward in rationalising its research and development was taken recently with the minimum of fanfare and publicity. Quite simply, the BSC now has a Chief Scientist and a Controller of R and D, in the true Rothschild tradition of the "customer-contractor principle".

The annual research budget of some £13 million may not seem much by comparison with the corporation's losses, which are now running at about £8 million a week, but when the BSC is properly on its feet again, it will undoubtedly profit from the more razor-edged research arrangements that now seem in prospect.

As from the beginning of last December, Dr Robert S. Barnes, until then Director, Research and Development, became Chief Scientist, and Mr James Mackenzie, who had been Technical Director of the General Steels Division, became Director, Research Laboratories. This means, essentially, that Dr Barnes says what he wants done and Mr Mackenzie establishes that it can be done and sees that the work is carried out.

At present the two men are sizing their new jobs up and it will be a few months before they finally sort out precisely how their responsibilities should be divided. It is fairly certain, for example, that Dr Barnes will have under him a team which will be responsible for investigations into the cost-benefit of research done by the BSC and for techno-economic analysis. Until December, research was carried on within the corporation's four divisions and at three "corporate laboratories" which used to make up the old British Iron and Steel Research Association, BISRA. This somewhat decentralised system has its roots back in the days before British Steel was nationalised, and it is no secret that there has been some overlap and duplication of work, which admittedly has been decreasing over the years.

The corporation has no plans to close any of the laboratories or to cut its spending on research, and any redundancies that may occur will be part and parcel of the BSC's overall labour strategy. The changes do mean, however, that laboratories will lose some of their autonomy under Mr Mackenzie, who will be based in Teesside in North-east England. And there

seems little chance of major new research avenues being funded with new money in view of the corporation's perilous financial situation.

These changes in research and development do little, of course, to help the corporation with its immediate problem of turning itself into a viable entity. Since nationalisation in 1967, BSC's capacity of some 27 million tonnes a year has been maintained while the number of individual steel plants has been reduced from 40 to 30, and the corporation's basic aim is to produce some 80% of a projected output of 35–37 million tonnes (in the mid-1980s) in just five major integrated steel complexes—two in Wales producing 9.5 million tonnes a year between them, two in North-east England with a combined output of 16 million tonnes and a Scottish complex (4 million tonnes). In these giant plants, ore will be turned into a finished product on a single site. The remaining 20% of the output will be mainly of special steels, and this activity will, as at present, be centred on Sheffield.

Up-to-the-minute though this may sound, BSC will be doing no more than the Japanese and others have already achieved: the Nippon Steel plant at Fukayama, for example, has an annual output of some 16 million tonnes, and that at Dunkirk in France produces about 8 million tonnes a year. It is widely agreed that a really viable steel plant must be sited near a deep-water terminal (thus eliminating the relatively very high cost of transporting ore by rail) and should have an output of several million tonnes a year (thus opening up the advantages of ore transportation in 250,000-ton bulk carriers).

## US ENERGY

# Saving without changing

*An aggressive energy conservation programme would enable the United States to meet all its energy requirements for the next 25 years without recourse to environmentally destructive new sources of supply, according to a provocative study published this week. Colin Norman reports from Washington.*

FULLY half of the energy now used in the United States is wasted, and massive savings are possible without major changes in the American way of life, according to a study written by Denis Hayes, a former energy adviser to the Governor of Illinois. The study was published by the Worldwatch Institute, a relatively new Washington-based research organisation whose previous analyses of global problems, such as food supply, have attracted considerable public attention.

The conclusions reached by Hayes run counter to the conventional wisdom that energy consumption is so closely correlated with standard of living that major reductions in energy use would precipitate severe economic dislocations and cause living standards to drop drastically. Hayes says, however, that his conclusions rest on the assumption "that lifestyles will change only cosmetically—that Americans will continue to travel as many miles, keep their homes just as warm, operate as many appliances, and eat what they now eat". Moreover, he argues that a strong energy conservation program would actually increase employment and "save consumers billions of dollars a year".

Hayes told a group of reporters last week that he reached his conclusions about energy conservation after becoming convinced of the potential difficulties in opening up new sources of supply. Noting that economic and technical problems have caused some of the leading industrial contenders to drop out of the effort to develop oil shale, that increased use of coal would create unacceptable environmental pollution, and that nuclear energy is beset with troubles, he said that "source after source is becoming increasingly less optimistic". Moreover, since oil and gas reserves in the United States are dwindling fast, Hayes suggested that "we are consuming energy like a childless society", rapidly depleting energy reserves "with little regard for the future energy needs of our children".

The American way of life is "rife with opportunities to conserve energy", Hayes says in his report.

- The major opportunities lie in transportation. Hayes estimates that some 42% of total energy consumption in the United States is accounted for, directly and indirectly, by transportation; he reckons that half of that amount could ultimately be saved. His suggestions include gradually tripling the mileage performance of vehicles, mostly by reducing the weight of automobiles; greater use of public transportation and car pooling; and shifting freight from trucks to more efficient means of transport such as railroads and waterways.

- Stricter insulation standards for new buildings and increased insulation of existing structures, coupled with greater use of solar energy for heating and air conditioning, could save as much as 16% of present consumption, he calculates.

- Technical improvements in agricultural production and changes in the way food is packaged and sold could save another 5%.

- Improvements in the efficiency of electricity generation, through more use of waste heat and better generating technology, could save 3% of present energy consumption.

- Finally, greater use of recycling and elimination of unnecessary packaging could save 4% of current energy needs.

Few of those suggestions are new. In fact, most of them were aired in a massive study of energy policy options for the United States, published in 1974 by the Ford Foundation's Energy

Policy Project. The catch, of course, is that the road between devising an energy conservation programme and implementing it is paved with political problems. Though Hayes notes in his study that such problems exist, he offers few suggestions for overcoming them.

To achieve the level of energy saving which his study suggests would require considerably increased government regulation of various industries, use of tax incentives for increasing efficiency and other similar devices. Most of those measures would be opposed by a powerful coalition of industrialists, energy interests and financiers.

But perhaps the chief political problem is that the greatest single incentive for energy conservation would come from greatly increased energy prices, which are still comparatively low in the United States. Though he does not discuss prices at length in his study, Hayes said last week that he would personally favour much higher prices than even a free market would produce (natural gas and oil prices are now controlled to some extent by the federal government). But he added that if prices are allowed to rise, an income distribution scheme would be required to prevent the burden falling on the poor. That, of course is a politically explosive issue. Last year, Congress balked at decontrolling oil and gas prices, partly because of the suspicion that oil companies would be able to reap greater profits if controls were removed, but mostly because of the fears of a voter backlash provoked by rising energy costs.

## Boost for biomedical research

CONGRESS last week handed President Ford a stunning political defeat when it voted, by a surprisingly large margin, to ram a budget bill for the Department of Health, Education and Welfare (HEW) into law over his objections. By its action, Congress has lifted the sagging budgetary fortunes of the National Institutes of Health, for the bill contains a large helping of money for biomedical research—considerably more than Mr Ford wants to spend. There are still a few political battles to be fought before NIH can spend the money, however, and the exact amount and the timing of its release by the Treasury are not yet certain.

The HEW budget bill—which applies to the fiscal year which began more than 7 months ago—has been tangled in a struggle between Congress and the Ford Administration over spending priorities. The supporters of the overriding action have

argued that since Congress had already cut the defence budget, an increase in the HEW budget would not add to total government spending, but merely shift priorities from defence to domestic programmes.

As far as NIH is concerned, Mr Ford had proposed that it should receive slightly less money this year than it received in the 1975 fiscal year. The bill passed by Congress, however, will increase NIH's budget by some \$200 million.

Mr Ford might still be able to delay the expenditures and perhaps, reduce them a little. In the next few days he will formally propose to Congress that some of the money should not be spent this fiscal year; Congress will have 45 days in which to act on that proposal. That means NIH will not get its budget sorted out until three quarters of the fiscal year has gone by. Another battle will then begin over HEW'S Fiscal year 1977 budget.

## BRAZIL

Two Brazilian ecologists are making progress in their fight to save the "mico"—a small, round-faced, long-tailed monkey of the genus *Cebus*—from extinction. A generation ago, when Rio de Janeiro's famous Copacabana beachfront neighbourhood was a quiet, distant retreat for fishermen and weekend trippers, with hardly any permanent residents, countless thousands of micos played in the branches of trees that proliferated in that district. Now, with Copacabana turned into an overpopulated jungle of high-rise apartment buildings, almost no micos are left in Rio. (Fewer than 1,000 are known to exist in the whole of Brazil.)

For several years, however, ecologists Adelmar Coimbra Filho and Alceu Magnanini of the Rio State Engineering and Environment Foundation, have been battling to prevent the mico from disappearing. They started out by keeping a few micos in the safety of their back yards and encouraging them to breed. In 1972 they obtained a foreign grant and created a biological preserve in Rio's still-untouched Tijuca Forest. Today the mico population there has grown to 58.

The prospects for keeping the mico from becoming extinct are now better than ever before. Brazil's federal Land Reform and Colonisation Institute has promised Coimbra Filho and Magnanini that it will expropriate a wooded tract of land north-east of Rio—a former natural habitat of the mico—and turn it into a restricted-access biological area where the principal priority will be to preserve this species of monkey.

Magnanini, who at one point in his career was ready to pronounce the mico extinct (until his partner, Coimbra Filho, happily discovered one), says the mico had the misfortune to be best adapted to Brazil's humid Atlantic coastal region—where development of the country has been most intense.

● Brazil's Health Ministry has released partial results of its most intensive

survey to date on the incidence of Chagas Disease, and the picture is not very bright. Researchers found the ailment prevalent in 1,238 of 1,750 counties that were surveyed (Brazil has nearly 4,000 counties). These results led to estimates that 8 million people in this country may have the disease, either in its latent or acute form.

Chagas Disease is a Latin American malady for which there is no known cure. It is caused by a protozoan parasite known as *Trypanosoma cruzi* and is transmitted by an insect known colloquially as the "barbeiro" (Portuguese for "barber bug") or "chupao" ("sucker"). Chagas Disease, which attacks the heart, causes long term debility, often resulting in death. Most fatalities are among people 25-50 years old who come from rural areas.

The disease is transmitted in a bizarre way: "barber bugs" living in the thatched roofs or mud-brick walls of peasant farmers' shacks come out at night and bite people, usually near their eyes. Then the insect defecates into the bite, sending the dangerous parasite directly into the person's bloodstream. The Health Ministry survey showed that Chagas Disease is further spread through unsupervised blood transfusions—even in seemingly modern, advanced cities such as Belo Horizonte and Sao Paulo, where there are large colonies of farm migrants.

"In Brazil, most cases of Chagas Disease go unrecognised, because of a lack of good medical care in rural areas," declared Dr J. Romeu Cancado, head of the medical clinic at the Federal University of Minas Gerais Medical School. He added that the problem of Chagas Disease has been further complicated by failure to include a detailed study of the disease in leading Brazilian medical schools. Most medical researchers at present doing work on Chagas Disease are in fact non-Brazilians.

Asked about prospects for finding a cure for Chagas Disease, Dr Cancado said that several drugs had been pre-

sented recently as cures for Chagas Disease, but most had turned out to be too toxic or ineffective in humans.

● Brazil is seriously determined to cut its petroleum consumption (it had to import four-fifths of its crude oil in 1975, at a cost of around US \$3,800 million), and President Ernesto Geisel has asked petroleum researchers to develop an efficient Brazilian product that would contain 20% alcohol.

Brazil has great potential for producing alcohol. It is the world's biggest cane-sugar grower, and it has vast plantations of cassava root and sweet potatoes, which are thought to be alternative sources of extractable alcohol. The nation's present rate of alcohol production is 270 million litres a year. Based on figures for petrol consumption, Brazil would have to boost alcohol production to 3,000 million litres annually to meet the 20% goal.

Brazilian gasoline now contains about 5% alcohol. Some say that the alcohol mixture can be increased to 20% without lowering the efficiency of automobile engines, but Mario Gellini, an engineer with the Brazilian subsidiary of the Ford Motor Company, says that 15% is the maximum amount of alcohol that can be tolerated if cars are not to run badly.

### Competition 5

As correspondents continue to point out, *Nessiteras rhombopteryx* is an anagram of "Monster hoax by Sir Peter S." or "Yes both pix are monsters, R." (for Rines). A prize of £10 is offered for the best anagram of any scientific concept. Closing date for entries is March 10.

FOR **Competition 4** readers were invited to submit about 100 words culled from the pages of *Nature* 100 years hence. Entries from F. P. Hughes and S. Gilbert deserve special mention, but the winning entry came from R. Ternbach, of Cambridge, Massachusetts, who receives £10 for this submission:

The Lunar Observatory for Orthomolecular Nebulosity has surveyed one of the twelve equally spaced peculiarities recently shown to surround the galaxy at cosmological distances. Optical plates exposed through the moonstation telescope show a ring (head) with an arc (horns) above.

Gas clouds are ejected from twin singularities (nostrils) in the head at a rate of  $10 \text{ min}^{-1}$  (breathing rate). Glitches in the ejection rate (snort bursts) have a mean inter-snort interval of 1 sec. Absorption spectra of snort gases suggest a molecular composition strikingly similar to bovine breath.

**Fig. 1** Appearance of the peculiarity on optical plate made at the Lunar Observatory for Orthomolecular Nebulosity.

## SWEDEN

# Making sense of senselessness

*As progress falters in the drawn-out second round of the Strategic Arms Limitation Talks (SALT), concern is also growing about the implications of large-scale environmental warfare. But popular attention is often diverted away from both the true state of present technological developments and the strategically valueless damage which the military use of existing techniques has already done. From Stockholm, Wendy Barnaby reports.*

WHEN two such prestigious organisations as the Royal Swedish Academy of Science and the Stockholm International Peace Research Institute (SIPRI) collaborate to produce a public statement on a topical issue, it is not surprising that it should attract a lot of publicity. But press reports of their predictions about war and the environment, which are contained in the latest edition of the Academy's journal *Ambio*, have generally been both inaccurate and misleading.

The journal describes the damage done to the biosphere by war, and the ways in which natural environment phenomena could be manipulated for belligerent purposes. It also discusses some of the international negotiations to draw up treaties prohibiting modification of ecological systems for hostile ends. Most of the publicity surrounding the issue has concentrated on articles which document the worldwide spread of all types of sophisticated weapons, describe the likely results of a nuclear war in Europe, and catalogue the possibilities of weather manipulation.

Press accounts of the prospects for environmental warfare have dwelt on seeding clouds, modifying hurricanes, oceans, earthquakes and climates, and tampering with the ozone layer, without mentioning what *Ambio* stresses: that the techniques for doing these things involve many practical difficulties and are at the moment "theoretical and speculative" only. Geophysical modification as a weapon system is certainly not just around the corner, but the presumption is that the public has the right to know which stage in the sequence has been reached: a *fait accompli* is harder to oppose than something not yet completed.

The global proliferation of modern conventional weapons suggests that more attention might be paid to the damage they can cause. Dr Malvern Lumsden, a Research Fellow at SIPRI, describes the impact of strategic bombing in the Second World War, for example of Berlin, and of the bombing

of South Vietnam by the United States. He concludes that the level of social organisation (which is different from the level of "development") of the bombed population is the prime determinant of its ability to withstand environmental stress. This conclusion is interesting in the context of the environmental stress that urban guerillas seek to inflict through the use of terror—a topic on which the journal might have shed some light by considering which factors most often influence the outcomes of sustained campaigns of kidnapping, hijacking and attacks against embassies.

Apart from anticipating future weapon systems, the press could also publicise the extent of the damage caused by those presently deployed. In another article, a former US marine officer, Professor Arthur Westing, describes the three prongs of American tactics in South Vietnam between 1965 and 1973. Professor Westing, presently a botanist who visited SIPRI as a researcher in 1975, details the effects on the country's ecology of high explosive munitions, herbicides and land-clearing tractors ("Rome ploughs"): the instruments used by the USA to make the land inhospitable to enemy guerillas. One quarter of the land area of the entire country was covered by B-52 crater fields alone. One tenth of the land area—about 1.7 million hectares—was sprayed once or more with herbicides. And about 2% of the land area was cleared by Rome ploughs, 33,000-kg armoured tractors whose blades can split and topple trees of almost any size. These destructive techniques proved to be of only doubtful military value, but Professor Westing forecasts that future combatants will intensify their use in order to raise their military pay-off. The result will be even more desolation than was caused in South Vietnam.

Destruction on the scale implied by present levels of armaments can, of course, only be supported by enormous resources. Another SIPRI Research Fellow, Ronald H. Huiskens, calculates that world military expenditure totalled \$210.300 million in 1974, and that the raw materials used for global military purposes are at present worth about \$250.000 million—the equivalent of the combined gross national products of the 65 countries of Latin America and Africa. That natural resources are used to desecrate the environment in which they were formed represents just one of the many ironies characterising the present ridiculous levels of militarisation. □

## CERN

# II on target

*The Geneva-based European Organisation for Nuclear Research (CERN), in which 12 European governments participate in a collaborative programme of subnuclear physics research, largely through teams of visiting scientists, has two particle accelerators that have been operational for many years. Peter Collins reports on the super proton synchrotron (SPS) now under construction*

THE meeting of the CERN Council just before Christmas marked the end of an era with the retirement of Professor W. Jentschke following his five-year term as Director General of CERN I, the original CERN laboratory. Since January 1 of this year the two CERN laboratories—CERN I and the one to house the SPS, CERN II—have been combined. Instead of two separate Directors General, the whole complex has two men working side by side: Dr J. B. Adams, as Executive Director General, is responsible for everything concerned with management, while Professor L. van Hove of Belgium fills the new appointment of Director General responsible for research.

Interest at CERN inevitably centres, however, on the 400-GeV SPS. Unlike many (and perhaps most) such building projects, its construction is moving ahead on schedule and within its estimated budget. The last of 744 bending magnets in the 6.9-km ring was installed a month or so ago to coincide with the meeting of the CERN Council. According to Dr Adams, who was the Director General of CERN II, there have been few serious problems during construction of the new machine.

Apart from the apparently inevitable delays arising from late delivery of components, only one major difficulty seems to have arisen. This was the discovery, early in 1975, of serious deterioration in the insulation of a number of the magnets that had already been installed. Urgent and intensive detective work showed that the failure was always in the same area of the coils; it was found to be caused by the use, on the ends of cables, of a cleaning fluid that contained a high proportion of phosphoric acid. Where this had not been completely cleaned off, the acid attacked the resin used for insulation, and had the effect of continuing its "curing". The result was that the resin hardened, shrank, and eventually cracked, allowing the acid to get through into the glass cloth used for the inner insulation, and thence to the

THE annual review of the Christian names of the "top children" whose birth are announced in the London *Times* appeared as usual in the New Year. For the boys, James, Thomas and Nicholas headed the list, with, for girls, Sarah, Emma and Alexandra in the corresponding positions. This year the list has stimulated an interesting correspondence on the sociological problems relating to the choice of what are perhaps more accurately described by the American term "given" names. No *Times* reader apparently calls his child Tracy or Charlene, though there is a growing tendency to saddle girls with classical names like Corinna, Flavia, Gratia and Xanthe. One writer, from the Savage Club, calling the list "astonishingly class distinctive", recommended the introduction of a Christian Name Discrimination Act, banning socially-divisive names and having, like the French, an approved list from which names must be drawn. This last course has given difficulties to Breton nationalists who wish to use names of folk heroes who were not recognised by Napoleon.

Names may be as interesting to the parasitologist as to the sociologist. In 1939 I became involved in the problem of lousiness in English children. Before the war official statistics suggested that the head louse was almost extinct, for only one or two per cent of children were detected with the parasites by the officials of the School Medical Service in their routine school inspections. However, when town children were evacuated to the country to escape the risk of bombing in September 1939, far more than had been expected were found to be verminous. The Board of Education, as it then was, defended its statistics, and suggested that the children had become infested during the long summer holiday. Political arguments arose. Socialist education committees in towns accused Tory reception areas of exaggeration. No one seemed able to produce the facts

which had led to what was rapidly becoming an ugly situation, particularly as there was as yet no enemy bombing to distract people's attention.

As no one else seemed to be trying to find out the facts, I approached

## Names to remember

KENNETH MELLANBY

the Board of Education with a plan. To the Board's credit, I was given every encouragement and £200 to investigate. I found that, in our cities, over half the girls between 5 and 12 years old were lousy, and that a third of the boys were similarly affected. There was no evidence that the rate of infestation rose during the holidays. It was clear that most infestations were not being detected at routine inspections.

These results were all published with the approval of the Board of Education and the Ministry of Health, though they were clearly critical of work of those government bodies. My paper was censored only

in very minor ways. I was asked to omit a section where I identified the incidence of infection in children who were registered as belonging to different religions and different Christian denominations. I agreed that this information might exacerbate inter-sectarian quarrels. But I was also asked to cut out a section on Christian names, which was thought to be too frivolous for war-time publication, and I think that the information may now be revealed.

In one city which had a particularly high rate of lousiness (70 per cent of all ten year old girls) I noticed that children named after film stars, children with saints' names and children with the names of the Royal Family were the most likely to be lousy. Marlene (often spelt Marleen), Shirley, Bernadette, Margaret, Rose, Marina—they always warned me in advance what to expect.

This, of course, brings us back to the sociological field. Lousiness tended to be highest in large families, where reinfestation from siblings even after successful treatment was common, and where individual attention by the mother was less effective than when she had fewer children to care for. It has been suggested that children named after film stars or royalty come from families with less of a tradition than those where the same few names are used generation after generation, and where parental care may be greater. This may be the explanation. But I suggest that anyone studying sociological problems relating to names bears these observations in mind. During the war I found them useful. Although the results had to be confirmed by individual examinations, I could make a good estimate of the lousiness of a class of school children simply by reading through the register. As the head louse is now staging a comeback in some British towns, it will be interesting to see whether it still prefers to infest the holders of any particular names.

coils themselves. The insulation system itself then became a conductor.

Every one of the 300 or so magnets already assembled was examined, and dismantled, repaired or rebuilt where necessary. As an extra precaution, further insulation in the form of two layers of kapton foil was wrapped round each coil, and it was found possible to do this with those magnets which had not deteriorated, but had already been installed. Every one of the 744 magnets in the ring has been treated in this fashion.

The fact that nearly 300 of these big

magnets were rebuilt within the SPS Assembly Halls, without delaying the very strict construction schedule and using CERN's own staff and facilities, is an indication of the efficiency and skill with which the whole project is being handled. Tested under conditions with peak fields equivalent to the 400-GeV energy level for which they are intended, the magnets have shown no further failing, nor do there seem to be any serious problems with any of the other components.

Apart from some delays in delivery of magnets for the beam transfer lines

to the experimental areas, the rest of the construction is well on target, and the accelerator is expected to be operational in the latter part of 1976. This is perhaps no more than was to be expected from an establishment that runs as sweetly as CERN. To many it is an object lesson not only in international scientific and technical cooperation but in the noticeably pleasant atmosphere and evidently high staff morale as well. It could well be studied by certain international agencies of the UN family a few miles away in Geneva itself. □

## Proceedings against professor

SIR,—In *Nature* recently under the heading 'Anti-nuclear critic faces dismissal' (October 23, 1975, page 636) it was maintained that Professor Jens Scheer is "head of a university department" and is threatened with dismissal apparently because he criticises the construction of nuclear power stations. Both statements are incorrect.

(1) The "head" of our department is elected democratically each year by the professors, students and technical personnel. Professor Scheer has never held this office, which is at present occupied by Horst Diehl.

(2) It is true that various disciplinary proceedings have been initiated against Professor Scheer but the reason for these measures is neither his criticism of the West German nuclear programme, which is shared by a number of his colleagues against none of whom have any such proceedings been taken, nor simply his membership of what we consider a rather insignificant Maoist group.

Your readers might infer from the article that the West German authorities disregard individual rights and use improper methods in order to silence their critics and that the true reasons for the initiation of disciplinary proceedings against Professor Scheer are not those which had been stated officially. Such an inference would be wholly unfounded; readers should be aware of the following facts.

On two separate occasions, Professor Scheer was involved, with others, in violent activities at the University of Bremen: in October 1973 a meeting of Christian Democrat students was broken up by force, and in September 1975 a press conference of the Students Committee was pelted with eggs and tomatoes. In both cases the university took out disciplinary proceedings against Professor Scheer. The earlier case, in which the Rector imposed a fine on Professor Scheer, is under appeal; the latter is still under consideration. Professor Scheer's action in 1973 also led to the District Court of Bremen sentencing him to three months imprisonment (suspended) and a fine of DM3,000. This too is under appeal.

Action has also been taken against Professor Scheer by the Senate of the Free Hanse Town of Bremen under the provisions of the Bremen Civil Servants Law. Since December 9, 1975, he has been under suspension on half

pay as a result of his alleged anti-constitutional activities.

## Naming the blue-greens

SIR,—Recently, in several publications, organisms hitherto known as blue-green algae have been called "blue-green bacteria". It is appropriate to consider the popular name of the Cyanophyceae in a scientific journal since words, especially those used in science, should have clearly defined meanings and should not be subject to passing whims or personal preferences.

Cohn, more than a century ago, associated the apparently non-nucleate blue-green algae with the bacteria in the division Schizophyta (*Beitr. Biol. Pflanz.*, 1, 141–207; 1875). Chatton subsequently distinguished the characteristic cellular organisation of these types of organisms as "procaryotic", (*Titres et travaux Scientifiques*, Sète, Sottano, 1937), and on this basis Stanier and van Niel proposed a major taxonomic dichotomy among living organisms, establishing the Prokaryota and Eukaryota (*J. Bact.*, 42, 437–466; 1941). Although the Prokaryota are essentially the same as the Schizophyta, rules of priority have evidently been waived and this distinction has become generally accepted. The eighth edition of *Bergey's Manual of Determinative Bacteriology* (Williams and Wilkins, 1974) refers to "the blue-green algae" as "allied to bacteria and at a level of equal importance . . . to the remainder of the Kingdom" (that is the Prokaryotae). But this is not to say that they are to be considered as bacteria. If we were now to start referring to cyanophytes as 'blue-green bacteria', we would implicitly synonymise the words 'prokaryota' and 'bacteria'. To what useful end?

It is generally accepted that living organisms should be named according

to one of three texts: the International Rules of Botanical, Zoological and Microbial Nomenclature. If a creature is to be 'moved' from one kingdom to another, its whole taxonomic status has to be reviewed and may have to be revised. If those of a whole class were to be involved, this would entail a lot of extra, and in my opinion, unnecessary work and headaches.

The word 'algae' has no clearly defined taxonomic meaning. It is a useful and convenient term for most non-vascular aquatic plants capable of photosynthesis with  $O_2$  evolution. If the Cyanophyceae were to be shifted, lexicographically, from the algae to the 'bacteria', it would be necessary to change many other generalisations to conform with this transfer. For example, the primary producers which evolve  $O_2$  would include 'bacteria' as well as green plants. The photosynthetic 'bacteria' would include aerobes as well as anaerobes, would contain either chlorophyll *a* or bacteriochlorophylls in thylakoids or associated with other subcellular elements, and would fix  $CO_2$  either with or without  $O_2$  evolution. Many of the seaweeds which often dominate tropical shores would have to be regarded as 'bacterial' growths. What would we gain by such verbal changes?

Unlike non-photosynthetic prokaryotes, blue-green algae rarely cause disease or decay, and thus relatively little money is spent on them. (Anyone who questions this should compare the budget of a bacteriology department with that devoted to the study of blue-green algae.) But although cyanophycologists are in a less fortunate position than bacteriologists when it comes to funding for research, personal remuneration, or public support, they should not seek to better their lot by calling themselves blue-green bacteriologists. Scientists should not use words misleadingly for base ends. In spite of the fairly evident and generally accepted phylogenetic homogeneity of the Prokaryota, the distinction between the classes are worth retaining. Although we may now handle them by similar technologies, yeasts are fundamentally fungi, cells from tissue cultures remain basically animal or plant cells, and blue-green prokaryotes are, by accepted standards, algae.

Yours faithfully,

## Spacing out the histone genes

from Benjamin Lewin

THE organisation of clusters containing many identical copies of a gene(s) is among the more intriguing features of eukaryotic DNA. The first such cluster to be identified was that of the genes coding for ribosomal RNAs. Assisted by the ready isolation of ribosomal genes in the form of the amplified nucleolar DNA of *Xenopus laevis*, analysis of the rDNA has shown that the pattern of organisation takes the form of a repeating series of transcription units, each representing a precursor molecule containing the sequences of both major rRNAs, adjacent units being separated by a region of DNA that is not transcribed. The transcriptionally inactive DNA separating the sequences coding for the precursor RNA is often termed the non-transcribed spacer. Because the precursor is itself somewhat larger than the total length of both mature RNAs (the length of the excess varies with the organism), the part of the precursor that is discarded is sometimes known as the transcribed spacer; its sequence is invariant and it most probably functions at some step after transcription. One of the most striking features of the rRNA gene cluster is that in spite of mutational pressure the copies of each gene seem to be identical. This implies that some mechanism must exist for suppressing variation among the gene copies and this may be the role of the non-transcribed spacer.

The histone genes comprise another system of clustered repetitive genes. The histone genes of the sea urchin are all repeated several hundred-fold in the genome, and similar repetition is also found in other organisms to a varying degree. Because their base composition differs from that of the bulk of the genome, the histone genes can be isolated as a satellite fraction of distinct buoyant density. This in itself suggests that they are clustered into one or a small number of groups. Two types of arrangement might be possible—separate clusters each representing many copies of one of the five histone genes or a single type of cluster containing all five genes. Two recent series of experiments have demon-

strated the existence of a single type of repeating unit and also have implied that it may possess a spacer region(s) longer than the total coding length of the five genes.

These experiments were made possible by the fact that the restriction nucleases *Hin* III and *Eco* R1 make a limited number of cuts in what can be inferred to be a simple repeating unit. Because such a large amount of histone DNA is present in the sea urchin genome, its cleavage products can be identified directly without the need for extensive purification of the starting material. Kedes *et al.* (*Cell*, **6**, 359–369; 1975) showed that when the DNA of *Strongylocentrotus purpuratus* is treated with the enzyme *Hin* III, a single major fraction is present upon centrifugation through a sucrose gradient; this represents histone DNA and sediments at 17S. Treatment with *Eco* R1 nuclease generates two major fractions, sedimenting at 14S and 11S. Starting with partially purified histone DNA (5–30 fold enriched), Weinberg *et al.* (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 4815–4819; 1975) characterised the restriction products upon acrylamide gels. *Hin* III generates a single fragment with a mobility suggesting a length of about 6,300 base pairs; *Eco* R1 produces two fragments, with mobilities corresponding to 1,800 and 4,500 base pairs. Only these fragments hybridise with histone mRNA; their gel mobilities are consistent with the sucrose sedimentation rates. The model immediately suggested by these results is that histone DNA consists of a single type of repeating unit, which happens to have a single site recognised and cleaved by *Hin* III and to have two sites that are subject to attack by *Eco* R1 nuclease.

By mixing *S. purpuratus* DNA cleaved by *Eco* R1 with the *Eco* R1-treated DNA of plasmid pSC101, Kedes *et al.* (*Nature*, **255**, 533–537; 1975) isolated hybrid plasmids carrying random parts of the sea urchin genome. Hybrid plasmids carrying histone genes were identified (after cloning in *E. coli*) by hybridisation with labelled histone mRNA. Two plasmids carrying histone

genes were characterised: pSp2 includes a DNA fragment estimated at 4,400 base pairs by gel electrophoresis and pSp17 carried a fragment of 1,700 base pairs. When Kedes *et al.* (*Cell*, *op. cit.*; 1975) investigated the nature of these histone gene sequences, they found by electron microscopy of heteroduplexes that pSp2 and pSp17 are homologous only along the 8,700 base pair length of the pSC101 sequence itself. The contours of the single strand loops give more accurate assessments of the lengths of the eukaryotic fragments, 4,800 base pairs in pSp2 and 2,200 base pairs in pSp17. Hybridisation experiments confirmed that the pSp2 plasmid carries the sequence of the 14S fragment cut from histone DNA by *Eco* R1 whereas the pSp17 plasmid represents the 11S sequence. The lack of homology between the 4,800 and 2,200 base pair sequences supports the idea that the repeating unit of histone DNA has been cut into two parts.

Which histone genes are represented on these two parts of the repeating unit? Histone mRNA can be isolated from the polysomes of developing sea urchin embryos as a 9S fraction and the mRNA of *S. purpuratus* has been separated into several classes on acrylamide gels. Two of these classes, A and C, have been shown to code for histones H1 and H4 respectively (Levy *et al.*, *Cell*, **4**, 239–248; 1975). The classes B1, B2, B3 and B4 together code for H2A, H2B and H3; the individual classes have not been equated with particular histones, but comparison with the template activities of the corresponding classes in another sea urchin, *Lytechinus pictus*, suggests tentatively that B1 may code for H2A, B2–3 for H2B, and B4 for H3. When these messenger fractions were hybridised to the hybrid plasmids Kedes *et al.* found that A, C and B4 annealed exclusively with pSp2 whereas B1 and B2–3 annealed only with pSp17. Using histone mRNA fractions separated in the same way, Weinberg *et al.* obtained precisely the same results with the *Eco* R1 histone DNA fragments separated on acrylamide gels. This suggests a map for the histone genes:

Two features are implicit in this map; it represents a regular repeating structure containing all five histone genes; and it must have appreciable spacer regions since the total length needed to code for all five histones is only 2,100 base pairs. This organisation obviously raises the question of whether the histone genes are transcribed as a single unit, presumably cleaved later into the individual messengers that represent the only form in which template activity for histones has been identified. Histones H2A, H2B, H3, H4 are found in equimolar amounts in chromatin, which makes their coordinate gene expression an attractive model, but H1 is found in smaller amounts. No precursor to histone mRNA has been identified, but it is interesting that such a model would imply that at least some of the spacer is transcribed. What is known about the sequences of the histone messengers and genes suggests that there cannot be much variation in the copies of each gene; probably they are all identical. This is subject to the caveat that although H2A, H2B, H3 and H4 all display unique amino acid sequences, some variation is found in H1, which may therefore be represented by more than one type of gene; how the H1 genes might be arranged and controlled within the repeating cluster is a matter

of some interest. In contrast to the apparent homogeneity in the copies of each histone gene in a given sea urchin species, Grunstein *et al.* (*Cold Spring Harbor Symp. quant. Biol.*, **38**, 717-724; 1973) noted that there is only limited homogeneity between the corresponding histone genes in different sea urchin species (in spite of the common amino acid sequences of the corresponding proteins); this emphasises the evolutionary stress that must be placed on conservation of sequence within a species. What is responsible for the maintenance of identity among the gene copies? It is tempting to speculate that some of the regions which do not code for histones might represent non-transcribed spacer, in which case a common type of structure might be proposed for both the rRNA and histone gene clusters, with a non-transcribed spacer perhaps implicated in helping to suppress variation. Of course, it is also possible that the unidentified regions of the histone gene cluster may code for other proteins or represent transcribed spacer. Important future experiments therefore will be to define completely the location of each histone gene in the repeating unit and to investigate the sequence organisation of the remaining sequences, and to determine whether they represent transcribed or non-transcribed regions.

The scene for the recent reports was set a few years ago by De Maeyer and his colleagues who boldly applied RNA, extracted from either mouse or monkey cells which had been induced to synthesise interferon, directly to heterologous cells and showed that the recipient cells were able to make murine or simian interferons, respectively (De Maeyer-Guignard *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **69**, 1203-1207; 1972). The amount of interferon made was quite small (not more than 30 units) perhaps due to the probable inefficiency of exogenous mRNA when applied directly to cells.

The obvious extension of this work has now been reported by De Maeyer and his coworkers (Thang *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 3975-3977; 1975) who have translated RNA extracted from induced mouse cells in a wheat germ cell-free system to yield an antiviral product with the properties of mouse interferon. About 700 units per  $\mu$ g added RNA were made. Similar results have also been described for RNA extracted from human cells in cell-free extracts from mouse ascites cells and rabbit reticulocytes (Pestka *et al.*, *Proc. natn. Acad. Sci., U.S.A.*, **72**, 3898-3901; 1975; Reynolds *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 4881-4885; 1975).

In view of these findings it is naturally to be expected that if such RNA preparations were to be injected into frog oocytes then translation of the exogenous mRNA would occur. That this is indeed the case has been demonstrated by Reynolds *et al.*, (*op. cit.*) who have achieved interferon titres of 100,000 units in homogenised oocytes after a 24 h incubation. Moreover, when  $^3$ H-leucine was included in the incubation and the product partially purified, using either immunoprecipitation with anti-interferon antibody or by affinity chromatography on a concanavalin A-agarose column, then subsequent electrophoretic analysis on polyacrylamide gels yielded a distinct peak of radioactivity with mobility corresponding to a molecular weight of 25,000 (this is about the expected value for human interferon). When RNA from cells not induced to make interferon was injected into oocytes very much less radioactivity was found in this peak. These results are striking when one considers that the injected RNA was the total mRNA fraction (containing poly(A)) from the induced cells and that the messenger for interferon could only comprise a very small proportion of this.

It seems likely that interferon is the first biologically active eukaryotic protein to be synthesised in a cell-free system dependent on added mRNA. But where does this get us? First it

## Interferon translated

from David Metz

INTERFERON is the antiviral protein synthesised by animal cells following infection with viruses. Since it is a cellular protein one would naturally suppose there to exist a corresponding mRNA species which could be translated in a cell-free protein synthesising system to yield, one would hope, the biologically active antiviral molecule. Three recent papers confirm this expectation.

The demonstration of the translation *in vitro* of interferon mRNA is made possible by the remarkably high biological activity of interferon. Although it has not yet been purified to unequivocal homogeneity, it is clear that the specific activity of interferon

must be at least  $10^9$  units of biological activity per mg protein. Thus the synthesis of exceedingly small amounts, by weight, of the active macromolecule may still be detectable by bioassay in which the reduction of virus yield is determined. A second convenient property of interferon is that of species specificity. Thus, for example, mouse interferon is active on mouse cells and not on human cells. Consequently if mRNA for human interferon is translated in an *in vitro* system prepared from mouse cells, one is able to verify that the antiviral activity synthesised is coded by the exogenous human mRNA and not by any endogenous murine messenger.

should enable the synthesis of interferon and its regulation to be studied in the intact cell since the mRNA as well as its product may be quantitated. Furthermore, *in vitro* synthesis of interferon should permit one to approach the question of the role of carbohydrate substitutions in interferon activity. Interferon has long been known to be a glycoprotein but whether the glycosylation is essential for activity remains unclear (if it is, then it must be occurring in the *in vitro* systems.)

Second, the apparent efficiency of the oocyte in translating interferon mRNA may assist in the determination of the primary structure of the protein, especially if the messenger can be at all purified from the other cellular mRNAs. The acquisition of sufficient pure interferon for amino acid sequencing by conventional techniques would be a formidable undertaking (though it is being attempted; Anfinsen *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 3139-3142; 1974) since the very high specific activity implies the need for

very great volumes of comparatively low titre starting material. The ability of the oocyte to synthesise interferon highly labelled in various amino acids may well expedite the task of determining the primary structure. If this were known then chemical synthesis of the molecule could be attempted. If this in turn was achieved then it might, because of the very high specific activity, prove to be a more economic way of preparing the quantities of interferon required for clinical trials than the cell cultures now used. □

## The A, B, C viruses

from Arie J. Zuckerman

VIRAL hepatitis now constitutes the main hazard of transfusion of blood and certain blood products. It was estimated in 1972, for example, that transfusion-associated hepatitis caused more than 30,000 cases of overt hepatitis and 1,500 to 3,000 deaths each year in the United States (*US Department of Health, Education and Welfare*, 1972). Since there are many sub-clinical cases of viral hepatitis the actual incidence in the USA has been estimated as high as 150,000 cases annually.

The existence of two types of viral hepatitis in man, infectious or epidemic hepatitis (hepatitis A) and serum hepatitis or homologous serum jaundice (hepatitis B) has been recognised for many years, and there is substantial evidence that these two types of infection are caused by antigenically distinct viruses. But it was difficult to distinguish clearly between these forms of hepatitis in the absence of specific laboratory tests. Differences were based principally on epidemiological observations and transmission experiments to human volunteers, faecal-oral transmission and an incubation period of about one month in the case of hepatitis A, and essentially tissue penetration and a long incubation period of up to six months in the case of hepatitis B.

The discovery of hepatitis B surface antigen (Fig. 1) and its association with infection has led to the development of a bewildering array of tests for screening blood donors and blood products. It was soon firmly established that blood containing this antigen was associated with a high risk of hepatitis and that such blood should not be used for transfusion. It rapidly became apparent, however, that the elimination of antigen-positive blood reduced post-transfusion hepatitis type B by about only 30% in some areas (*WHO Techn. Rep. Series*, No. 512, 1973). Although

the more recent introduction of sensitive methods of detection such as radioimmunoassay reduced further the incidence of post-transfusion hepatitis, cases of hepatitis B and non-B infections continue to occur (Koretz *et al.*, *Lancet*, **2**, 694; 1973). These remaining infections were generally ascribed to still insufficiently sensitive assay techniques for hepatitis B (Hollinger *et al.*, *New Engl. J. Med.*, **289**, 385; 1973 and *ibid.*, **290**, 1104; 1974) and to hepatitis A, which can also be transmitted by blood.

The identification by immune elec-

tron microscopy of virus-like particles (Fig. 2) in faecal extracts of patients with hepatitis A (reviewed in *Nature*, **252**, 193; 1974) and in experimentally infected marmosets and chimpanzees, provided an antigen which could be used for serological tests for hepatitis A antibodies and thus for evidence of infection. Immune electron microscopy has been used widely but immune adherence haemagglutination, complement fixation and radioimmunoassay techniques have been developed and are being applied on a limited scale. Sera from patients with hepatitis B-negative post-transfusion hepatitis in the United States were recently examined for evidence of infection with hepatitis A virus, and although relatively few patients have been tested so far sero-

**Fig. 1** The morphology of hepatitis B antigens showing three distinct entities, small 22 nm spherical particles, tubular forms of varying length and a large 42 nm double-shelled spherical particle. Original magnification  $\times 252,000$ . (Reproduced with permission from *Human Viral Hepatitis*, North Holland and American Elsevier, 1975.)

**Fig. 2** Virus-like particles measuring 27 nm in diameter found in faecal extract from a chimpanzee infected with human hepatitis A. Original magnification  $\times 275,000$ . (Electron micrograph from a series by A. Thornton, A. J. Zuckerman and J. D. Almeida.)

conversion to hepatitis A was not found in any of these patients (Feinstone *et al.*, *New Engl. J. Med.*, **292**, 767; 1975). A new term was coined; non-A: non-B hepatitis.

Feinstone and his colleagues were unable to implicate infection with cytomegalovirus or Epstein-Barr virus, which are known to induce liver damage as part of the generalised infection caused by these herpes viruses. Recently, Alter and his associates (*Am. J. med. Sci.*, **270**, 329; 1975) pointed out that in the United States when blood obtained from volunteer donors is pretested by radioimmunoassay for hepatitis B surface antigen approximately 90% of the remaining cases of post-transfusion hepatitis are serologically unrelated either to hepatitis A or hepatitis B viruses. It was considered, therefore, that a previously unrecognised human hepatitis virus may exist. This agent may be hepatitis virus C, a term introduced by Prince and his colleagues (*Lancet*, **2**, 241; 1974). They noted that an agent other than hepatitis B was the cause of 71% of 51 cases of post-transfusion hepatitis identified during a prospective serological study of 204 patients in New York. The incubation period was relatively long and the clinical and epidemiological features of the infection were not consistent with hepatitis A.

It is thus evident from these studies that a hepatitis virus C may indeed exist, although the precise criteria which would be virologically acceptable for a new infective agent have not yet been satisfied, despite the application of a battery of modern virological techniques. □

## Wigner cusps in nuclear reactions

from P. E. Hodgson

WHEN a proton is incident on a nucleus, many different reactions can take place. It may be elastically or inelastically scattered, it may be captured to form a compound nucleus which subsequently emits neutrons, protons or other particles, it may undergo (p,n) charge exchange, it may pick up a neutron to form a deuteron, it may knock out an alpha particle and so on. The relative probabilities of these processes depend on how easily the particles can get in and out of the nucleus (barrier penetration factors) and on the structure of the nucleus. The penetration factors depend on energy, and as the energy of the incident particle increases more and more reactions become possible.

At low energies the compound nucleus processes dominate, and then the cross section for all the non-elastic reactions depends on the penetration factor for the incoming particle, and this increases smoothly with energy.

As this energy increases this cross section has to be shared out among more and more of the reaction processes. The situation is rather like steadily increasing the flow of water into a closed tank, and at the same time making more and more holes of different sizes in the side of the tank. If we then concentrate our attention on the water coming out of one particular hole, we still see that at first it increases because of the increasing flow of liquid into the tank, and then decreases because more and more of the water is flowing out of all the other holes.

If we look very carefully, we may notice another effect: the flow of water out of our one hole falls slightly just after another hole has been made. This is because at any one time the total flow out must be the same as the total flow in, since the tank is closed and water is incompressible.

A very similar effect in nuclear reactions was predicted by Wigner in 1968 (*Phys. Rev.*, **73**, 1002). Each reaction process has a threshold energy: if the incident particle is below this energy the reaction cannot take place, but as soon as it is exceeded the cross section increases rapidly from zero. (This is the counterpart to punching another hole in the tank.) But since the total flux is constant, this must produce a small reduction in the cross section for all the other processes, and Wigner calculated the shape of the resulting cusps in the cross section as a function of incident energy.

It is interesting to try to observe these cusps as they would provide a delicate test of nuclear reaction theory but they are not easy to see. Usually there are so many hundreds or thousands of reactions taking place at the same time that the opening of another reaction channel, as it is called, does not make any perceptible difference.

The best conditions for observing Wigner cusps occur in the reactions of light nuclei, for in this case the level density is smaller and hence there are fewer channels. The effects of opening another channel are then more prominent, and indeed several cusps have been observed in light nucleus reactions, associated with the crossing of thresholds in neutron-induced reactions.

It is also interesting to look for Wigner cusps in proton reactions on heavier nuclei, and a remarkable example has recently been found in the  $^{63}\text{Ni}(p,\gamma)^{64}\text{Cu}$  reaction by Mann and his colleagues at the California Institute of Technology (*Phys. Lett.*, **58B**, 420; 1975).

This reaction was chosen because even though it is on quite a heavy nucleus it provides especially favourable conditions for the observation of

Excitation function for the  $^{63}\text{Ni}(p,\gamma)^{64}\text{Cu}$  reaction showing the Wigner cusps due to the crossing of the neutron threshold at 2.46 MeV. The curves show the results of Hauser-Feshbach statistical model calculations with (full) and without (dashed) the width fluctuation correction.

a Wigner cusp. These are that the new channel opens quickly, absorbing an appreciable fraction of the total flux, and that there are very few channels open already to share the resulting decrease in flux. These conditions are very well satisfied for the  $(p,\gamma)$  channel on  $^{64}\text{Ni}$  at the opening of the neutron threshold. The lowest excited states of  $^{64}\text{Ni}$  are at relatively high energies and this, together with the low energy of the neutron threshold (opening of the  $(p,n)$  channel), reduces the contribution of the inelastic scattering and compound elastic processes to the total reaction cross section. A possible competing reaction, alpha particle emission, is strongly inhibited by the Coulomb barrier, so that the total reaction cross section below the  $(p,n)$  threshold is mainly composed of the  $(p,\gamma)$  channels. Another favourable feature is the high density of low-lying states in  $^{64}\text{Cu}$ , the final nucleus in the  $(p,n)$  reaction, which ensures that the total  $(p,n)$  cross section increases very rapidly, producing a strong depletion in the  $(p,\gamma)$  cross section.

The measurements of the  $(p,\gamma)$  cross section were made from 1.1 to 3.7 MeV in 100 keV steps, and the yields for the reaction to the first three excited states of  $^{64}\text{Cu}$  were summed to give the results shown in the figure. It is notable that the cross section increases steadily from 1 to 2.5 MeV and then drops dramatically by a factor of 10 over the next 0.5 MeV as a result of the opening of the  $(p,n)$  thresholds. In this case the Wigner cusp is not a tiny perturbation but a major feature of the cross section. Many neutron thresholds are passed above 2.5 MeV, and these all contribute to the drop in the  $(p,\gamma)$  cross section.

A small resonance is visible in the  $(p,\gamma)$  cross section at about 3.27 MeV. This is attributed to the state in  $^{64}\text{Cu}$  that is the analogue of the first excited state of  $^{63}\text{Ni}$ .

At such low energies the reaction is dominated by the compound nucleus process; the incident proton is captured by the  $^{64}\text{Ni}$  nucleus to form a compound nucleus  $^{65}\text{Cu}$  and after a long time on the nuclear scale it emits one or more gamma rays until it returns to the ground state. The cross sections for such processes can be calculated by the Hauser-Feshbach statistical theory, using barrier penetration factors calculated from the appropriate optical model potentials. Since the number of open channels is small, this reaction is a severe test of the theory.

The results of Hauser-Feshbach calculations are shown by the dashed curve in the figure, and are in qualitative agreement with the measurements. If account is also taken of the correlations between the partial widths in the

entrance and exit channels by including the width fluctuation correction the improved results shown by the full line are obtained.

This comparison shows that the Hauser-Feshbach theory is well able to account for the Wigner cusps, and that it is important to include the width fluctuation correction.  $\square$

## Disappearing habitats

from Peter D. Moore

It is believed that the Romans were responsible for the construction of an extensive series of draining channels in the low-lying coastal area between Newport and Cardiff in South Wales, commonly known as the 'Monmouthshire levels'. The value of this land, mainly for pasture, is maintained by a careful control of the water table, which has long been effected by these drainage ditches, locally termed 'reens'. The reens have an additional value in that they represent a diverse series of habitats for aquatic plants and animals and serve as an extensive refuge for a large number of plant and animal species.

Recently this area has come under threat from a number of quarters and an ecological survey of the area and the various interrelationships between such physical factors as water table and plant and animal communities was urgently required. Just such a survey has been conducted recently by P. M. Wade of the University of Wales Institute for Science and Technology, Cardiff, and some of the conclusions were presented during a recent meeting of the British Ecological Society in Cardiff.

The floristic diversity of the reens has been confirmed by Wade's study, in which he recorded over 400 plant species associated with the waterways and their adjacent hedges and meadows. He feels, however, that recent land use changes in the area are combining to reduce this diversity.

The drainage channels are arranged in a rectangular grid system, where subsidiary reens coalesce into main reens which ultimately discharge their load into the Bristol Channel through simple, one-way sluice gates. These gates are not always perfectly efficient and there is an occasional movement of estuarine water back into the reens, which serves to diversify yet further the habitats within these channels. The fields which are bordered by the reens are drained by small furrows on their surface, from which run-off water reaches the reens.

Recent land-use changes have included the installation of sub-surface drainage pipes which have resulted in a more efficient water-ridding system and a consequential improvement of the meadows for pasture. This has meant that field size can be increased by reducing the number of reens, either by allowing them to silt up or by actively filling them. It has also allowed an increase in stock density to take advantage of the improved pasture yield.

Historically, the reens have served the subsidiary function of providing water for the resident cattle. This practice has also brought its problems, because the trampling of stock around the ditches has damaged banks and increased the rate of silting. An increased stock density, of course, makes this an even more serious problem. An answer has been found in the provision of water troughs situated in the centres of fields which attract animals away from the ditches.

At this stage a farmer is bound to ask the question whether he needs the reens any more. Their maintenance is expensive; at one time they were dug out by hand, but now excavation can be carried out mechanically. This, however, has involved the removal of most of the accompanying hedgerows which themselves provided food and shelter for wildlife. The growth of emergent aquatic plants can be controlled by spraying herbicides and this reduces the need for frequent ditch clearance, but spraying is itself an expensive process particularly because of the labour involved. So, since the reens are no longer useful as a water resource for livestock, it seems advantageous to lower the water levels within them or even to empty them completely. The use of mechanical pumps to replace the earlier crude sluice system has now made this possible.

Inevitably these changes have become more widespread until the traditional management of the reens has practically disappeared and subsequently the character and the biotic richness of the habitats which they represented is also vanishing. At this point one can predict that naturalists and wildlife conservationists will begin to muster and cry out for the retention of the old system in at least a portion of the area occupied by these low-flying levels. It is not difficult to summon up sympathy for such views, especially since they emanate from a part of the country where man's recent activities have reduced biological diversity to an extraordinarily depauperate level. The remaining fragments must assume a particularly high status in the eyes of those members of the local populace who appreciate such things. One cannot help reflecting, however, upon the

innate conservatism of mankind and one wonders whether the Romans were faced by a similarly militant Celtic environmental lobby when first they dug the ditches! □

## The EISCAT project

from G. N. Taylor

THE recent announcement that the UK Science Research Council is joining EISCAT draws attention to some significant current developments in upper atmospheric research. EISCAT stands for the European Incoherent Scatter Organisation, an association of research organisations from six countries which has been set up to build and operate a large new radar system in the auroral region of Northern Scandinavia. In this case the capital and running costs, and overall control of the project, are being shared between Research Councils or similar bodies in Britain, France, Finland, West Germany, Norway and Sweden. After preparatory discussions and technical studies lasting several years it has been decided to base the main technical centre at Tromsø in Norway, and the administrative headquarters at Kiruna in Sweden. The organisation will be governed by a Council made up of representatives from all the parent bodies, and Professor Tor Hagfors from the Technical University of Trondheim has been appointed as the first Director of the facility.

The incoherent scatter technique originated from a proposal by W. E. Gordon in 1958, for building a very large radar system in order to detect weak Thomson scattering from thermal electrons in the ionosphere. Originally conceived as a way of measuring electron density and temperature in the upper ionosphere from the ground, the method has developed into one of the leading diagnostic tools not only for the upper atmospheric plasma but also for thermonuclear plasmas. From experimental work done in the 1960s, it was soon discovered that both electron and positive ion temperatures could be measured independently, and later that plasma drift speeds and fluxes of super-thermal electrons could also be determined. From these direct measurements, which are made as functions of height and time, many other physical parameters can be derived indirectly: among the most important are the electrostatic field strength, the temperature and wind speed of the neutral air, and energy fluxes. In collaboration with other ground-based techniques, or with rocket or satellite-borne instruments, incoherent scatter can give remarkably

complete information about physical processes and conditions in the upper atmosphere. Incoherent scatter does not however supersede satellite experiments, even though some of the parameters measured are the same. For complete understanding, the upper atmosphere must be seen as a three-dimensional time-varying medium: the radar works in height and time, whereas most satellite measurements are expressed as functions of latitude and longitude.

Incoherent scatter radars are complicated and expensive, requiring very high power transmitters, large antennae and sophisticated data processing equipment. Until now, no more than seven stations world-wide have ever been operating at the same time, and most of these have been at middle latitudes. The EISCAT facility will be only the second station in either of the auroral zones, which are the key regions for observing interactions between the ionosphere, the magnetosphere, the neutral atmosphere and the interplanetary plasma, and where many important and poorly understood phenomena occur. The radar should come into operation in 1978 or 1979, and will then be operated intensively for at least a decade, with its time shared between a routine synoptic programme and special experiments by scientists from the participating countries. In Britain, research groups from a number of Universities and from the SRC's Appleton Laboratory are planning to use the facility. The scientific scope for European workers will be enhanced by the proximity of two rocket launching sites, and of many other ground-based instruments, at well established upper atmospheric observatories in adjacent areas

of each of the three Scandinavian countries. A wide variety of other data will thus be available to complement and enhance EISCAT observations.

In contrast to most of the earlier incoherent scatter sites, the EISCAT system will be designed solely for upper atmospheric research. It will be unusual in having two radars on widely different frequencies. One in the VHF band (at 224 MHz) will be a conventional monostatic type, designed to achieve the maximum sensitivity, and to explore the highest and lowest regions. The other will operate in the UHF band (at 933 MHz), and will be a multistatic radar of the type pioneered in France, and also used in Britain, capable of determining the true vector plasma drift velocity. The transmitters for both radars will be at Tromsø: the VHF receiver and one UHF receiver will be co-sited with the transmitters, while remote UHF receiving stations will be built at Kiruna and at Sodankylä, in Finland, respectively 200 and 400 km distant from Tromsø. Both radars will be designed with very flexible modes of transmission modulation, which should allow for a wide variety of experiments to be conducted. Comprehensive on-line and off-line data processing equipment will also be provided to obtain the maximum possible rates of useful information, and to monitor the progress of observations in real time. These features, together with the uniquely favourable geographical position of the site, should allow European scientists to make significant new contributions to an important field of geophysics. □

## Bacterial chemotaxis and methionine

from John S. Parkinson

NEARLY a century ago, Engelmann, Pfeffer and others showed that bacteria are attracted or repelled by various chemicals. Today studies on chemotactic behaviour in *Escherichia coli* and other bacteria have begun to reveal molecular mechanisms of sensory transduction and motility in micro-organisms. The central machinery of chemotaxis is still, however, very much a mystery. Several recent reports suggest that the amino acid methionine may provide the biochemical key to understanding chemotactic behaviour in *E. coli*.

The methionine requirement for chemotaxis is a specific and continuous one. *E. coli* mutants that are unable to synthesise methionine become non-chemotactic when deprived of exogenous methionine and chemotactic ability returns upon restoration of this amino

### A hundred years ago

THE first general meeting of the Mineralogical Society of Great Britain and Ireland is held to-day at the Scientific Club, Saville Row, at 12 o'clock (noon), when the chair will be taken by Mr. H. C. Sorby, F.R.S. The first ordinary meeting will be held at the same place and time to-morrow, when a paper will be read on the Scottish Rhombohedral Carbonates, by Prof. M. Forster Heddle, M.D.

from *Nature*, 13, February 3, 274; 1876

acid. Since no other amino acids produce such an effect, it cannot be related simply to effects on protein synthesis. In fact, ongoing protein synthesis is not needed for chemotaxis once the machinery has been assembled.

The behavioural manifestation of methionine deprivation is a change in the organism's swimming pattern. Normal swimming in *E. coli* resembles a random walk in three dimensions with occasional turning or tumbling movements serving to reorient the direction of forward motion. During chemotaxis the cell's tumbling machinery is modulated by chemoreceptors that detect changes in attractant or repellent concentration. Whenever the organism happens to swim toward an attractant or away from a repellent, tumbling is suppressed, which causes net movement in the appropriate direction. Methionine-starved cells are non-chemotactic because they are no longer capable of tumbling. Methionine therefore seems to have a major role in the production or regulation of tumbling movements, events central to the chemotactic process.

Springer *et al.* (*Proc natn Acad. Sci U S A*, **72**, 4640-4644; 1975) have tried to determine, by examining the effects of methionine deprivation on *E. coli* mutants with very high tumbling rates (tumbly mutants), whether methionine was directly involved in the tumbling process. They found that methionine starvation caused several of the mutants to lose tumbling ability, and that the time required for complete loss of tumbling was related to the chemotactic ability of the strains. Tumbly strains with poor chemotactic responses continued tumbling for several hours after removal of methionine from the medium. One mutant, in fact, never lost the ability to tumble.

Springer *et al.* also showed that exhaustion of the organism's internal reserve of methionine available for tumbling was accelerated by incubating the bacteria in attractant compounds during methionine starvation. Although unchanging attractant concentrations do not ordinarily modify tumbling behaviour, they evidently elicit increased consumption of methionine by the chemotaxis machinery.

Until more is known about the physiological defects of tumbly mutants, it is not possible, on the strength of present evidence, to conclude that methionine is directly used in generating tumbles. The data of Springer *et al.* and results of Aswad and Koshland on *Salmonella typhimurium* (*J. Bact.*, **119**, 640-645; 1974) are perhaps best explained by postulating an indirect role for methionine in the tumbling process. For example, methionine might be consumed in destroy-

ing tumble-inhibiting signals produced by the chemoreceptors. In the absence of methionine these signals would build up (faster in the presence of attractants) until tumbling was suppressed. Tumbly mutants might be less sensitive to such signals, necessitating higher signal levels (hence longer starvation times) to turn off the tumbling machinery in these strains.

A more direct way of investigating the role of methionine in chemotaxis is to determine the chemical fate of exogenously supplied methionine. Earlier work by Armstrong and by Aswad and Koshland had suggested that a compound derived from methionine called SAM (S-adenosylmethionine) was involved in chemotaxis. Since SAM is a donor of methyl groups in many biochemical reactions in the cell, Kort, Goy, Larsen and Adler (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 3939-3943; 1975) reasoned that perhaps the methyl group of methionine is transferred by way of SAM to one or more components of the chemotaxis machinery. To show this, they looked for transfer of radioactive label from the methyl group in methionine to proteins of the cytoplasmic membrane in the absence of *de novo* protein synthesis. Their search focused on membrane proteins because most of the known chemotaxis machinery is intimately associated with the cell's inner membrane.

Kort *et al.* were able to detect a membrane protein that is extensively methylated by methionine. Chemotactic stimuli increase both the rate of methionine utilisation and the amount of label transferred to the membrane protein. Also, the methyl groups on the membrane protein seem to turn over, perhaps reflecting the continuous requirement for methionine in chemotaxis. Chemotaxis mutants, including tumbly and non-tumbling strains, often had very different labelling patterns compared with the wild type. Most of the mutants (defining several different genes) had significantly less activity and correction of these mutations by reversion also resulted in normal methylation levels.

So the methylation reaction seems to be involved in chemotaxis and might conceivably be the primary site of action of methionine in the chemotactic process. But Kort *et al.* found some chemotaxis mutants (in the same genes as those mentioned above) which had normal or greater than normal methylation levels and yet were completely non-chemotactic. Detailed information about methylation and demethylation rates in these mutants should clarify the presently confused relationship between methylation and chemotactic ability.

Even if the role of methionine in bacterial chemotaxis proves to be a minor one, which seems unlikely, it still offers a promising new approach to learning more about the biochemistry of the tumbling process. Future studies will undoubtedly attempt to identify the gene(s) encoding the methyl-accepting membrane protein and to determine their role in chemotaxis through a combination of genetic and biochemical methods. When this has been accomplished, the significance of methionine to chemotaxis will be considerably clearer. □

## Heated discussions on Sun and weather

from John Gribbin

1976 seems destined to be the year of the Solar-Terrestrial Relationship conference. International jamborees on the topic are planned later in the year for Frascati (under the auspices of the European Space Agency) and Boulder, Colorado (organised by the American Geophysical Union); a more limited view of these relationships, within the confines of their relevance to meteorology and climate, was the theme of the January 21 meeting of the Royal Meteorological Society, where although the staunch believers in direct solar effects on the weather received a rough ride from some meteorologists there was a firm but reluctant undertone of belief even among the critics that there is evidence of some effect of solar activity on weather.

THE highlight of the meeting was a confrontation between J. W. King (Appleton Laboratory), a firm believer in solar cycle influences on the weather, and B. J. Mason, the Director General of the UK Meteorological Office, the most senior 'establishment' opponent of these ideas. King presented a breathtaking array of data in the form of graphs, charts and correlations between meteorological parameters such as the height of the 500 mbar level and solar parameters, especially the 22 yr cycle which, in magnetic terms, is a more fundamental feature than the superficial 11 yr cycle derived simply by counting sunspots. Among these correlations—in phase as well as in magnitude—most of the figures quoted by King suggested a probability of at least 99% that the relationships are genuine, and he tended to dismiss probabilities of around 95% as rather poor.

Mason responded at length to King's points, complaining that he had presented too many different correlations for the audience to grasp at one sitting, pointing out that they are all *post hoc* deductions and that sunspot cycle fanatics have now had "a hundred years of failure" in attempting to predict weather changes. He stated once again his unwillingness to accept such statistical evidence in the absence of a plausible physical mechanism behind it.

Asked how he had selected the data presented, King replied that they are typical of results obtained by comparing solar activity with published meteorological data, and that in round terms the Appleton team find in 95% of all the published data they have examined a correlation which could arise only about 2% of the time by chance. Mason objected that this meant the data were not new, but when pressed by King to say whether meteorologists should throw out the evidence replied "No", agreeing that solar effects must influence the high atmosphere, and asking that the theorists concentrate on explaining those effects before looking "downstairs" in the troposphere.

Two members of the Met. Office then described different studies in which rigorous statistical analysis had failed to remove every trace of a solar influence from their data. B. N. Parker surveyed links between the planetary mean geomagnetic index and surface pressure anomalies on a monthly timescale over the Northern Hemisphere, and C. K. Folland looked at relationships between sunspot and other quasi-cyclic fluctuations and circulation over the British Isles. The evidence seemed to show significant but not dominant solar influences in some stretches of data at least—not a good enough relationship for forecasting purposes, but suggestive for any theorist studying interactions between the Sun and the Earth. Again, the 22 yr cycle reared its head, and meteorologists took some persuading that this is indeed the more basic solar cycle, not just a harmonic of the 11 yr sunspot number cycle. All this, unfortunately, kept the emphasis of the meeting well away from the short term effects of specific solar events on the atmosphere of the Earth, which surely provide a better handle to grasp the physics of what is going on than any number crunching of cycles, quasi-cycles and pseudo-cycles.

It was left to D. M. Willis (Appleton Laboratory) to summarise possible mechanisms. It might have come as a surprise to meteorologists sceptical of some of King's statistics to learn how much room there is to doubt astrophysical ideas about the Sun and the constancy of the solar parameter. Among many speculations aired before, Willis

rightly emphasised the newer ideas of the influence of solar proton events on the atmosphere. This work is closely related to the study by Reid *et al.* (*Nature*, 259, 177; 1976) of faunal extinctions at times of magnetic reversals, and suggests that solar cycle influences on the weather may be the accumulation of solar proton effects on the ozone layer. It is also clear, however, that the state of the art in measuring the solar parameter is not yet good enough to rule out the possibility of a change by  $\pm 1\%$  over the solar cycle, changing mean global surface temperatures by  $\pm 1$  K.

The overall flavour of the meeting seems clear. Solar-Terrestrial relationships affecting the weather are real, but not dominant, and are not well enough understood for their use in Met Office forecasts as yet. But they may provide clues of great value to astronomers investigating the nature of the Sun and solar wind. This explains, perhaps, the apparent rift between meteorologists and space physicists; in fact, they are essentially in agreement on the reality of the link, but view it from very different positions. □

## Let booming sands boom

from Peter J. Smith

HARDLY surprisingly in view of their weird effects, sounding sands are incorporated into folklore and legends going back at least 1,500 years. Not that our ancestors were always listening to the same sounds. The most common of the musical sediments is probably squeaking (otherwise known as singing, barking or whistling) sand which produces a high frequency note in the range 500–2,500 Hz. But there is also screeching sand which emits an even higher frequency note ( $>2,500$  Hz) reminiscent of that produced by rubbing a finger around the top of a wine glass; and at the other end of the scale, low frequency booming sand can give rise to a sound like thunder which under ideal conditions can be heard up to 10 km from its source. The essential condition for the production of sound is either natural or forced movement; still sand is inevitably silent sand.

A recent paper by Criswell *et al.* (*J. geophys. Res.*, 80, 4963; 1975) investigates booming sand, which generates not only acoustic but also seismic waves. Both emissions are produced by natural slumping of the sand,

although they may also be produced manually in short bursts by digging in the sand, by forcing it downhill or even by walking on it. The natural slumping of an area of many square metres of sand may persist up to 15 min, giving rise to a 'roar', or on occasions a 'hum', rather like the sound of a low-flying propeller aircraft. But whatever the sound, it is always accompanied by ground vibrations which can be felt through the feet of anyone standing on or near a booming dune and through the fingers of someone generating artificial booming by digging in the sand. One observer has compared such vibrations to a mild electric shock from household current (50–60 Hz).

Though not particularly common, booming dunes have been reported at more than 30 sites in all continents except Antarctica and, curiously, Australia. The sound frequencies at some of these sites have been estimated before by reference to pitch pipes; but Criswell *et al.* have now carried out the first simultaneous measurement of acoustic and seismic spectra from a booming dune (Sand Mountain in Nevada) using, respectively, air microphones and geophones. The emissions were generated artificially by digging holes in the sand with a flat-bladed shovel.

Not entirely unexpectedly, the scientific aspects of booming dunes turn out to be rather dull and hardly a match for the subterranean ghosts, the shoeing of horses in underground caverns and the clanging of bells in buried monasteries to which sand sounds have been attributed in the past. The most "significant finding" is that the frequency spectrum of a short ( $<2$  s) forced booming event comprises sharp peaks largely in the range 50–80 Hz for both acoustic and seismic emissions. These results throw little light on the mechanism by which the vibrations are generated, which remains unclear; nor do they do much to justify the original aim of the work, which was to see whether a similar mechanism on the Moon could account for surface moonquakes.

Criswell and his colleagues do obtain one interesting result, however. A comparison of an acoustic amplitude trace from a Sand Mountain note with the trace of an 88-Hz organ tone from the opening stanza of Bach's C-Minor Passacaglia and Fugue shows that sand and expertly crafted organ pipes produce notes of comparable purity.

Perhaps Criswell and others should take the hint from Walt Whitman who, tiring of the learned astronomer's proofs, figures and charts, "wander'd off . . . in the mystical moist night-air, and from time to time, look'd up . . . at the stars." □

*X-ray analysis, circular dichroism, receptor binding and biological potencies of chemically modified insulins suggest that the conformation of the insulin molecule is critical to the formation of both the zinc insulin hexamer and the insulin-receptor complex. Results are consistent with an insulin receptor-binding region including many of the hydrophobic residues important to dimerisation in addition to more polar surface residues. There is a further possibility of formation of an antiparallel sheet structure between the insulin and receptor molecules in the complex similar to that between monomers in the insulin dimer.*

THE use of synthetic insulin analogues in the treatment of diabetes may become vitally important in the near future. Progress in presently underdeveloped countries means that demand for insulin is likely to exceed supply and this makes the synthesis of analogues a medical priority.

An understanding of the nature of the receptor-binding region of a protein hormone, and especially as complex a molecule as insulin, is essential for the proper design of such synthetic analogues. Fortunately the elucidation of the molecular structure of porcine insulin by X-ray analysis has made possible a more rational approach to the definition of the receptor-binding region<sup>1,2</sup>. Studies of the biological activities and sequences of insulins from different animals strongly suggest that a largely invariant region on the surface of the insulin monomer is a good candidate for this receptor-binding region. The three-dimensional structure shows that this region might include both A chain residues—A1 Gly, A5 Gln, A19 Tyr and A21 Asn—and adjacent B chain residues—B24 Phe, B25 Phe, B26 Tyr, B12 Val and B16 Tyr (for reviews see refs 3 and 4). Their involvement in receptor binding must now be tested by studying the biological properties of insulins specifically modified at one of these residues.

Modification of insulin may change the biological activity either by reducing the affinity of the hormone for the receptor or by decreasing the ability of the complex, when formed, to elicit a biological response. Either or both these effects may be brought about by direct interference of the modifying group, by changes of charge distribution or by induced conformational changes in the hormone. Thus the position of the modifying

group and the conformational changes induced by it must be defined in detail; this has not been done in previous work. Further, measurements of receptor binding as well as biological activity are essential to test any hypothesis concerning the location of the receptor-binding region, and the effect of chemical modification<sup>5</sup>.

We have carried out parallel studies of high resolution X-ray diffraction, circular dichroism, receptor binding and biological potency in fat cells of native insulin and various chemically modified insulins. The studies have further clarified the factors leading to decreased potency and provide evidence as to the nature of the receptor-binding region.

### Chemical modification and X-ray analysis

We studied a series of insulins with modifying groups of increasing size attached to the  $\alpha$ -amino group of A1 glycine, one of the invariant residues in the putative receptor-binding region. Techniques of specific chemical modification, developed in our laboratories, were used to prepare A1-acetyl insulin<sup>6,7</sup>, A1-*t*-butoxycarbonyl insulin<sup>8</sup> (A1-Boc-insulin) (this has also been prepared by Levy<sup>9</sup>) and A1-2-dimethyl-3-formyl-L-thiazolidine-4-carbonyl insulin (A1-'thiazolidine' insulin)<sup>10</sup>. A1-Boc-insulin was in part provided by H.-J. Friesen, Aachen (Diplom. Arbeit, T. H. Aachen, 1975).

Rhombohedral crystals of bovine derivatives formed more easily than those of porcine derivatives. They crystallised at pH 5.8 as opposed to pH 6.2 for native porcine insulin, whereas large crystals of native bovine insulin were prepared only at pH 6.7. For this reason we have studied modified bovine insulins, and also carried out control experiments on native bovine insulin.

Crystals of the chemically modified and bovine insulins proved to be closely isomorphous with porcine insulin although there are small changes in cell dimensions as indicated in Table 1. X-ray photographs of the A1-'thiazolidine', A1-Boc and A1-acetyl-insulins resemble each other, but the extent of the intensity changes from native insulin increases in the order A1-acetyl < A1-Boc < A1-'thiazolidine' insulin.

Three-dimensional X-ray data for the isomorphous bovine, A1-Boc and A1-'thiazolidine' insulins were collected on a four-circle diffractometer to the resolutions given in Table 1. As the differences between the A1-acetyl and bovine insulins were small, but rather similar in nature to the other two derivatives, we decided that it was not useful to carry out a full high resolution analysis of this derivative.

\*To whom enquiries should be addressed.

Table 1 Comparison of insulins

Insulin	Modifying group	Cell dimensions (Å)		Data resolution (Å)
		$a = b$	$c$	
Porcine	—	82.5	34.0	1.9
Bovine	—	82.5	33.8	2.3
A1-acetyl	CH <sub>3</sub> -CO-	82.5	33.8	—
A1- <i>t</i> -Boc	(CH <sub>3</sub> ) <sub>3</sub> C-O-CO-	82.5	33.5	3.0
A1-'thiazolidine'	-CO-	82.5	33.8	2.3

Structural differences between the insulins were investigated using a series of electron density maps computed with coefficients

$$m(nF_D - (n-1)F_P) \exp i\alpha_P$$

where  $F_P$ ,  $m$  and  $\alpha_P$  are the observed structure factor amplitudes, the figure of merit and the best phase for the porcine insulin crystals, and  $F_D$  is the observed structure factor amplitude of the derivative crystals. Values of  $m$ ,  $\alpha_P$  and  $F_P$  for porcine insulin crystals were provided by Professor Dorothy Hodgkin and her colleagues. Conventional difference maps, with coefficients  $(F_D - F_P)$  were used to indicate changes of electron density between the porcine and derivative crystals. But electron density maps calculated with  $n = 2$  were used in building models of the derivative structure as the map should give a reasonable approximation of the derivative crystal electron

Fig. 1 View of (a) electron density and (b) molecular structure for the A-chain helix and neighbouring residues of A1-'thiazolidine' insulin, the projection corresponds to a depth of 10 Å through the structure of the  $n = 2$  map obtained for the derivative (see text).

density and can be compared directly with a model if an optical device is used.

These electron density maps indicate that the bovine insulin dimer is closely similar to the porcine dimer, although there are small changes in the position of one zinc atom and indications of some further cation binding and of a small shift of the molecule in the unit cell. Negative peaks in the difference maps correspond to the sequence differences: A8 Thr and A10 Ile in porcine insulin are replaced by A8 Ala and A10 Val in bovine insulin and these changes are thought to be responsible for the slight differences in packing observed in the bovine and porcine structures. Similar differences of packing occur in the A1-Boc and A1-'thiazolidine' bovine insulins; in addition in both derivatives the region around A1 shows extensive conformational changes in both the molecules of the crystallographic dimer. The changes are qualitatively similar in the two derivatives but are greater in magnitude in A1-'thiazolidine' insulin.

Figure 1 shows the electron density and molecular structure close to A1 in molecule (2) of A1-'thiazolidine' insulin. The thiazolidine group is extended into the solvent region, apparently displacing water molecules, and comprises a distorted extension of the A-chain helix. The Boc group occupies a similar position in A1-Boc insulin. The electron density of the 'thiazolidine' and Boc insulins indicates a rotation of the helix A2-A5 around its axis in a clockwise sense when viewed from the N-terminus. The side chains of A2 Ile, A4 Glu and A5 Gln have been pushed away from the A1 position and the side chain of A19 Tyr has shifted about 1.5 Å from A2. A similar rotation and displacement of side chain groups occurs in the other molecule (1) of the dimer, but the modifying group appears to be closer to the helix axis and the shift of A5 side chain is less. There is also a very small displacement of the residues B24 to B28 away from the modifying groups at A1.

### Circular dichroism

Spectra of chemically modified insulins have been published<sup>7,12-14</sup> but interpretation is difficult since chemical modification usually affects quaternary structure<sup>15</sup>. We have shown elsewhere that changes in circular dichroism resulting from changes in insulin concentration and the zinc-insulin ratio can be accounted for by changes of environment of the chromophores on changing the equilibrium populations of monomers, dimers and zinc hexamers. We concluded that the structure of the protomer seen in the crystals of zinc insulin hexamers is largely retained by the molecule in solution. Thus chemical modification of insulin may affect the circular dichroism by changing the population of associated molecules, the overall tertiary structure of the modified insulin being essentially the same as the native molecule.

We have measured the circular dichroism spectra using a Cary 61CD spectrometer, in both the near and far ultraviolet in 0.025 M Tris-HCl buffer pH 7.79, for the A1-'thiazolidine' and A1-Boc insulins in similar concentration ranges and in the presence of zinc ions. Representative spectra are shown in Figs 2 and 3. The spectra of the derivatives at a given concentration correspond generally to the spectra of the native protein

at higher dilutions, indicating that these derivatives probably associate less strongly than native bovine insulin. A similar comparison of the spectra of the two derivatives suggests that A1-'thiazolidine' insulin associates less than the A1-Boc insulin. This decrease in association can be explained by the change of charge at A1 and small conformational changes induced in the B chain residues B24-B28 which are directly involved in dimerisation. We have already observed that such changes occur in the electron density map but it is probable that the differences between native and derivative structures are slightly greater in the isolated monomer, being decreased in the dimer when the  $\beta$ -sheet is formed. The need to readjust the structure of the modified insulins slightly on dimerisation would explain the decreased ability to dimerise, and account for the decreased dimerisation of A1-'thiazolidine' insulin compared with A1-Boc insulin, a difference which cannot be explained by changed charge or direct interference of the modifying group.

Apart from the shifted concentration and zinc dependence of the circular dichroism, the spectra are very similar, indicating that the derivative insulins also have structures in solution comparable with bovine insulin. There are, however, small differences in ellipticity in both near and far ultraviolet between bovine and derivative insulins at all states of association which may arise from the movement of the A19 tyrosine chromophore as observed in the crystal structure. The general structure of the derivative insulin molecules in solution, however, is probably very similar to that in the crystal.

### Biological potency

The potency has been assessed by incorporation of 3-<sup>3</sup>H-glucose into fat cell lipids<sup>16,17</sup>. The relative potency of A1-acetyl insulin has been determined as 35-40% (refs 7 and 18). The derivatives exhibit the same maximal activity (efficacy) as insulin with respect to lipogenesis from glucose as has been found for several modified insulins<sup>18</sup>. In the experiment shown in Fig. 4a, (left) A1-Boc insulin exhibited a relative potency of 15.6%. The mean of five such experiments was  $17.0 \pm 3.1$  (s.d.). Figure 4a (right) shows a similar experiment with A1-'thiazolidine'

Fig. 2 Near ultraviolet circular dichroism spectra of zinc-free A1-t-Boc insulin at  $10^{-6}$  M (—),  $10^{-5}$  M (---) and  $10^{-4}$  M (···), showing the dependence of the spectrum on protein concentration. A similar concentration dependence is shown by bovine insulin.  $\bar{w}$ , Mean residue weight.

insulin and the mean of five experiments was  $12.8 \pm 1.6$  (s.d.). It is further seen from Fig 4a that A1-'thiazolidine', when added to native insulin in the concentration ratio 10:1, and A1-Boc insulin (ratio 5:1) had additive effects in submaximal doses. This is characteristic of a full agonist which is acting through the same mechanism and with the same rate-determining step as native insulin.

Receptor binding of the insulin derivatives was determined as their ability to inhibit binding of <sup>125</sup>I-insulin to fat cells as previously described<sup>16</sup>. Figure 4b shows that the relative binding affinities of A1-Boc insulin and A1-'thiazolidine' insulin are both similar to the relative potencies. This means that the ratio between the concentration which causes half-

Fig. 3 a, Far ultraviolet and b, near ultraviolet circular dichroism spectra of bovine (—), A1-Boc (---) and A1-'thiazolidine' (···) insulins at a protein concentration of  $10^{-4}$  M with 0.33 Zn ions per protein monomer.

**Fig. 4** *a*, Potency of A1-*t*-Boc insulin (left) and A1-'thiazolidine' insulin (right). The ordinate denotes the conversion of 3-<sup>3</sup>H-glucose (0.5 mM, 0.2 mCi mmol<sup>-1</sup>) to lipids in fat cells after incubation for 2 h at 37 °C. The potency of the derivatives (●) relative to native insulin (○) was calculated as

$$(\text{'K}_{\text{action}} \text{ insulin} / \text{'K}_{\text{action}} \text{ derivative}) \times 100$$

The effect of addition of derivative to native insulin in the concentration ratio of 5:1 for A1-*t*-Boc insulin and 10:1 for A1-'thiazolidine' insulin is shown as Δ. The smooth curve running through these symbols is the expected addition curve for a full agonist with the potency as calculated from the experiment, that is 15.6% for A1-*t*-Boc insulin and 10.8% for A1-'thiazolidine' insulin. Each point represents the mean of four replicates ± s.d. *b*, Binding affinity of A1-*t*-Boc insulin (left) and A1-'thiazolidine' insulin (right). The ordinate denotes the ratio <sup>125</sup>I-insulin bound per l of fat cells/<sup>125</sup>I-insulin per l of medium. The <sup>125</sup>I-insulin was present in a concentration of 0.7 nM and the abscissa indicates the concentration of native insulin (○) or derivative (●). Each point represents the mean of six replicates ± s.d. The binding affinity of the derivatives relative to native insulin was calculated as

$$(K_i \text{ insulin} / K_i \text{ derivative}) \times 100$$

where  $K_i$  (the inhibition constant) was determined as described<sup>16</sup>. In the experiments shown the relative binding affinities were (with 95% confidence limits) 14.8% (13.7–16.0) for A1-Boc insulin and 10.2% (9.6–10.9) for A1-'thiazolidine' insulin.

maximal activity ( $K_{\text{action}}$ ) and the concentration which causes half-maximal displacement of specific binding of <sup>125</sup>I-insulin ( $K_d$ ) is about 1:50 both for native insulin and for the derivatives. Since the specific binding sites are believed to mediate the stimulation of lipogenesis from glucose<sup>19</sup> it follows that a derivative-receptor complex causes the same effect as an insulin-receptor complex.

## Receptor-binding region

In summary, chemical modification at A1 leads to a loss of the free α-amino group which is mainly positively charged in native insulin at physiological pH. This may account to some extent for the reduced biological potency of the modified insulins, in particular A1-acetyl-insulin. X-ray analysis, however, shows that addition of larger modifying groups at A1 results in changes in the structure of the helix A1–A7 and movement of the side

chain of tyrosine A19, which in turn give rise to distortions in the arrangement of the B-chain residues involved in dimerisation. The changes are similar in A1-Boc-insulin and A1-'thiazolidine' insulin, but are more pronounced in the latter. The X-ray precession photos of A1-acetyl-insulin indicate the presence of small but similar changes in this derivative also. These differences of conformation probably contribute to the variation of dimerisation, receptor binding and potency among the modified insulins; direct steric hindrance may also contribute to decreased receptor binding, but X-ray analysis shows that it cannot account for the decreased ability to dimerise.

The results are consistent with a model in which hydrophobic residues such as B24 Phe, B25 Phe, B26 Tyr, B12 Val and B16 Tyr are involved in receptor binding in a manner similar to their involvement in dimerisation. The affinity constant for receptor binding ( $10^9$ ), however, is much greater than the dimerisation constant ( $10^5$ ). Therefore, additional interactions must exist. The proposed receptor-binding region is indicated in Fig. 5. It includes residues such as A1 Gly, A19 Tyr and A21 Asn which play no direct part in dimerisation. Their involvement is also consistent with the low receptor binding of pro-insulin<sup>3,16</sup>. If this is correct, the B25 Phe side chain—in contrast to dimerisation—would be completely buried in the insulin-receptor complex.

Residues A1, A4, A19 and A21 are probably on the periphery of the receptor-binding region. For A1 this is consistent with the results on receptor binding and potency of modified insulins<sup>5,18</sup>; the chemical nature of the modifying group can sometimes be varied with little change in the reduction of potency. A19 Tyr may be partly buried when insulin is bound to the receptor although the consensus of results on receptor binding of monoiodinated insulins indicates that the affinity is not greatly reduced<sup>20</sup>.

Certain residues outside the region proposed may also come close to the receptor. It is interesting that turkey and chicken insulins which have a histidine at A8 have considerably enhanced receptor binding<sup>21,22</sup>. A8 lies just outside the putative receptor-

**Fig. 5** The residues of the proposed receptor-binding region of insulin are indicated by a box enclosing the residue number. They include those residues on the surface of the molecule involved in dimerisation such as the residues B24–B26, and B12 and B16 in addition to the residues such as A1 and A21 which play no role in the association of insulin molecules. The diagram of the three-dimensional structure of the insulin molecule is taken from ref. 20.

binding region, and variation of this residue between threonine and alanine in porcine and bovine insulin has no effect on receptor binding. It is possible that histidine, which is larger than alanine (bovine) or threonine (porcine), forms further stabilising interactions with receptor residues and so increases the affinity of the receptor for the insulin. But it is also possible that the presence of the histidine induces a small rearrangement in the structure of the receptor-binding residues which increase the affinity. Further structural studies are required to resolve this point.

It is an attractive idea that the receptor binding should in part be analogous to dimerisation, involving a sheet hydrogen bond system between main chain functions as well as hydrophobic interactions of side chains. Hydrogen bonds in an apolar environment would contribute considerably to the stability of the hormone-receptor complex. This emphasises the critical role of the three-dimensional structure in maintaining the arrangement of these groups and would provide a mechanism for attaining a correct relative orientation of insulin and receptor.

The model for insulin receptor binding has three important consequences. First, a change in the three-dimensional structure would decrease receptor binding; this is certainly consistent with these results and with the low receptor binding<sup>23</sup> of des A21 Asn des B30 Ala insulin<sup>24</sup> and guinea pig insulin<sup>22, 23, 25</sup>, which have very disturbed structures although they retain the B-chain residues thought to bind the receptor. Secondly, full receptor binding is attained by interaction of several insulin residues with the receptor, and loss of any one residue would not be expected to abolish receptor binding; rather it would decrease it as in the case of des-pentapeptide B26-30 insulin, for example<sup>18, 26, 27</sup>. Finally, it implies that receptor binding is additive through hydrophobic interactions and formation of specific hydrogen bonds. The importance of hydrophobic interactions may be rather general in hormone receptor binding; certainly it is important in the related hormone glucagon.

This model does not preclude the possibility that certain areas within the receptor-binding region have different roles. It is possible that the interaction of certain residues of the hormone with the receptor contribute little to the stability of the insulin-receptor complex but nevertheless are relatively important to the biological response. This cannot be true of A1 as reduction of potency is paralleled by a reduction of

receptor binding. Further, De Meyts *et al.*<sup>28</sup> suggested that the residues involved in intradimer contacts are critical for the phenomenon of negative cooperativity although residues in the region of A1 are not.

As the organisation of the receptor binding region becomes better defined, the intriguing possibility, is that it may soon be possible to mimic this region in an analogue, that is more easily synthesised commercially than is the complex two-chain insulin protein.

We thank the German Diabetes Association and Hoechst AG for supporting a workshop which stimulated this collaboration. R.A.P., S.P.W., I.J.T. and T.L.B. thank the Science Research Council and G.K., D.B., H.Z. thank the Bundes Ministerium für Forschung und Technologie for support. We thank Professor Dorothy Hodgkin and her collaborators, in particular Drs Guy and Eleanor Dodson, John and Sue Cutfield and Dan Mercola for encouragement and help. We also thank everybody who contributed in discussion to this work.

# Bursal dissections and gill pouch hormones

Jack W. Shields

Department of Medicine, Santa Barbara Medical Foundation Clinic, Santa Barbara, California 93102

*The terrestrial survival of birds and mammals depends on evolutionary changes in cloacal bursae and gill pouches. Comparative dissections of these pouches provide insight into the coordinated functions of cervical endocrine organs, especially as they affect lymphoid tissue.*

WHEN the lungs develop during vertebrate embryogenesis, the five paired gill pouches sequentially cease absorbing oxygen to supply epithelia for other cervical organs as follows. The first pouches supply the tympanic cavities and eustachian tubes. The second pouches supply the lateral pharynx and palatine tonsils. The third pouches supply the thymus and inferior parathyroid glands. The fourth pouches supply the superior parathyroid glands, and the fifth pouches supply the ultimobranchial bodies. In each case the

gill pouch endoderm invaginates into the cervical mesenchyme, respectively producing the hollow eustachian tubes, the palatine tonsillar crypts and the stranded epithelium of paired or fused thymus glands, paired parathyroid glands and paired ultimobranchial bodies which fuse with the thyroid primordium derived from the midline endostyle<sup>1</sup>.

## Bursal dissections

During the embryogenesis of freshwater turtles and birds gill pouch evolution occurs in this way, but in addition, cloacal pouches called cloacal bursae develop. Their structures resemble derivatives of the second to fourth gill pouches.

Dissection of the paired cloacal bursae in freshwater turtles (Fig. 1a and c) reveals pouches opening to the cloaca immediately caudal to the ureteral orifices. The

**Fig. 1** *a*, Male freshwater turtle (*Cyclemis dentata*). The cloaca (5) is opened in the dorsal midline and attached structures are dissected to expose from above downward: the bladder (1) opening into the cloaca in the midline, the paired kidneys (2) and ureters (3) which open into the cloaca, the colon (4) incised but not opened to the left and the paired cloacal bursae (6) opening into the cloaca caudal to the ureters and the colon at (7). *b*, Pekin duckling with the kidneys to the right and the right ureter coursing over the cloacal bursa of Fabricius (6). The right side of the lower colon (4) and cloaca (5) are resected to expose the opening of the bursa into the cloaca just above the anus and caudal to the ureter (7). *c*, In the turtle bursa the pseudostratified columnar epithelium (8) evaginates into the lumen like gill folds in fish. Submucosal lymphoid tissue is inconspicuous. *d*, In the avian bursa the pseudostratified columnar epithelium (8) invaginates (9) into the submucosa to produce epithelial sheets which are infiltrated with lymphocytes and surrounded by dense lymphoid tissue.

pouches are lined by pseudostratified columnar epithelium similar to that in the gill pouch orifices of fish and tadpoles. The epithelium folds into the underlying connective tissues. Subepithelial lymphoid tissue is sparse.

Dissection of the single cloacal bursa (bursa of Fabricius) in birds (Fig. 1*b* and *d*) reveals a midline pouch open to the cloaca immediately caudal to the ureteral orifices. The pouch is lined by pseudostratified columnar epithelium which folds into the lumen, and invaginates into underlying connective tissue to form bottle-necked epithelial sheets infiltrated with lymphoid cells, surrounded by dense organised lymphoid tissue. This 'lympho-epithelial tissue' resembles the thymus gland of bony fish, tadpoles, turtles, birds and mammals; but differs in that its epithelium does not become separated from that lining the gut lumen and it does not contain Hassall's corpuscles, epithelial cysts, myoid cells or clusters of parathyroid cells (similar to those common in turtle thymus). The avian bursa also resembles the palatine tonsils in that the epithelium invaginates deeply, does not become separate from gut luminal epithelium, is heavily infiltrated with lymphoid cells and is surrounded by dense organised lymphoid tissue. It differs from the palatine tonsils (but not the adenoids) in that the surface epithelium is columnar instead of squamous; and in that germinal centres do not develop in the surrounding lymphoid tissue.

These dissections suggest that the cloacal bursae in freshwater turtles and the avian bursa of Fabricius are homologous structures which, in turn, share homologies with the second to fourth gill pouches.

## Bursal functions

In 1590 Hieronymus Fabricius<sup>2</sup> described the cloacal bursae in birds. In 1733 Perrault<sup>3</sup> recorded their presence in some species of turtles. In 1914 Jolly<sup>4</sup> suggested that such "anal sacs" in turtles are phylogenetic precursors of avian

bursae. Functions of these bursae remained obscure until the 1950s.

In 1958 Smith and James<sup>5</sup> reported that paired cloacal bursae are rudimentary or lacking in terrapins and sea turtles, but well developed in freshwater turtles which normally hibernate underwater at temperatures less than 40–60 °F. They concluded that freshwater turtles use these bursae as gills when water is flushed in and out of the cloaca during hibernation. Having low basal metabolic rates, especially during hibernation, freshwater turtles (especially Emydidae) derive sufficient dissolved oxygen through cloacal respiration to survive through the winter under ice-covered water<sup>5–7</sup>. In Pleurodira the cloacal bursae are partially fused<sup>8</sup> (resembling the single avian bursa). Soft-shelled turtles (for example, *Trionyx triunguis*) lack cloacal bursae, but facultatively respire underwater through the epidermis or through pharyngeal gills<sup>7</sup> (in the second gill pouch position where mammalian tonsils develop). Retaining functional gills either in the pharynx or in cloacal bursae, the freshwater turtles (like tadpoles) are pivotal in the evolution of respiration and associated adaptations essential to survival on land.

In 1956 Glick *et al.*<sup>8</sup> reported that surgical bursectomy in newly hatched chicks results in deficient antibody production. Their observation established that the single bursa of Fabricius has an important immunological role in neonatal birds. Moreover, it revolutionised modern concepts of mammalian immunology when the effects of testosterone bursectomy were compared with those of surgical thymectomy in newborn rodents<sup>9–11</sup>. The new concepts<sup>11–13</sup>, especially those concerning bursa-dependent B cells, are open to criticism for diverse reasons<sup>14</sup>, some of which are as follows. (1) Mammals lack a caudal anatomical counterpart of the avian cloacal bursa<sup>13,14</sup>. (2) In human babies with "third and fourth pouch syndromes" wherein the thymus and the parathyroid glands failed to develop, in addition to tetany

and various cervico-facial anomalies, variable defects in immunoglobulin production are evident<sup>15,16</sup>. (3) Surgical bursectomy in chicks on the fourth day of incubation (before the cloaca opens into the chorio-allantoic sac) does not completely suppress immunoglobulin production in surviving chicks, and usually suppresses thymic development<sup>17</sup>. Testosterone bursectomy in hatching chicks also suppresses thymic development<sup>17</sup>, while testosterone produces thymic involution in mammals<sup>18-20</sup>. Bursectomy in birds and thymectomy in mammals do not cause serious immunological defects a few weeks after birth<sup>8,10</sup> once a critical extrathymic lymphoid tissue mass<sup>21</sup> is established with thymic involution<sup>14,20</sup> and normal foraging<sup>14</sup>.

(4) Among other differences, birds differ from mammals in that they lack tonsils with germinal centres and intestinal Peyer's patches<sup>4,22</sup>. Birds also lack maternal immunoglobulin passed through the placenta before birth and from milk after hatching. In mammals the tonsillar and Peyer's patch germinal centres commence development with the onset of independent breathing and eating<sup>14,22</sup>. After development of such germinal centres, endogenous antibody production commences in quantity<sup>13,23</sup>. Whereas the tonsillar crypts develop such that they may trap newly ingested food along with airborne or food-borne bacteria, the avian bursa is oriented to 'trap colonic contents' containing the undigested or 'commensal' remains. In addition, the avian bursal epithelium demonstrates unique capacities for the pinocytotic digestion of colloidal intestinal contents, while the bursal musculature contracts in synchrony with respiration<sup>24</sup>. Such distinctive anatomico-physiological arrangements may be cogent to neonatal antibody production in the respective species.

(5) Implantation in Millipore diffusion chambers has shown that thymic and bursal effects on lymphoid tissue development and immunity in mammals and birds are

mediated by hormones produced in associated epithelial cells<sup>21,26-28</sup>. Although distinctive bursal hormones remain to be isolated, a thymic-epithelial hormone (thymosin) with reproducible lymphocytopoietic activity has been partially purified<sup>29,30</sup>, and corrects immunological and nutritive deficiencies in neonatally thymectomised animals and congenitally athymic human babies<sup>31</sup>. Irrespective of species, many, if not all thymic relationships to body growth, immunity and stress can be explained simply in terms of thymosin's trophic action on DNA metabolism in local and distant lymphoid tissue<sup>14</sup>.

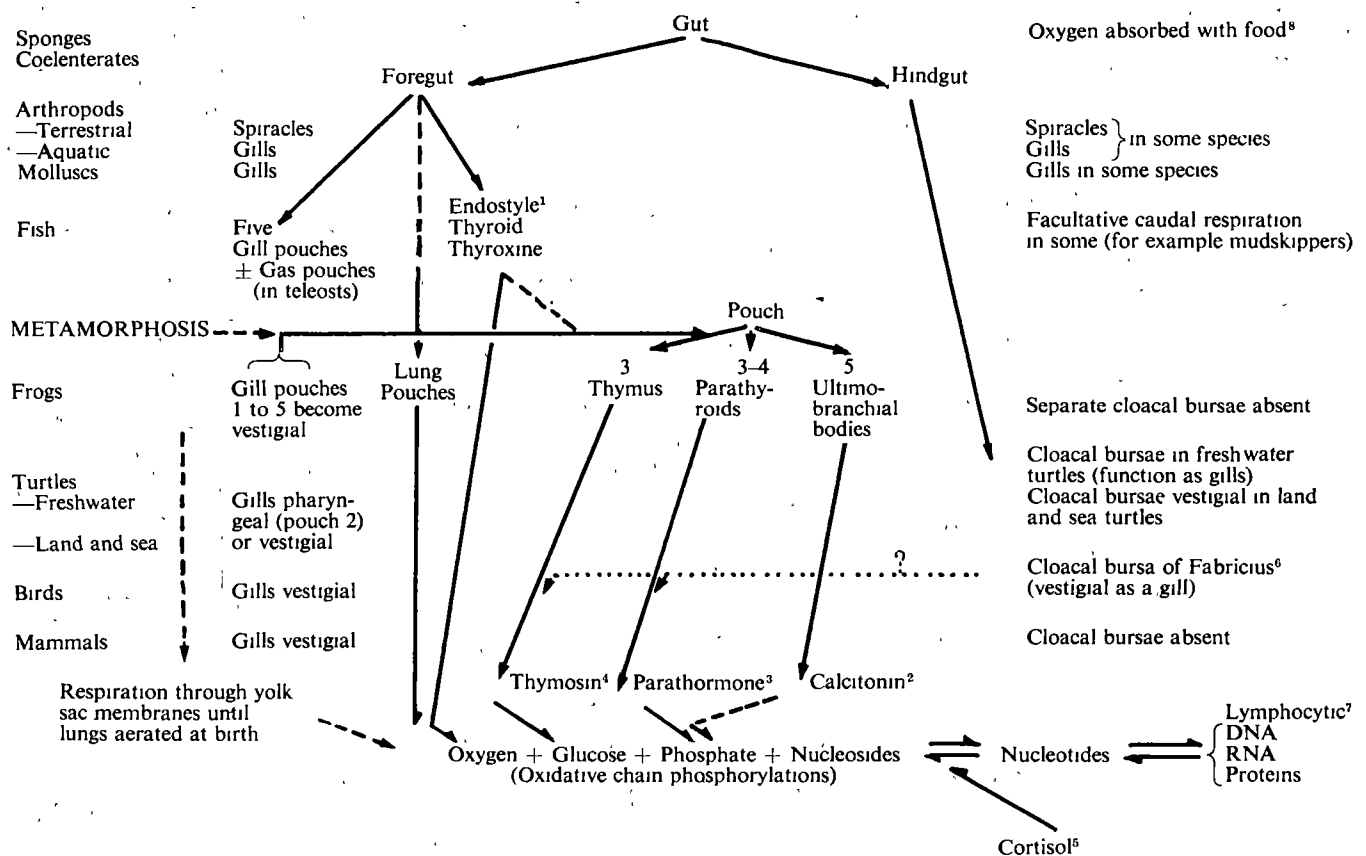

(6) Studies<sup>32,33</sup> of poikilothermic vertebrates (fish, amphibia, reptiles) reveal evidence of humoral immunity and immunoglobulin production (chiefly IgM) from lymphocytes in thymus, spleen and kidneys before bone marrow develops, and in the absence of cloacal bursae in all species except temperate (as opposed to tropical<sup>15-7</sup>) freshwater turtles. As Jordan<sup>22,34</sup>, Marine<sup>19</sup> and Cooper<sup>32</sup> pointed out, attention to gill and thymic evolution in anuran amphibians (especially larval frogs) may supply promising avenues of research into the endocrine system.

Thus it can be surmised that in several species of freshwater turtles the cloacal bursae function like gill pouches in fish and tadpoles. In birds which are close phylogenetic relatives of turtles, the cloacal bursa appears to function like an organ hybrid from the second to fourth gill pouch derivatives in mammals, that is the tonsils, thymus and parathyroid glands; and an organ which may contract like gills in synchrony with respiration.

## Respiration and cervical endocrine evolution

In embryonic birds and mammals when the third to fifth branchial pouches undergo metamorphosis into cervical endocrine glands and the lung pouches are developing, res-

Fig. 2 Evolution of entodermal pouches concerned with respiration.

piration continues through the vitelline membranes within the liquid environment of the egg or the uterus<sup>1</sup>. When breathing under water suddenly changes to lung breathing with hatching or birth, the cervical endocrine epithelia continue to produce hormones which accelerate the internal metabolism of oxygen, glucose and phosphate, especially within lymphoid tissues<sup>14</sup>. The teleological relationships are tentatively outlined in Fig. 2.

The superscript numbers in Fig 2 are interpreted as follows. (1) The thyroid gland, derived from the endostyle<sup>1</sup>, produces thyroxine which accelerates metamorphosis<sup>22,34</sup> and the rate oxygen is consumed to create high energy phosphate bonds in nucleotides<sup>35</sup>, especially in lymphoid tissues<sup>14,35</sup>. Thus the rates of DNA synthesis and growth in lymphoid tissues parallel the basal metabolic rate during phylogenesis<sup>14,36</sup>, ontogenesis<sup>22,34</sup>, puberty<sup>36</sup>, alimentation<sup>37</sup>, and hyperthyroidism<sup>14,35</sup>, irrespective of the growth rate in other tissues.

(2) The ultimobranchial bodies evolve into the parafollicular cells of the thyroid gland which produce calcitonin<sup>35</sup>.

(3) Parathormone and calcitonin govern phosphate availability and calcium ion concentrations potentially favourable to oxidative chain phosphorylations<sup>35</sup>. Parathormone stimulates growth of lymphoid tissue, especially in thymus<sup>18,19</sup>. Also it affects the oxygen affinity of erythrocytes by actions on the phosphates of 2,3-diglycerolphosphate and adenosine diphosphate<sup>38</sup>.

(4) Thymosin accelerates nucleic acid synthesis, especially in lymphocytes<sup>29,30</sup> which grow faster, contain higher concentrations of DNA, and release DNA more readily than other cells in the body<sup>14</sup>. Because of its insulin-like effect on lymphoid tissue<sup>38</sup> and because its action diametrically opposes that of cortisol<sup>14</sup>, thymosin's action appears to be on the glucose moiety in oxidative chain phosphorylations. Parallel to thyroxine, it seems to increase the high energy nucleotide-bound phosphate yield per quantity of glucose consumed, particularly in lymphoid tissues. (5) Cortisol interferes with the utilisation of glucose in oxidative chain phosphorylations essential to lymphocytic DNA and protein synthesis<sup>39-43</sup>. Characteristically it engenders lysis rather than synthesis of DNA in lymphoid tissues, especially in the thymus gland<sup>14,43-46</sup>.

(6) If the "third and fourth pouch syndromes"<sup>15,16</sup> in immunodeficient human babies are clues, hormones from the avian cloacal bursa seem to have actions like those of thymosin plus variable quantities of parathormone. The combined actions seem to foster RNA synthesis essential to immunoglobulin production, as well as the prerequisite DNA synthesis and formation of appropriate messenger RNA.

(7) Together with lymphotropic actions, thyroxine, thymosin, parathormone and calcitonin exert others essential to survival in vertebrates destined to crawl out of the water, breathe air and move on land. Actions on bone calcification and erythrocytopoiesis are especially important not only after birth, but also during metamorphosis when sequentially: the thymus, parathyroid and ultimobranchial bodies develop out of the gill pouches<sup>1</sup>; the lung pouches commence development<sup>1</sup>; the cartilaginous skeleton commences calcification to stiffen the spine and provide 'a relatively rigid thorax', calcifying cartilages are invaded by erythrocytopoietic mesenchyme<sup>1,22</sup>, while the limbs develop to bear weight; haemoglobin structure changes to carry more oxygen<sup>12,22,34</sup> organised lymphoid tissues commence to grow in a periarteriolar environment of relatively high oxygen tension<sup>14,47,48</sup>.

With the establishment of intramedullary erythrocytopoiesis and the attendant enucleation of erythrocytes in mammals<sup>12,22</sup>, lymphocytes multiply around the arterioles in the thymus, spleen, nodes, marrow and intestine to become the most common nucleated cells and constitute 1-3% of the total body mass in the healthy, well fed mammal<sup>14,36</sup>. Hypoxia engenders sudden lymphocytolysis with shrinkage

of the lymphoid tissue mass in minutes or hours<sup>14,48-49</sup>. Starvation (eliminating the exogenous supply of glucose, phosphate and precursors for nucleosides) causes lymphocytolysis with shrinkage at a slower rate, but at a rate far exceeding that of cellular attrition in the liver or other tissues<sup>14,45-50</sup>. The lymphocytolytic effects of anoxia and starvation are mediated by adrenal glucocorticoids<sup>14,45,46</sup> which make lymphocytic proteins available for gluconeogenesis<sup>43,46</sup> and release nuclear material rich in high energy nucleotides, especially during stress<sup>14</sup>.

(8) The invertebrates and fish are included in the diagram to indicate various forms of respiration which take place during vertebrate phylogenesis<sup>51</sup>, as well as mammalian embryogenesis.

If accurate, these teleological correlations based on comparative pouch dissections will necessitate revisions in immunological theory and provide new insights into endocrinology. In turn, when thymosin, parathormone and calcitonin become available in quantity, as are thyroxine and adrenal glucocorticoids, increasingly rational hormonal treatment of diseases involving bones, erythrocytopoietic and lymphocytopoietic tissues may follow.

This study was inspired by a previously reported<sup>52</sup> visit to the freshwater turtle exhibit at the San Diego Zoo, and was funded by the Santa Barbara Medical Foundation Clinic. I thank Delbert Dickson and Jim Cronshaw for assistance.

# letters to nature

## Obese 'neutron' stars

WE show here that non-rotating, spherically symmetric, general relativistic 'neutron' stars of mass  $\geq 3M_{\odot}$  are consistent with the known laws of physics. In particular, for the 'bag' model of hadrons, we find  $M_{\max} \approx 3M_{\odot}$ . The maximum mass for polytropic equations of state is found to be  $\approx 5M_{\odot}$ .

This is particularly interesting since it has been repeatedly claimed<sup>1</sup> that the X-ray source Cygnus X-1 is a binary star system containing a black hole accreting matter from its relatively normal companion star HDE226868. The arguments leading to this conclusion, while requiring many assumptions (for example that Cyg X-1 is a binary rather than a triple star system; that the X-ray source is powered by accretion and is not, say, the result of the radiation of spin energy of a rapidly rotating white dwarf; that general relativity is correct beyond its tested domain) depend most crucially on the existence and value of an upper mass limit for 'neutron' stars. (Throughout this discussion the term 'neutron' star is used to refer to a stable matter configuration of mean density  $\approx 10^{14}$ – $10^{15}$  g cm<sup>-3</sup>, whether the system is predominantly composed of neutrons, quarks, or some other hypothetical state of matter.) Estimates<sup>2,3</sup> for the mass of Cyg X-1 range from  $2.6M_{\odot}$  to as much as  $15M_{\odot}$ . Most recently, Bahcall<sup>4</sup> has suggested a value of  $M \approx 4.7 (d/2)^2 M_{\odot}$ , where  $d$  is the distance to the object in kpc. Since it seems that  $d \approx 2 \pm 0.5$  kpc, one has  $M_{\text{Cyg}} \approx 3$ – $7M_{\odot}$ . Based on the claim<sup>5</sup> that the absolute upper mass limit for non-rotating, general relativistic neutron stars is  $3.2M_{\odot}$  whatever the equation of state of matter at supernuclear densities, many authors have concluded that Cyg X-1 must be a black hole. Because of the significance of this result, we have examined

**Fig. 1** Equations of state: *a*, extreme causal equation;  $p = (\rho - 2 \times 10^{14})c^2 + P_m$ ; *b*, equation producing Rhoades-Ruffini result;  $p = (\rho - 4.6 \times 10^{14})c^2$ ; *c*, quark bag model;  $p = (\frac{1}{3})(\rho - 2.28 \times 10^{14})c^2$ ; *d*, free Fermi gas of neutrons; *e*, an extension of Negele's nuclear model.

the dependence of the neutron star upper mass limit on assumed properties of high density matter.

We consider here only the solutions to the hydrostatic equilibrium problem for spherically symmetric, non-rotating, general relativistic neutron stars. The proper gravitational mass  $M(r)$  inside a radial distance  $r$  is given by

$$M(r) = \int_0^r 4\pi r'^2 \rho(r') dr' \quad (1)$$

where  $\rho(r)c^2$  is the total (matter and field) local energy density. The equation of hydrostatic equilibrium relating the pressure  $p(r)$  to  $\rho(r)$  and  $M(r)$ , the Oppenheimer-Volkoff equation<sup>6</sup>, is

$$\frac{dp}{dr} = -\frac{GM(r)\rho(r)}{r^2} \left[ 1 + \frac{p(r)}{\rho(r)c^2} \right] \left[ 1 + \frac{4\pi r^3 p(r)}{M(r)c^2} \right] \left[ 1 - \frac{2GM(r)}{rc^2} \right]^{-1} \quad (2)$$

Given an equation of state

$$p = p(\rho) \quad (3)$$

and specific boundary conditions (central density and surface pressure or density) a unique model arises.

For most equations of state  $p = p(\rho)$ , the hydrostatic equilibrium equation cannot be integrated analytically and so must be evaluated numerically. One simple analytical case, however, demonstrates two of the results we have found numerically. If  $p = \alpha \rho c^2$ , then a closed form solution for the case of infinite central density is

$$\rho(r) = (c^2/2\pi G)[\alpha/(\alpha^2 + 6\alpha + 1)](1/r^2). \quad (4)$$

Taking this equation to be valid above some density  $\rho_s > \rho_N$  (where  $\rho_N = 2 \times 10^{14}$  g cm<sup>-3</sup> is a characteristic nuclear density) one has for the 'core' of a model neutron star (matched to an outer envelope with a 'realistic' nuclear equation of state, but which in general contains no more than  $0.1M_{\odot}$ ) a mass

$$M = (c^3/G^{3/2})(2/\pi)^{1/2}[\alpha/(\alpha^2 + 6\alpha + 1)]^{3/2}(1/\rho_s^{1/2}). \quad (5)$$

We immediately see that for  $p = \alpha \rho c^2$ ,  $M$  is maximised when  $\alpha = 1$ , that is, for  $dp/d\rho = c^2$ . We note further that  $M$  depends on the inverse square root of that density above which the equation of state  $p = \alpha \rho c^2$  applies. We find that for  $\alpha = 1$  and  $\rho_s = \rho_N$ , one has  $M_{\text{core}} \approx 2M_{\odot}$ .

The real equation of state of matter at densities  $\geq 2 \times 10^{14}$  g cm<sup>-3</sup> is unknown. Something can, however, be deduced from known properties of several neutron stars. The mass<sup>7</sup> of the X-ray emitting object Her X-1, probably a neutron star, seems to be  $1.3 \pm 0.1M_{\odot}$ . The binary star system<sup>8</sup> containing the pulsar PSR1913+16 has a total mass  $2.9M_{\odot}$ . If, as seems plausible on evolutionary grounds<sup>9</sup>, the unseen companion is a white dwarf (which must be slowly rotating with a mass  $\lesssim 1.4M_{\odot}$ ), then the pulsar (neutron star) mass is  $\geq 1.5M_{\odot}$ . Most recently<sup>10</sup> the binary X-ray source Vela X-1, with a pulse period of  $\approx 283$  s, has been found to have a most probable mass of  $\approx 1.7M_{\odot}$ . Numerically integrating equations (1) and

(2) with the central density as a parameter and assuming that neutrons form a cold, perfect Fermi gas up to arbitrary density, Oppenheimer and Volkoff<sup>6</sup>, and later Misner and Zepolsky<sup>11</sup> found the maximum mass to be  $\approx 0.7M_{\odot}$ . We can now conclude that matter at supernuclear densities, at least in some neutron stars, does not behave as a free Fermi gas of neutrons. Neither does a soft-core potential<sup>12</sup> describe neutrons at high densities, since it yields a value of  $M_{\max}$  as low as  $0.27M_{\odot}$ . Other equations of state, such as that of Malone, Johnson and Bethe<sup>13</sup> (with  $M_{\max} \approx 1.85M_{\odot}$ ) have upper mass limits only just consistent with the observed masses of neutron stars.

In view of the uncertainties in  $p(\rho)$ , we have numerically investigated some hypothetical equations of state in order to get a better feel for what  $M_{\max}$  depends on. We chose an equation of state to be either a free Fermi gas of neutrons or a more realistic equation<sup>14</sup> of state which accounts for the attractive part of the nuclear potential up to a density  $\rho_s$  (the final result is quite insensitive to this choice). For  $\rho \geq \rho_s$ , polytropic equations of state were chosen of the form

$$p = \beta \rho^{\gamma} + p_0 \quad (6)$$

with  $1 \leq \gamma \leq 5/2$  and with a range of values of  $\beta$  which includes values for which  $dp/d\rho > c^2$ . The hydrostatic equilibrium equation was then numerically integrated for given values of  $\beta$ ,  $\gamma$  and  $p_0$ , with the central density as a parameter.

The main result of these calculations was that for given values of  $\beta$  and  $\gamma$  (with  $p_0 = 0$ ),  $M_{\max}$  varied approximately as  $1/\rho_s^{1/2}$ , as in the analytical case with  $p_{\text{cent}} = \infty$ . The greatest value of  $M_{\max}$  for  $dp/d\rho_{\text{cent}} \leq c^2$  was reached for the case which smoothly matched  $p = \rho c^2$  to the 'true' nuclear equation of state at  $\rho_s = \rho_N = 2 \times 10^{14} \text{ g cm}^{-3}$ , keeping both the pressure and density continuous across the change of state (no 'phase' transition), that is

$$p = (\rho - \rho_N)c^2 + p_M \quad (7)$$

(see Fig. 1, curve *a*). The resulting plot of the mass against the central density is shown in Fig. 2 (curve 1). It can be seen that the curve has a maximum at  $\sim 4.8M_{\odot}$ . (This agrees with the results for the same model found independently by others<sup>13,15</sup>.) Such a star is stable and has an equation of state consistent with everything known about nuclear physics at or below nuclear density. The difference between this mass limit and the one found by Rhoades and Ruffini<sup>5</sup> (curve 2 in Fig. 2) arises almost entirely from the choice of matching density and is just the factor  $(\rho_r/\rho_N)^{1/2} \approx 1.5$ , where  $\rho_r = 4.6 \times 10^{14} \text{ g cm}^{-3}$  is the density to which they extrapolated the equation of state of nuclear matter above nuclear density.

Fig. 2 Mass as a function of central density for: (1) *a* matched to *d*; (2) *b* matched to *d*; and (3) *c* matched to half the free Fermion equation. Stars to the left of the peaks are stable. Matching equations of state *a*, *b* or *c* to either *d* or *e* made little ( $< 0.1 M_{\odot}$ ) difference in the resulting mass limits.

It should also be noted that, for the range of  $\gamma$  we tested the computed values of  $M_{\max}$  depended only weakly on  $\gamma$ . But, for such a polytropic equation of state, as  $\gamma \rightarrow \infty$ ,  $dp/d\rho \rightarrow 0$ , so that the fluid becomes incompressible. In this limit, for a star of uniform density  $\rho = \rho_N$ , one finds<sup>15</sup>  $M_{\max} \approx 8M_{\odot}$ .

These results gain physical significance when one considers the possibility of achieving a very stiff equation of state at or near nuclear density. In particular, the recently proposed 'bag' model of hadrons produces a stiff equation of state at low densities. In essence, for densities just above nuclear, overlapping bags of quarks act as a sea of relativistic massless (or low mass) free fermions. From the results of Degrand *et al.*<sup>16</sup> which fit bag model parameters to elementary particle properties, one finds an equation of state

$$p = \frac{1}{3}(\rho - \rho_B)c^2 \quad (8)$$

where  $\rho_B \approx 2.28 \times 10^{14} \text{ g cm}^{-3}$  is one of their two model values of  $\rho_B$ . Using this equation of state (curve *c*, Fig. 1), one finds a maximum mass of  $M_{\text{bag,max}} \approx 2.8M_{\odot}$  (curve 3, Fig. 2). Most of the mass arises from near the region  $\rho \approx \rho_B$ : the equation of state for  $\rho \gg 10^{15} \text{ g cm}^{-3}$  and for  $\rho \ll 10^{14} \text{ g cm}^{-3}$  is virtually irrelevant to the determination of this value. Such a star is, of course, no longer a neutron star but a quark star. (The possibility that supernuclear matter in 'neutron' stars consists of free quarks has also been considered by Collins and Perry<sup>17</sup>, though they did not explicitly calculate any stellar models.)

It therefore seems possible to have a stable (not fully collapsed) neutron star with a mass in the range  $3-5M_{\odot}$ . These numerical results are consistent with the results of others<sup>18</sup> (for essentially uniform density models) that massive ( $\approx 5M_{\odot}$ ), spherically symmetric, general relativistic neutron stars are in principle possible. Though the overlap between the masses of models considered here and the mass range deduced for Cyg X-1 is small, it seems too early to rule out the possibility that Cyg X-1 is not a black hole but simply a bag of quarks, or that it exists in some other unusual state of supernuclear matter.

We thank Professor K. Johnson (MIT) for suggestions. K.B. thanks the NSF for financial support.

## Recognising simulated earthquakes

KOLAR AND PRUVOST<sup>1</sup> have suggested that explosives could be detonated to provide all the characteristics of earthquakes when they are recorded by distant seismographs. Should this experiment be confirmed the effect on efforts to solve the seismological problems which at the moment preclude satisfactory agreement on an underground nuclear test ban would be profound, we present here the results of a relevant experiment.

Fig. 1 Typical microseismic noise spectrum (a), (maximum, 10  $\mu$ m) superimposed on the broad-band (b) and the LRSM short period (c) seismograph response. The LRSM response peaks here at an amplification of 30,000 but may be operated at amplifications of up to 300,000. The broad band rarely operates at an amplification of more than 10,000.

What Kolar and Pruvost demonstrated was that the direction of first motion could be effectively disguised. They showed that a complex P waveform could be created, and that the conventional magnitudes,  $m_b$  and  $M_s$ , could be so manipulated that unsuspecting observers would find that all the criteria conformed with those used to establish the occurrence of an average earthquake.

For their demonstration, however, Kolar and Pruvost<sup>1</sup> used recordings made on the narrow band seismograph systems developed especially for the Long Range Seismic Measurement (LRSM) project, primarily used to detect low yield explosions. Bearing in mind Pasechnik's demonstration<sup>2</sup> of spectral differences between earthquakes and explosions we repeated Kolar and Pruvost's experiment, using a recording from a less sensitive, broader band seismograph (see ref. 3). Our diagram of the relative amplitude responses of the LRSM and broad band seismographs (Fig. 1) include a roughly drawn noise spectrum which illustrates the principal recording problem faced by seismologists. Though

Fig. 2 The maximum broad-band P-wave signal period against the short period magnitude reported by NEIS. ●, Earthquakes; ○, explosions.

the broad-band system includes the peak in the noise spectrum, it falls off at 12 dB an octave beyond a period of 12 s; it is a broad-band instrument only for body waves.

In the first half of our experiment we tested Pasechnik's assertion<sup>2</sup> that the broad-band body-wave data provide means for distinguishing between earthquakes and explosions. Though the sample is small, the data of Fig. 2 give almost total separation between the P-wave periods of two disturbances above and below the 3-s ordinate. The single exception is known from evidence of a reliable surface reflection pP wave to be an earthquake at a depth of 40 km. The second stage of the experiment consisted of repeating Kolar and Pruvost's procedure for body waves in every detail, except that a broad-band recording of an explosion was used in place of the LRSM record (Fig. 3).

No change of period between the original and mixed signal is observed, so the mixed 'event' remains in the explosion population of Fig. 2. (The experiment was also repeated with Rayleigh waves and, as expected because of the much longer period, the original and mixed signals were virtually identical in shape.) Only the P waves of the larger

Fig. 3 a, P-wave generated by a Kazakh explosion recorded on the broad-band system and used to simulate the Kolar-Pruvost experiment; b, the resultant seismogram after summation. Note that the predominant period remains almost the same.

explosions would have been observed in this particular case; the earlier ones of the series are below noise level. Therefore, to illustrate the experiment in more detail, to recapitulate the technique, and to carry the test a little further, a synthetic, broad-band explosion signal was summed with no noise (Fig. 4) and the amplitude spectra of the original and final signal were taken (Fig. 5). The peak amplitude remains stable at 2 s; Kolar and Pruvost<sup>1</sup> designed their experiment to reduce the power at 1 s, thereby reducing the apparent body-wave magnitude for their narrow band recording.

The explosion signal shown in Fig. 3a represents a yield of 100 kt on a relatively quiet day in the UK. It implies

that the smallest explosion which could be detected by broad-band seismographs in the UK would be about 50 kt, which is about as far as earthquake simulation technique can be taken, depending as it does on several narrow-band instruments detecting the smaller (by a factor of 10) explosions.

We propose that the broad-band seismograph looks promising as a safeguard against attempts to camouflage moderately large underground tests with a carefully timed series of explosions. It seems likely that the detection level at most stations could be better than 50 kt after array processing (experiments are in hand), though according to Kondorskaya and Aranovich<sup>4</sup> the resolution of the period discriminant is likely to be weaker at lower magnitudes. Nonetheless a serious would-be violator, in allowing for the possible occurrence of exceptional recording conditions, unknown improvements in techniques and the possible existence of undisclosed stations, would have to credit

Fig. 4 Model simulation of the multiple explosion, illustrating the development of the final signal. *a*, 3 kt; *b*, + 9 kt, delayed 0.3 s; *c*, + 29 kt, delayed 1.1 s; *d*, + 29 kt, delayed 2.9 s; *e*, + 29 kt, delayed 2.7 s; *f*, + 100 kt, delayed 5.7 s; *g*, + 100 kt, delayed 6.0 s; *h*, + 100 kt, delayed 6.3 s.

Fig. 5 *a*, Amplitude spectrum of the single explosion used in the simulation experiment; *b*, amplitude spectrum of the resultant multiple explosion. Note that the large, low frequency, spectral peak remains at the same frequency.

'national networks' with somewhat better detection capacities than publicly revealed. A safety factor of two would not be an unreasonable margin to allow. Thus, the geophysical uncertainties operate against the violator.

## Anomalous geomagnetic field during the late Ordovician

MEASUREMENTS of the Lower Palaeozoic magnetic field in the British Isles<sup>1</sup> show that it changed from around  $D=355^\circ$ ,  $I=-50^\circ$  to  $D=20^\circ$ ,  $I=-54^\circ$  (corresponding to an apparent shift of the south palaeomagnetic pole from  $0^\circ$ W to  $35^\circ$ W along the present Equator) between Ordovician and Devonian times. Following unpublished work by W. E. Tremlett and J. C. Briden, we report here conflicting evidence from the intrusive rocks between Conway and Pwllheli, North Wales. These rocks therefore seem to show either previously unrecognised tectonic rotations or hitherto unsuspected variation in the palaeomagnetic field.

Throughout North Wales, an area of complex Palaeozoic tectonism, a large number of acid igneous intrusions occur whose ages within the Lower Palaeozoic are ill defined. Some bear strong petrogenetic affinities with the Ordovician acid extrusive rocks of the area and on field evidence there is little doubt that such intrusions as the Tan-y-Grisiau microgranite, the Myndd Mawr microgranite, the Penmaenbach rhyolitic intrusion and the Cader Idris granophyre<sup>2-5</sup> are of Ordovician age, and it has commonly been inferred that the bulk of acid igneous activity in the region is coeval. On the other hand, the view is held by some workers that

\*All mean directions quoted are *in situ* except for that of the Cader Idris basalts which has been tilt-adjusted by simple rotation about the present strike.

†Statistics presented are the within-site result from a single site at Foel Fras and Yr Eifl.

The notation used is as follows:  $R$  is the resultant of  $N$  unit vectors,  $k (= N-1/N-R)$  is the estimate of Fisher's<sup>13</sup> precision  $\kappa$ ,  $\alpha_{95}$  is the semi-angle of the cone of 95% confidence about the mean direction  $D$  (declination in degrees east of north) and  $I$  (inclination from horizontal, positive indicating downwards),  $d\psi$  and  $d\chi$  are the semi-angles subtended by the major and minor axes of the ellipse of 95% confidence about the mean pole position.

some intrusions belong to a late stage of the Caledonian orogeny. In particular, W. E. Tremlett has argued that the granodiorite complex of northern Llyn is associated with NE–SW Caledonoid faults of that area, and is therefore probably of early Devonian age; it is geochemically distinct from the Ordovician acid rocks<sup>7–9</sup>. He has also argued on field evidence that the Penmaenmawr microgranodiorite is post-orogenic, and in disagreement with Davies<sup>6</sup> assigns a similar age to the Foel Fras granodiorite 6 km south of Penmaenmawr (W. E. Tremlett, personal communication). The Penmaenmawr intrusion has given a K–Ar age of 375 Ma<sup>10</sup> from an admittedly weathered sample. The Llyn granodioritic intrusions have yielded Hercynian ages (R. M. McIntyre, personal communication) but there is no geological evidence to suggest massive igneous activity in North Wales at that time, and these apparent radiometric ages are therefore to be regarded as minimum estimates.

Many of the intrusions have been sampled during our new study and the palaeomagnetism of those possessing stable remanences after a.f. cleaning is reported here (Table 1, Fig. 1). Typically at least six independently orientated specimens were obtained at each site. Total NRM's were generally well grouped, but in a few cases large randomly directed magnetically soft components were removed in low alternating fields, enabling a well grouped stable remanence to be isolated. The criterion for optimum magnetic cleaning is that of Briden<sup>14</sup>. In all cases, progressive a.f. demagnetisation experiments have shown the observed remanences to be of high coercivity and in most cases directionally stable to peak alternating fields > 100 mT. Microscopic examination of polished specimens generally shows euhedral-subhedral magnetite grains with lamellar intergrowths of ilmenite, a textural combination associated with high temperature (> 600 °C) petrogenesis<sup>11</sup>. In spite of the unavailability of baked contact tests or other geological evidence for the age and origin of remanence, the stable NRM is therefore likely to be a TRM acquired during initial cooling. With the exception of the results from the Myndd Nefyn granodiorite, which may be deviant due to slight relative movement in an area of undeniably complex faulting<sup>9</sup>, the *in situ* remanences are well grouped with an overall mean of  $D=143^\circ$ ,  $I=-71^\circ$  corresponding to a conventional palaeomagnetic pole at  $108^\circ\text{E}$ ,  $68^\circ\text{S}$ .

This mean pole is nearly  $90^\circ$  away from published Ordovician–Devonian poles for Britain and an explanation must be sought.

Inevitably there are time gaps in the palaeomagnetic record, and it may well be that the new data fall in one of these. Gaps of the order  $10^7$  yr are to be expected given the sparseness of published data. Therefore if the discrepancy is to be explained in terms of polar shift on the assumption of an axial geocentric dipole field, then apparent polar wander at an average rate approaching  $20^\circ \text{ Myr}^{-1}$  has to be invoked. This is an order of magnitude greater than apparent polar wander arising from plate motions in more recent geological times. Even if it were accomplished by minimum lateral motion (given by the palaeolatitude change) together with rotation about a vertical axis close to the sampling area (to accommodate the declination discrepancy), motion of  $> 50 \text{ cm yr}^{-1}$  is required, which is still excessive on any plate tectonic analogy.

An interval of  $10^7$  yr might also be thought reasonable for the emplacement of these widely spaced North Wales bodies. It is hard to imagine an overall intrusion time of  $< 10^6$  yr for such a province. Hence the possibility that these rocks record a single geomagnetic polarity transition is effectively excluded because estimates on Tertiary to Recent transition times indicate that they typically take  $10^3$ – $10^4$  yr. Nevertheless it is intriguing to note that the pole position from the North Wales studies is almost equatorial to the typical Ordovician palaeomagnetic field. This is in common with the finding of Shaw<sup>12</sup> that the field paused in this half-way state during a polarity transition recorded in the palaeomagnetism of some Icelandic rocks.

In an area of such complex structural history as North Wales it might be expected that the *in situ* remanences of the intrusions require adjustment for tilt and/or local rotation. This does not, however, seem to be the case, as these massive intrusions, many of which have near vertical 'stock-like' shapes, would require an unlikely  $60^\circ$  northward rotation about a horizontal axis to remove the palaeomagnetic discrepancy. Also, they are seen to carry near vertical contemporaneous dikes. Table 1 and Fig. 1 also contain the tilt-adjusted palaeomagnetic results from the structurally simple Ordovician Upper and Lower Basic Lavas of Cader Idris. Their overall mean magnetisation falls within the group of *in situ* results from the intrusions. The magnetic stability of the lavas was comparatively low, but the similarity of the two results does reinforce the suggestion that the intrusions have suffered little tectonism. Therefore unless evidence is produced to show that the bodies sampled in this study, which are geographically

widely scattered from Cader Idris to Conway, have all been rotated by the same amounts by a bodily movement of North Wales, then their *in situ* remanences must be considered to define the geomagnetic field at the time when those remanences were acquired.

In North Wales there is no geological evidence of any large scale post-Caledonian thermal event at high enough temperatures to explain the stable remanent magnetisations observed in this study. In any case the only known palaeomagnetic field corresponding to these results is that of Tertiary to Recent times. The small amount of Tertiary igneous activity in North Wales could not have been responsible for magnetising rocks on the large scale necessary to explain the observations.

Fig. 1 Stereographic projection of site mean remanences after a.f. cleaning of intrusives from North Wales, and the basic lavas of Cader Idris. O, *In situ* remanences in all intrusive rocks except Myndd Nefyn; the star indicates their overall mean direction; □, the *in situ* results from Myndd Nefyn; Δ, tilt-adjusted results from the basic lavas of Cader Idris. The present axial geocentric dipole and the present geomagnetic field directions are marked ♦ and labelled D and P respectively. Open symbols indicate negative (upwards) inclinations and closed symbols positive (downwards) inclinations.

All conventional interpretations of the results of this study are therefore unsatisfactory, and instead, the possibility of an anomalous geomagnetic field lasting several million years during the Lower Palaeozoic must be seriously considered. It is most likely that we have recorded only one such anomalous event in this study because of the improbability of successive intrusions repeatedly occurring at similar geomagnetically anomalous instants. Evidence of precisely when this anomaly might have existed is inconclusive. Its occurrence in late Ordovician times would, however, be compatible with the inferred primary TRM of the intrusions, their possible Ordovician age and the similarity of their remanence directions with that of the proven Ordovician Cader Idris lavas.

The reality of an anomalous magnetic field lasting  $\sim 10^7$  yr would be of considerable geomagnetic interest. Whether

it exists or not should be capable of resolution by palaeomagnetic studies elsewhere in the world.

## Palaeomagnetism of a slowly cooled plutonic terrain in western Greenland

PALAEOMAGNETIC results from a high grade Precambrian terrain in western Greenland show many features attributable to magnetisation during very slow cooling caused by gradual uplift and erosion. They may locate a whole segment of the Laurentian apparent polar wander (APW) path with unusually high precision and also indicate the probable direction of movement.

The magnetic effects described here are analogous to those experienced by radiometric systems during slow cooling<sup>1,2</sup>, and are attributable in part to the fact that magnetic minerals have a range of blocking temperatures at which the magnetisation becomes effectively fixed. The effective blocking temperatures of magnetic grains will be considerably lowered during slow cooling, possibly to as low as 200 °C (refs 4 and 5) so that magnetisation would be acquired during the later stages of unroofing, when moderate erosion rates can be expected. Average present-day erosion rates have been variously estimated at 30 and 76 m Myr<sup>-1</sup> (refs 6 and 7, respectively), and if a slightly higher rate of 100 m Myr<sup>-1</sup> is assumed together with a geothermal gradient of 20 °C km<sup>-1</sup>, and a blocking temperature range of 50 °C for stably magnetised grains, then the magnetisation of any one specimen would take 25 Myr. Also, because the magnetisation will be acquired as the rocks pass through the (presumably horizontal) isotherms corresponding to their critical range of blocking temperatures, rocks at higher structural levels will become magnetised earlier than those at lower levels. For example, with an erosion rate of 100 m Myr<sup>-1</sup>, a difference in level of 2 km would correspond to a difference in the mean time of magnetisation of the order of 20 Myr.

Slow cooling during unroofing should therefore produce several effects in the palaeomagnetic record.

- Apart from the effects of APW all of the rocks formed before uplift should be magnetised in the same direction and give the same pole position, even though geological evidence indicates that they are of different ages.

- Because secular variation should effectively be averaged out within each specimen, between-site scatter attributable to this cause should be small.

- If APW occurred during the magnetisation period then poles from sampling sites at different original structural levels should be strung out along a trend corresponding to that particular section of the APW path, with higher sites at the older part of the trend and lower sites at the younger part.

● If they have the same mean blocking temperature different sampling sites at the same structural level should give poles close together. Any variation in mean blocking temperature, however, will clearly affect the time of magnetisation, and so poles from sites with high blocking temperatures should be displaced towards the older part of the trend compared with sites with lower blocking temperatures at the same level. Because of this it is unlikely that there will be a perfect relationship between the position of a pole in the trend of poles and the structural level of the corresponding sampling site. Determination of mean blocking temperatures in the laboratory should confirm the sense of time along the trend indicated by comparing the position of poles from sites at different structural levels.

● As any specimen has probably taken millions of years to cool through its critical range of blocking temperatures it should contain the magnetic record of that interval of time. Progressive thermal demagnetisation should therefore effectively move the magnetisation of a specimen from the lowest to the highest blocking temperature direction. Two possibilities arise. First, if the blocking temperature spectrum has two peaks corresponding, for example, to haematite and magnetite, then two distinct magnetisations may be present, an older one corresponding to haematite and a younger one corresponding to magnetite. Progressive demagnetisation would cause the magnetisation to move towards the older direction, but the actual movement would simply follow the great circle connecting the two directions. Such results have been reported from the Grenville province<sup>14</sup>. Secondly, if there is a continuous spectrum of blocking temperatures attributable, for example, to a continuous variation in grain size or ionic substitution, then a continuous spread of directions of magnetisation should exist between those corresponding to the highest and lowest blocking temperatures. Progressive demagnetisation would again cause the magnetisation to move towards the older direction, and the actual movement should indicate, after suitable vector analysis, the form of that particular section of the APW path.

● If rocks cool through their critical range of blocking temperatures during a period when the Earth's field is reversing itself at the same rate as at present they would be effectively demagnetised<sup>8</sup>. For rocks to acquire any magnetisation they must cool either during a prolonged period of constant polarity, or in a period when one polarity is dominant. Thus in a slowly cooled terrain one would expect either that the rocks should carry no stable magnetisation, or that they should all be magnetised with the same polarity.

The results reported here are from an area about 20 km square near Itivdlek some 40 km south of Holsteinsborg in western Greenland. The area is just within the early Proterozoic, Nagssugtoqidian Mobile Belt, close to its gradational boundary<sup>9</sup> with the Archaean craton to the south. The terrain comprises granulite and amphibolite facies gneisses cut by dolerite dykes which vary from fresh to almost completely autometamorphosed but which are essentially undeformed. There is strong geological evidence<sup>10</sup> that the area was at metamorphic temperatures when the dykes were intruded.

Stable magnetisation was found in both dykes (18 sites) and gneisses (4 sites), and after suitable alternating field (a.f.) demagnetisation most sites showed an unusually low within-site scatter of directions. Fourteen sites had a precision parameter,  $k$ , of better than 300 (corresponding to a circle of 95% confidence with a radius  $\alpha_{95}$  of less than  $3.2^\circ$ ), and at no site was  $k$  less than 50 ( $\alpha_{95}=7.9^\circ$ ). Largely because of the accuracy with which the site poles are determined the effects of slow cooling can be recognised.

Figure 1 shows that 18 poles (15 dykes and 3 gneisses) are arranged in a linear trend approximately  $10^\circ$  wide and

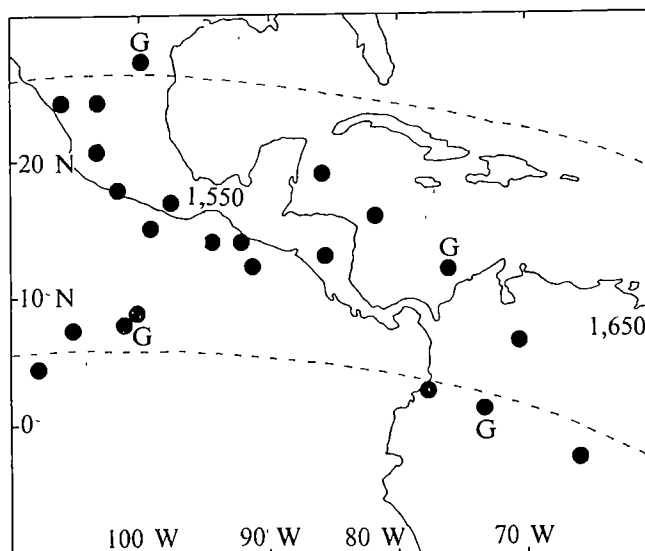

Fig. 1 The 22 site poles. Each is the mean of, generally, eight separately oriented specimens. The 18 dyke poles are unlabelled; G, the four gneiss poles. The poles have been rotated to correct for the drift of Greenland away from North America<sup>11</sup> to allow comparison with the appropriate part of the latest published APW path<sup>12</sup> for Laurentia (dashed band, with assigned ages in Myr). Most site poles initially showed southerly movements with progressive a.f. demagnetisation, presumably due to the removal of recently acquired viscous components, and at 7 sites (see text and Fig. 3) these were followed by systematic south-easterly movements. The pole selected for each site was generally either at the end point of the southerly movement or at the point where the southerly movement changed to a south-easterly movement, and was usually at a higher demagnetising field than that which gave the best within-site precision.

$45^\circ$  long, running NW-SE, and making a slight angle with the appropriate portion of the latest Laurentian APW path<sup>12</sup>. The remaining 4 poles are grouped together just to the south-west of the trend, which cannot be explained at present. All 174 specimens examined were magnetised with the same polarity. After correcting for the drift of Greenland away from North America<sup>11</sup> the mean direction of magnetisation for all 22 sites gives a pole at  $13^\circ\text{N } 91^\circ\text{W}$ , with  $k=47.1$  and  $\alpha_{95}$  of  $4.6^\circ$ .

All of the sampling sites were within 50 m of sea level, so if the linear trend of poles is attributable to differences in the original structural level there must have been a slight tilting of the area subsequent to magnetisation. For example, a tilt of  $5^\circ$ , which would be difficult to detect geologically in such a terrain, would be equivalent over a horizontal distance of 20 km to a change in the original level of 1.8 km. This possibility is supported in this case by a general, though imperfect, relationship between the position of a pole in the linear trend of poles and the geographical position of the corresponding sampling site (Fig. 2): most of the sites in the NNW part of the area give poles in the south-eastern part of the trend, and sites in the SSE part of the area give poles in the north-western part of the trend. If the north-western part of the trend is the younger, the results suggest that the SSE part of the area represents the lowest structural level, that is, that there has been tilting of the terrain towards the NNW. The poles from sites D16, D17 and G20 (Fig. 2) clearly do not conform to this pattern, those sites are the most northerly in the area and so their poles should plot at the south-eastern and not the north-western end of the trend. But a prominent E-W fault, for which there is some geological evidence that the movement has been predominantly vertical (D. Nash, personal communication), separates them from the remainder of the sampling area. The apparent displacement of the anomalous poles could thus be caused by the area north of the fault having moved up with respect to the area to the south.

Fig. 2 The relationship between sampling site positions and corresponding pole positions for the 18 poles in the linear trend. Ordinate, the angular distance north-west along the linear trend to each pole from the D13 pole (the most south-easterly pole); abscissa, distance SSE to each sampling site from an imaginary ENE trending line through site G20 (the most northerly site).

If the linear trend of poles is due to APW during slow magnetisation then the scatter of poles attributable to other causes, represented by the  $10^\circ$  width of the trend, is equivalent to an angular standard deviation of about  $4^\circ$ . This is much less than the values of  $9\text{--}24^\circ$  quoted for secular variation for the appropriate palaeolatitude<sup>13</sup> indicating either that magnetisation was extremely fast, which seems inconceivable on geological grounds and would not in any case explain the linear trend, or that it was so slow that secular variation was effectively averaged out.

During progressive a.f. demagnetisation the site mean pole at seven sites showed small but very systematic movements always in a south-easterly direction (Fig. 3). As there is probably a reasonably close relationship between coercive force and blocking temperature, the systematic movements may represent the movement of the magnetisation from a younger direction, corresponding to grains with lower blocking temperatures, to an older one attributable to grains with higher blocking temperatures. Vector analysis of the movements indicates that, in general, the component actually removed in each step moves progressively in a south-easterly direction, suggesting either that there are two distinct magnetisations with overlapping coercivity spectra, or that there is a continuous spread of magnetisations. The latter seems more likely because the average direction of systematic movement is close to the trend of the poles, indicating that both record the APW path over that period of time. The linear trend of the poles is not greatly different in direction from the trend of the latest published APW path at that point<sup>12</sup>, and the sense of time along the trend of poles as indicated by the systematic movements (younger towards the north-west and older towards the south-east) is in accord with the age dates assigned to the APW path.

Thermal demagnetisation studies were carried out on six specimens from sites which all showed systematic south-easterly movements during a.f. demagnetisation. Up to  $520^\circ\text{C}$  the mean pole moved generally southwards but

between  $520$  and  $560^\circ\text{C}$ , when by far the major decrease in the intensity of magnetisation occurred, the mean pole moved systematically in a south-easterly direction very close to the mean direction of the systematic a.f. movements (Fig. 3). It therefore seems that the stable magnetisation of the specimens resides in grains of magnetite or titanomagnetite which have blocking temperatures (measured on the laboratory time scale) of between  $520$  and  $560^\circ\text{C}$ , and that the systematic south-easterly movements also occur over that interval.

According to the assigned ages on the latest APW path the trend of poles covers an age range from about  $1,525$  to  $1,650$  Myr BP, but an examination of the well dated poles in the area suggests that this portion of the APW path may be about  $100$  Myr older than indicated. Ages are not yet available from the sampling area, but regional K-Ar mineral ages from the Nagssugtoqidian Belt as a whole range from  $1,650$  to  $1,790$  Myr BP, and provisional U-Pb studies on zircons give ages of  $2,200\text{--}2,600$  Myr BP (ref. 14). There thus seems to be good agreement between the time of magnetisation and the setting of the K-Ar mineral clocks, indicating that the magnetisation was probably acquired during a fairly late stage of uplift and cooling long after the peak of metamorphism.

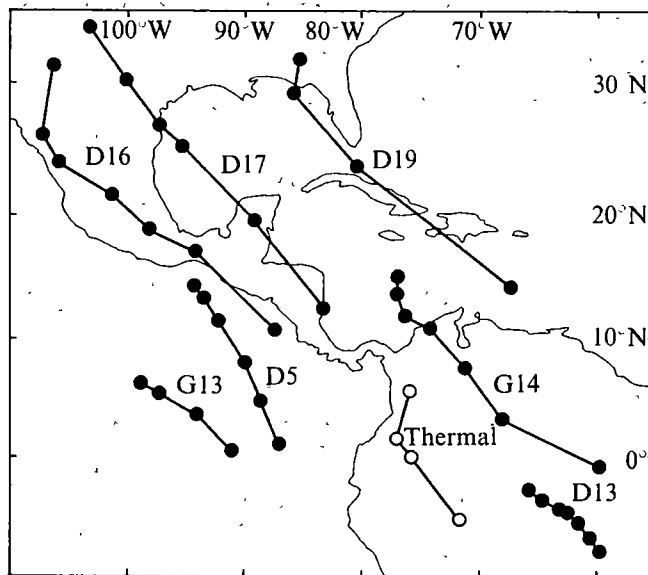

Fig. 3 Systematic south-easterly movements of the mean pole with progressive a.f. demagnetisation at seven sites. For several sites the final part of the southerly movement is also shown to illustrate the transition from southerly to south-easterly movement. ○, The movement of the mean pole of six selected specimens with progressive thermal demagnetisation between  $500$  and  $560^\circ\text{C}$ . All of the poles have been corrected for the drift of Greenland as in Fig. 1. The poles for D17 and D19 have also been moved  $10^\circ$  north, and the thermal poles  $9^\circ$  south-west, to improve the clarity of the diagram. The demagnetising fields (oersted) were—D5: 200, 300, 400, 600, 800, 1,000; D13: 150, 200, 300, 400, 600, 800, 1,000; D16: 0, 50, 100, 200, 300, 400, 600; D17: 50, 100, 150, 200, 400, 600; D19: 100, 150, 200, 400; G13: 600, 800, 1,000, 1,200; G14: 100, 150, 200, 400, 600, 800, 1,000. For thermal demagnetisation the temperatures were  $500$ ,  $520$ ,  $540$  and  $560^\circ\text{C}$ .

The results thus seem to show all of the characteristics to be expected from a slowly cooled terrain. If results of this type prove to be common in plutonic terrains they will not only provide valuable details about apparent polar wander, but could also be a useful tool for investigating movements, such as tilting and faulting, which have occurred subsequent to magnetisation, and which often cannot easily be studied by other methods.

Assistance in the field from Drs G. E. J. Beckmann and J. Watterson, and discussions with Professor Janet Watson and Dr A. Richardson are gratefully acknowledged.

The thermal demagnetisation work was done by Dr G. E. J. Beckmann at Newcastle University. This study was carried out during the tenure of a Natural Environment Research Council research studentship.

## Effect of depth of burial and tectonic activity on coalification

THE study of variations in coal rank is important to coal geologists and the coal industry, and a proper understanding of the coalification process is also important to oil exploration geologists. The rank of coals, which occur as thin seams or lenses in oilfield sediments, can be regarded as an indicator for the degree of maturation of the organic matter (kerogen), finely dispersed in the sediments. Coal and kerogen are somewhat similar in chemical composition, and so are controlled by the same physical and chemical factors. If tectonic pressure can be shown to advance coalification, then it follows that a higher maturation of kerogen can be expected near a fault zone.

Coalification occurs when original plant material becomes buried, and gradual changes in its chemical composition and physical properties take place. The changes can lead to the formation of lignite, brown coal, bituminous coal or anthracite. During the late nineteenth century, it was widely supposed that burial pressure on coal was responsible for the advancement of coalification. In some tectonically disturbed coalfields, for instance, the presence of high rank coals were found which led geologists to believe that tectonic pressures accelerated coalification<sup>1</sup>. Other studies in coalfield geology and coal chemistry have convincingly shown that the role of pressure is insignificant in the process of coalification<sup>2–6</sup>, and the results of experiments simulating coalification<sup>6</sup> indicate that the lower the pressure, the more rapid the coalification at a given temperature. From thermodynamics it is known that the gross reaction in chemical processes, including coalification, is determined mainly by temperature and time, and that static pressure retards reactions because it restricts the removal of reaction products<sup>7</sup>. A coalification pattern which does not seem to fit these studies has been reported for the Bowen Basin of Queensland, Australia (see ref. 7; and Fig. 1). We believe, however, that the pattern in this area is attributable to differences in the original depths of burial below subsequently eroded sediments.

During the Palaeozoic, a sediment-filled, linear downwarp formed along the eastern margin of Australia, separating an old land mass to the west from a rising orogenic belt to the east. During the Permian, coal-bearing formations were deposited; they were followed by as much as 5 km

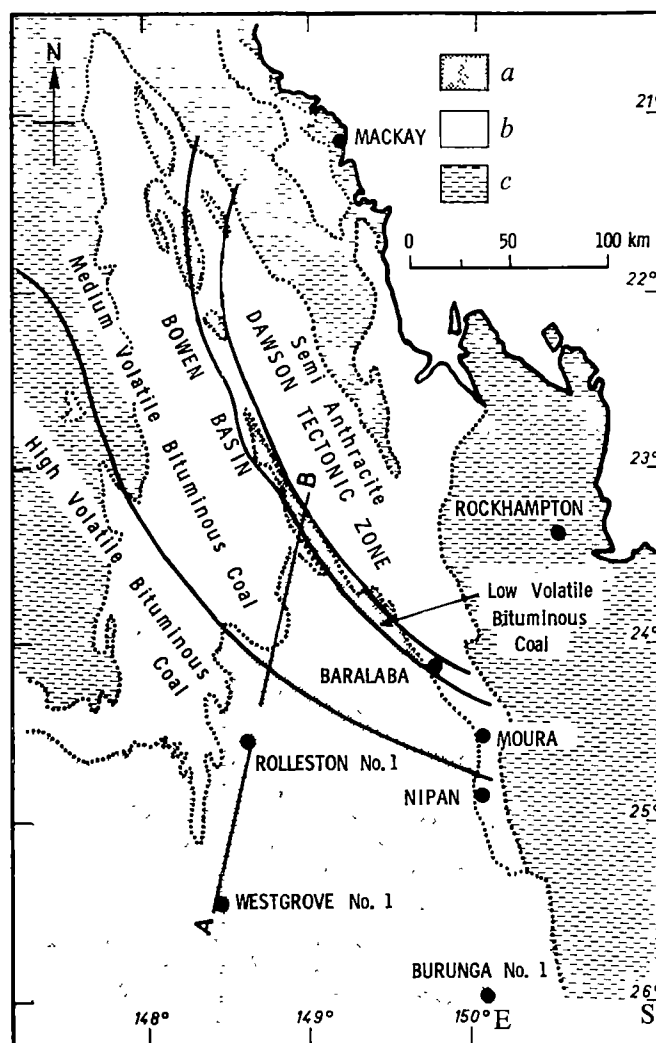

Fig. 1 Coalification trends in the Bowen Basin (after ref. 7). A–B, Location of cross section shown in Fig. 2. a, Mesozoic sediments; b, Permian sediments; c, pre-Permian sediments.

of Triassic sediments. After the deposition of these sediments, the area, particularly the northern part, became uplifted and suffered intense erosion. Contemporaneously, a large synclinal structure formed along the downwarp, the northern part of which is now the Bowen Basin. Tectonic activity was particularly strong along the eastern flank of the Bowen Basin, and the so-called Dawson Tectonic Zone formed. In areas close to this zone, semi-anthracite coals are now exposed at the surface. With increasing distance from this zone towards the south-west, the rank of outcropping coal seems to decrease regularly, down to that of high volatile bituminous coals over a distance of 100 km. This coalification pattern may have been generated by the formation of the Dawson Tectonic Zone (see, for example, ref. 7). Possibly, the tectonic activity together with the deep burial of the coal seams may have been responsible for the increase in rank<sup>8</sup>, though pressure tends to inhibit rather than promote increase in rank<sup>9</sup>. Shibaoka *et al.*<sup>10</sup>, however, have shown that temperature increases attributable to deep burial were probably responsible for the increase in rank around the Dawson Tectonic Zone.

No evidence has been given to explain why the degree of tectonic disturbance gradually and regularly decreases away from the Dawson Tectonic Zone—only the zone itself is heavily disturbed. Even if tectonic pressure did decrease regularly over 200 km, it would not affect the coalification over such a distance<sup>2–6</sup>. The only real effect that the

Fig. 2 Reflectance profiles from Westgrove to the Dawson Tectonic Zone showing two alternative models for the isorank lines: a, isorank lines controlled by depth of burial followed by uplift and erosion of the western part of the area; b, isorank lines drawn assuming a heat source associated with the Dawson fracture.

Dawson Tectonic Zone could have had on coalification must have been attributable to the heat generated during the tectonic activity.

If the zone formed within the space of a few years, which is questionable, the heat generated could possibly have been sufficient to have heated the coal-bearing formations up to at least 200 °C. In that case the isorank planes would incline steeply (Fig. 2b) unless the heat source was extremely deep. We have measured the reflectance of coals in boreholes from this area to construct isorank planes. The planes are inclined at an angle of about 1° 30' (3 km in 110 km) between Rolleston and the Dawson Tectonic

Fig. 3 Depth-reflectance curves for coal bores and oil wells in the southern part of the Bowen Basin: a, Burunga No. 1; b, Rolleston No. 1; c, Nippan; d, Moura; e, Baralaba.

Zone (Fig. 2a), thus requiring a local heat source at least 40 km deep. It therefore seems difficult to explain how the geographical variation of coal rank can be attributed to heat generated along the Dawson Tectonic Zone.

A more likely cause of a gradual increase of temperature towards the Dawson Tectonic Zone could have been a thickening of Triassic overburden which has subsequently been lost by erosion. During the Triassic an old land mass lay to the west, and Triassic sediments became progressively thicker towards the depositional centre of the trough which was probably near the present axis of the Bowen Basin.

The Dawson Tectonic Zone may have coincided<sup>11,12</sup> with the zone of maximum deposition during the Permian and the Triassic. Geological mapping indicates that originally there could very well have been as much as 3 km of Triassic sediments in the central and northern parts of the Bowen Basin. Depth reflectance curves for coal samples from various oil wells suggest that the palaeogeothermal gradient was much the same over the whole southern part of the Bowen Basin, and that where high rank coal is now at a shallow depth, a thick overburden would have been lost by erosion. At Moura, for example, an extra 1,900 m of Triassic sediments could have been lost, compared with a minimal loss at Burunga (Fig. 3). It also seems that a reverse trend may have followed the termination of the downwarp.

We believe that the increase in coal rank in the Bowen Basin was caused neither by tectonic pressure acting on coal seams, nor by the heat generated by the tectonic activity of the Dawson Tectonic Zone. We believe that the main cause was a normal geothermal gradient in thick sediments.

## Desert varnish and marine ferromanganese oxide nodules: congeneric phenomena

BLACK, hydrated ferromanganese oxide (FMO) concretions of microscopic to macroscopic size and complex mineralogy cover ocean floors all over the world at depths of up to 8 km (ref. 1). These amorphous-crystalline nodules have a total Cu, Ni and Co content of 40 p.p.m. to 4% and vary greatly in trace element content, apparently because of varying growth rates caused by the different *Eh* and *pH* in their environments. Black, amorphous, hydrated desert varnish (DV) coatings, 10–100  $\mu\text{m}$  thick, are extensively found in limited areas of the world's arid lands<sup>2,3</sup> in both the subtropics and in non-sterile areas of the Antarctic dry valleys<sup>4</sup>. Marine FMO nodules are formed principally by biological fixation processes; the mode and rate of formation of DV, on the other hand, are not understood, but concern anthropologists in their efforts to date petroglyphs and other artefacts of ancient man<sup>5</sup>.

The broad similarities in element enrichment shared by FMO forms from terrestrial and marine deserts<sup>6</sup> (Fig. 1) indicate a shared formation process<sup>7</sup>. Here, similarities between the natural FMO forms are compared to postulate a formation process for DV. This process seems to be started geochemically but later to involve the cation-scavenging properties of colloidal, hydrated  $\text{MnO}_2$  (ref. 8) as affected by chemolithotrophic bacteria<sup>9–11</sup>. All natural FMO forms seem to show broad similarities in elemental composition and nucleation, which should logically lead to a similar mineralogy on subsequent crystallisation, if this occurs.

Figure 2 shows the 'genetic classification' diagram of Bonatti, Kraemer and Rydell<sup>12</sup> for lake and marine nodules. Hydrogenous deposits (the group *a*, *b* and *c*) seem to grow extremely slowly, by the precipitation of Fe and Mn from normal seawater in oxidising conditions. In contrast, hydrothermal deposits associated with geothermal activity (group *d*, *e* and *f*) grow quickly, whereas the diagenetic group (*g*, *h* and *i*) forms at varying rates through the remobilisation of Mn from sediments in reducing conditions. Halmyrolytic deposits (not shown) result from the submarine weathering of basalt.

In general, the slowly accreted nodules have high Th/U ratios, transition and trace element levels and degrees of

crystallinity. Nodular Ce/La ratios and rare earth element (REE) contents are also inversely proportional to accretion rates<sup>13</sup>, whereas low Mn/Fe ratios and REE depletion are connected with rapid growth in shallow continental margins. The low Co–Ni–Cu content of varnishes places them in the rapidly formed hydrothermal group, *d*, *e* and *f* in Fig. 2. Although Ce has not yet been reported in varnishes, their La/Yb ratio approximates that of Glasby's<sup>13</sup> 'fast accreted' nodules from Aden and Loch Fyne. Desert varnish has formed in North African and Californian deserts within a period of 25–50 yr (refs 2 and 14).

Burns and Brown<sup>15</sup> have shown by microprobe transection that Fe deposition precedes that of Mn in the marine environment, thus ' $\text{MnO}_2$ ' on coral shows an increasing relative concentration of Mn towards surface. This is also the case for DV<sup>16</sup>, with Mn concentration increasing outwards from the leached rock surface as the Fe, Ca, Mg, Ti, Si, Al and K levels decrease. The initial deposition of  $\text{Fe}^{3+}$  has been attributed<sup>15</sup> to precipitation of  $\text{FeOOH} \cdot n\text{H}_2\text{O}$  at local high *pH/Eh* nucleating sites, where weathering has left concentrations of phosphate, silicate or carbonate; precipitation of negatively charged colloidal  $\text{Mn}^{2+}$  hydroxide, aided by the opposing zero charge potentials of the two hydroxides follows.

It has been suggested<sup>15,17</sup> that following nucleation,  $\text{Mn}^{2+}$  in a high *pH/Eh* marine environment reacts as follows: first, initial deposition

Second, adsorption of more  $\text{Mn}^{2+}$

Third, oxidation of todorokite to form  $\delta - \text{MnO}_2$

For deep nodules this process eventually leads to the single authigenic high pressure-stable crystalline phase, todorokite, which readily oxidises and dehydrates to yield minute platelets of  $\delta - \text{MnO}_2$  admixed with a separate exsolved  $\text{FeOOH} \cdot n\text{H}_2\text{O}$  phase. Detrital particles with (–) zero electric potentials, such as quartz, are excluded from the growing nodular surface and are also absent from DV.

Subsequent crystallisation occurs slowly, if at all, with the epitaxial intergrowth of species such as hollandite  $(\text{Ba}, \text{K}, \text{Pb}, \text{Na})_{1-2} \text{Mn}_8\text{O}_{16} \cdot n\text{H}_2\text{O}$ , psilomelane  $(\text{Ba}, \text{K}, \text{Mn}, \text{Co})_2 \text{Mn}_5\text{O}_{10}$ ,  $n\text{H}_2\text{O}$ , birnessite  $(\text{Ca}, \text{Na}, \text{Mn})_x \text{Mn}_7\text{O}_{14} \cdot 3\text{H}_2\text{O}$  and todorokite  $(\text{Na}, \text{Ca}, \text{Mn})\text{Mn}_3\text{O}_7 \cdot n\text{H}_2\text{O}$ , intergrown with polymeric ferrihydrite,  $\text{FeOOH} \cdot n\text{H}_2\text{O}$ .

These associations of elements suggest (Fig. 1) that the apparently amorphous dioctahedral 2:1 sheet silicate 'lattice' of DV probably contains cryptocrystalline microdomain manganese mineral phases as do the nodules, particularly as Ba appears in all reported DV. 'Goethite' has been reported<sup>14</sup> in one X-ray study of DV, and this work should be extended to obtain a comparison with the known line spectra of the marine nodular phases. These mineral and trace element suites have also been found in Australian desert soil microconcretions<sup>18</sup>. Rectilinear semi-log plots of DV Mn against Ba, Co, B, Sn, Y and Yb<sup>2</sup> have been obtained in partial agreement with ref. 12, where the Mn correlation to Ba and Co in marine nodules is shown. The DV data of Lakin *et al.*<sup>3</sup> though scattered, show a similar Mn–Ba–Co correlation. Colloidal scavenging of trace cations is probably involved in the formation both of DV and marine nodules. Murray<sup>19</sup> has shown that precipitated hydrated  $\text{MnO}_2$  adsorbs  $\text{Co} > \text{Mn} > \text{Ni} > \text{Ba} > \text{Sr} > \text{Ca} > \text{Mg}$ , with Co irreversibly sorbed at an alkaline *pH*, whereas manganite sorbs Ni, Ca, Zn, Mg and  $\text{Ti}^{4+}$  by lattice replacement.

Fig. 1 Average elemental abundance in deep-sea FMO nodules<sup>6</sup> relative to average desert varnishes (cited) ○, Taken from ref. 2. Averages for Stoddard rhyolite fan, Halloran andesite colluvial, and Sheephead andesite colluvial. ●, From ref. 3. Averages of DV3, 5 and 6.

Fig. 2 Ratio Fe:Mn:(Co+Ni+Cu) of representative desert varnishes and hydrothermal and diagenetic marine and lake FMO deposits. Groups a, b and c = hydrothermal; d, e and f = hydrothermal; g, h and i = diagenetic (data of ref. 12). Desert varnishes: DV1-6 and N1, 2, 3, 5 and 6 from ref. 3; E1, Stoddard rhyolite; E2, Halloran andesite; E3, sheephead andesite; E4, Coxcomb tuff of Engel and Sharp<sup>2</sup>.

As noted, nucleation in DV is similar to that in marine nodules but occurs in the alkaline, weathered rock surface where there are silicate, phosphate or carbonate salts. Hem<sup>20</sup> has shown that feldspar increases the rate of oxidation of Mn<sup>2+</sup> to Mn<sup>4+</sup>, and such phenocrysts may initially be more varnished than the matrix. They may, however, weather more rapidly than the matrix and lose their DV, as is the case for limestone. Dewfall (a major water source<sup>21</sup> and weathering agent in arid lands) is the likeliest source of the proper amount of moisture to form DV, which is soluble in rain<sup>5,14</sup>. Other 'constants' in the desert environment are a saline dustfall and an influx of chemolithotrophic microorganisms<sup>22</sup>. Airborne Egyptian desert dust (~20 µm diameter) contained 18% water solubles, chiefly gypsum and salt<sup>23</sup> whereas airborne Colorado Desert dust was also high in salt, gypsum, lead and iron, with small amounts of Zn and Mn. These conditions are necessary and sufficient for the growth of the ubiquitous desert algal microflora.

Following nucleation in the pre-dawn dewfall, biological growth then takes place during the warming and evaporating cycle. This activity is greatest just below the desert surface and would account for the thick 'groundline'<sup>2</sup> of varnish found on cobbles in pavement. The groundline band extends from 1 cm above to 3 cm below the soil surface. An exaggerated 'equatorial band' also develops on certain marine nodules at the sediment-water interface<sup>24</sup>, and this is probably a direct homologue of the DV structure. If desert pavement cobbles are turned over, their unvarnished red undersides become varnished in time, a phenomenon which strongly suggests the phototactic migration of thermophilic motile, inducible<sup>10</sup> Mn reducers and oxidisers (bacteria and fungi) along the rock surface, probably endosymbiotic with the ubiquitous cyanophytes of desert soils. Stones not in contact with the ground are most heavily DV patinated on upper surfaces and in depressions, which would provide favourable nutrient biological niches based on dustfall. This growth mechanism, and the variables involved, is an extension of that proposed by Scheffer *et al.*<sup>14</sup>. As rocks become varnished their blackbody radiation efficiency will also increase thus leading to a thicker DV coating on smaller rocks than on larger ones which cool more slowly. White inert stones such as bull quartz in pavements lack varnish, relative to their neighbours, because they have neither good blackbody radiation

characteristics nor weathering rugosities which trap nutrient dust. Varnishes should be examined for REE anomalies, such as Ce/La, which may apply to their growth rate and age; and they should be examined by means of scanning electron techniques for the surface presence of the admittedly hypothetical bacterial Mn oxidisers.

I thank Lucian Rarogiewicz for discussions, and Professor Robert P. Sharp for cogent criticism of the manuscript.

## Viscosity in the phase transition region of triblock copolymer systems

THE behaviour of melts of styrene-butadiene-styrene (SBS) triblock copolymer under oscillatory shear exhibits a marked departure from that of homopolymers in the low frequency range; the dynamic viscosity  $\eta'(\omega)$  increases continually with decreasing frequency, rather than exhibiting the Newtonian limiting value  $\eta_0$  expected of true fluids<sup>1</sup>. This peculiar behaviour has been explained in terms of phase separation which forms a lattice of linked polystyrene domains. Here we present rheological evidence directly demonstrating a thermodynamic transition.

We have studied  $\eta'$  at different temperatures for an SBS block copolymer (Shell TR-41-1467; molecular weight 9,600-47,500-9,400) plasticised to different degrees with dipentene ( $T_{\text{hom}}=178^\circ\text{C}$ ), a good solvent for both block types. All experiments were carried out on a Weissenberg Rheogoniometer Model R-17, using a platen diameter of 2.5 cm and a  $4^\circ$  cone angle. Readout of amplitude ratio and phase angle was taken from a strip chart recorder at low  $\omega$  and from Lissajou figures photographed from an oscilloscope at high  $\omega$ . Temperature control was achieved by means of an electric oven enclosing the platens. Small containers of solvent were placed in the oven to prevent solvent loss by the sample. Oscillation amplitudes were chosen to satisfy the conditions of linear viscoelasticity.

We observed that moderately plasticised systems exhibit a limiting viscosity,  $\eta_0$ , at low frequencies if the temperature is raised sufficiently but not so high to cause degrada-

tion of the material (a common problem when working with unplasticised polymer). Results for a system with approximately 30% dipentene are shown in Fig. 1. At 25 and 51 °C the low- $\omega$  anomaly is seen clearly, as reported earlier for the bulk polymer<sup>1</sup> at higher temperatures, but at 76 °C a Newtonian viscosity is recovered. This transition has never been reported for melts, presumably because degradation problems discouraged work at sufficiently high temperatures.

This change in viscosity behaviour can be explained in terms of the concept of 'separation temperature' ( $T_s$ ), as proposed by Leary and Williams<sup>2</sup>. At temperatures below  $T_s$  the domain system is thermodynamically the more stable state, but above  $T_s$  the more stable state is a randomly mixed system behaving as an ordinary liquid with measurable  $\eta$ . The results shown in Fig. 1 would indicate that for

Fig. 1 Dynamic viscosity  $\eta'$  for a styrene-butadiene-styrene block copolymer, with 30% dipentene at temperatures above and below the separation temperature,  $T_s$ . ●, From a chart recorder; ○, from an oscilloscope.

this system,  $T_s$  is between 51 and 76 °C. A light transmittance experiment with the same system using equipment previously described<sup>3</sup> showed a transition in the range 63 to 77 °C, in very good agreement with rheological measurements. Depression of  $T_s$  by solvent, as we observed, seems to explain why 'concentrated' solutions (say, 30% polymer) may exhibit no anomalous behaviour at 35 °C (ref. 3).

The rheological evidence tends to support the interpretation and existence of  $T_s$ , a concept not universally accepted. Rheogoniometry seems to measure  $T_s$  as accurately as previous methods, and identification of  $T_s$  values is essential for the design of fabrication processes. Meanwhile, extension of the Leary-Williams model to plasticised block copolymers is in progress<sup>4</sup>.

## Drag reduction in laminar flow

WHEN certain long-chain polymers are added to water, the drag exerted by the solution on fixed boundaries is reduced<sup>1</sup>. Although this applies to both internal and external flows, evidence indicates that the effect occurs only in the turbulent regime, at least for steady flow. The work reported here deals with the forced oscillation of a liquid column contained within a semicircular manometer tube, and shows that the addition of a polymer produces a reduction in drag when the flow is laminar.

The apparatus consisted of PVC tubing (3/16 inch bore) arranged in a semicircle (12 inch radius) on a vertical wooden board. The forcing pressure, which is applied to one side of the manometer, is provided by a servo controlled motor which operates rubber bellows through a cam mechanism. The speed of the motor, and thus the forcing frequency, was measured by timing a known number of revolutions of the cam.

The results are in the form of a resonance test, where the frequency of the forcing pressure is varied and the amplitude of the oscillation of the manometer liquid is measured. Several tests were performed so that the effect of changing the mixture strength could be observed. For each test a new length of tubing was used and the amount of solution in the tube was adjusted so as to preserve a common length of liquid column. Figure 7 shows the results for water and various solutions of Polyox WSR 301 dissolved in water. For the range of solutions tested the polymer produces various degrees of drag reduction, with the weakest solution (12.5 p.p.m.) producing the most effect.

If it is assumed that the displacement of the liquid column is harmonic, then the velocity, and thus the instantaneous Reynolds number, is also harmonic; however, a peak Reynolds number,  $\hat{Re}$ , can be calculated for any given amplitude and frequency, based on the maximum velocity of the liquid column in any one cycle. Thus, if  $x$  is the half-amplitude at a frequency  $\omega$ , then

$$\hat{Re} = 2\omega x r / \nu$$

where  $r$  is the internal radius of the tube and  $\nu$  the kinematic viscosity of the liquid. Thus, lines of constant  $\hat{Re}$  appear as hyperbola in the  $x$ - $\omega$  plane, as shown in Fig. 1. The results are well within the critical  $\hat{Re}$  boundary ( $\sim 2,000$ ) associated with steady flow.

Fig. 1 Amplitude of oscillation as a function of forcing frequency,  $\omega$ , and mixture concentration. —, water; ○, 100 p.p.m.; □, 50 p.p.m.; △, 25 p.p.m.; ▽, 12.5 p.p.m.; a,  $\hat{Re} = 2,000$ ; b,  $\hat{Re} = 1,500$ ; c,  $\hat{Re} = 1,000$ .

The critical Reynolds number for oscillatory flow is frequency dependent<sup>2</sup>, and the parameter which determines the variation from the steady flow case is the Valensi number,  $N_V$ , where  $N_V = \omega r^2/\nu$ .

According to Park and Baird<sup>3</sup> the critical Reynolds number increases from 2,000 when  $N_V > 30$ . In the apparatus described this happens when  $\omega > 7$  so that, for the frequency range in which the drag reduction occurs, the critical Reynolds number should still be about 2,000. It would seem that anomalous results are obtained when comparing the reduction of pipe wall drag for steady and unsteady laminar flows.

We draw attention to this because of its possible application. It is a small part of a more fundamental study under the direction of Dr W. D. McComb<sup>4</sup>, to whom grateful acknowledgement is made.

## Knowledge of magnetism in pre-Columbian Mesoamerica

THAT the pre-Columbian peoples of Mesoamerica were familiar with the property of magnetism has been suggested by numerous researchers, among them Coe and Fuson<sup>1</sup>. Indeed, a flattened oblong piece of haematite discovered by Coe during the excavation of the Olmec site of San Lorenzo in southern Veracruz state in 1973, has been thoroughly examined by Carlson<sup>2</sup>, who suggests that it probably was manufactured for use as a compass. Fuson has argued that the varied alignments of architectural complexes in many Mayan ceremonial centres may be explained by their having been oriented to compass directions which changed through time, and further, that the Mayas' knowledge of mercury would have permitted them to use vessels filled with this liquid, as well as the water-filled calabashes, to float their 'needles' or lodestones. In January 1975 during field studies at Izapa, in the Pacific coastal plain of south-eastern

Fig. 1 Carvings of snake and turtle heads at Izapa, located 30 m SE of the main pyramid.

Chiapas state, I discovered strong circumstantial evidence that the people of this Late Formative ceremonial centre not only knew about magnetism but possibly even associated it with the homing instinct of the sea-turtle.

While examining astronomical alignments of various of the structures at Izapa, I took a bearing along the axis established by two large sculptures located ~30 m south east of the main pyramid (Fig. 1). In common with the river cobbles that make up the facing of the pyramids and platforms of the site, the sculptures consist of dark brown basalt. Apart from the fact that they are larger and have been specially carved, they are in no way distinguished from the other exposed rock at the site. The smaller of the two sculptures measures 89 cm in length and is unmistakably a representation of a snake head. Some 114 cm behind the snake head, that is, further SE, stands an upright stone stela, roughly squared off but having no discernible

Fig. 2 Close-up of turtle head, with compass needle pointing toward snout.

carvings on any of its faces. A further 256 cm SE is a second stone sculpture, this one measuring 114 cm in length and 122 cm across at its widest point. This stone unquestionably depicts the head of a turtle. When a Brunton compass was brought near the turtle head a sharp deflection of the needle was observed, of more than 60°. No matter where the compass was moved along the perimeter of the sculpture, the needle continuously pointed to the snout of the turtle (Fig. 2). Discovery of this magnetic field prompted the testing of all other exposed rock at the site for magnetic properties, but no others were detected. This would suggest that the Izapans knew about magnetism in that they had reserved a basaltic boulder rich in iron for their carving of the turtle-head, and had executed it so carefully that the magnetic lines of force all came to a focus in the snout of the turtle.

The magnetic turtle-head is not the only representation of this creature found at Izapa. Overlooking the western end of the ceremonial ball court is a large altar carved from a single piece of basalt which is also unmistakably a turtle. A few metres to the south of this altar, adjacent to the wall of the main pyramid, is another sculpture, which has the appearance of an upturned turtle shell, again carved from a single basalt boulder. The latter would obviously have become filled with water during the rainy season, and may well have provided the frictionless surface needed for a shaving or needle of lodestone, floating on a small piece of wood, a leaf, or a straw, to serve as a compass. Clearly the Izapans, a sea-faring people, were impressed by

the navigational ability of turtle<sup>3</sup>, which are common in this area. It may be interesting to note that the theory that turtles navigate by magnetism has not yet been discounted<sup>3</sup>.

## Fish kill at low pH in a Norwegian river

THE decline in freshwater fish populations in parts of southern Norway is associated with increasing acidity in rivers and lakes<sup>1</sup>. The salmon has been eliminated from many rivers, and hundreds of lakes have lost their trout populations. The chief cause of increased acidity is acid precipitation which is the product of the emission, oxidation and long-distance transport of air pollutants, particularly sulphur dioxide<sup>2,3</sup>. Similar observations of acid rain and the disappearance of freshwater fish populations have been made in the United States, Canada and Sweden<sup>4-6</sup>.

Few cases of massive fish kill due to low pH have been documented in natural environments. A massive fish kill in the Tovdal River in southern Norway in the spring 1975 provided an opportunity to investigate physiological changes in the affected population. Formerly a major salmon river, the Tovdal River is now devoid of salmon, *Salmo salar* L., but still has a population of brown trout,

**Fig. 1** *a*, Chloride content in the blood plasma from *Salmo trutta* collected from different localities along the Tovdal river. The field stations are ranged in order of increasing fish mortality: station V had many dead fish, station I had none. The fish are a fairly representative sample of the population at each locality. Their weight varied between 17 and 250 g. Blood samples were taken by heart puncture in heparinised syringes within 30 min after capture, and the plasma was separated immediately by centrifugation. Chloride was determined coulometrically on 20- $\mu$ l samples. The analyses were performed in a mobile field laboratory. *b*, Water flow in the upper part of the river (station I) before, during and after the major snow melting, April 16 to May 30 ( $\text{m}^3 \text{s}^{-1}$ , lower curve). Acidity of the water was measured as pH and recalculated as  $\mu\text{M H}^+$  (centre curve). Plasma chloride ( $\Delta$ ) from the trout population at station I taken on April 23, May 15 ( $0^\circ \text{C}$ ) and May 23 ( $6^\circ \text{C}$ ).

**Fig. 2** Plasma sodium plotted against chloride from field localities with different degrees of fish mortality. The frame at the upper right corner indicates animals from station I, with no dead fish. Aberrant behaviour includes: lack of avoidance reaction, spiral swimming, and loss of equilibrium at the moment of capture. Plasma cations were determined by atomic absorption spectroscopy at 1/200 sample dilution. The linear regression line drawn has been calculated:  $\text{Na} = 0.746\text{Cl} + 55.35$ ,  $r_{xy} = 0.89$ . — — —, Equimolar concentration for sodium and chloride. Temperature  $0-6^\circ \text{C}$ .  $\bullet$ , No dead fish;  $\Delta$ , many or some dead; diamond, aberrant behaviour.

*Salmo trutta* L. The catchment area of the river is characterised by highly resistant bedrock, mainly granites and gneisses with thin and poorly developed soils. The valley is sparsely populated and has no industry. When the fish kill was noticed, the river was partly covered with ice and the bottom was littered with thousands of dead trout over a stretch of at least 30 km. The fish kill was apparently associated with an influx of pollutants during early phases of snow melting<sup>7</sup>.

Live trout were captured in shallow water by electro-fishing, and blood samples were drawn immediately. Blood plasma was analysed for Na, K, Mg, Ca and Cl. The fish population in the upper reaches of the river was found to be unaffected, and we were thus able to compare this population with samples of surviving trout from the area of severe fish kill. Figure 1 shows that most of the surviving population at the location with the highest incidence of dead fish (station V) had lower plasma chloride contents than those from the unstressed locality (station I). Fish from localities with fewer dead fish show intermediate values (station II, III, and IV). In Fig. 2 the plasma chloride has been plotted against sodium for all the field data. As might be expected, the decrease in plasma chloride is accompanied by a reduction in sodium. The calculated regression shows that for each chloride ion lost there is a decrease in sodium of 0.75 ions.

At the upper reaches of the river (station I) the snow started to melt on April 21, and continued at a moderate rate until May 6 (Fig. 1b). The increased acidity shown in Fig. 1b during the early phase of melting was accompanied by a similar increase in sulphate and other components associated with acidic precipitation. During this early phase of melting, pollutants accumulated in the snow pack are leached out<sup>7</sup> and may reach the river unchanged because of frost in the ground. Blood samples taken on May 15, contained significantly less plasma sodium and chloride than samples taken before and after the snow melting. The pH had dropped from 5.2 to a minimum of 4.65 ( $23 \mu\text{M}$ ) in the early phase of melting, but values as low as pH 4.0 ( $100 \mu\text{M}$ ) was registered in some of the small tributaries to the main river.

Fig. 3 Plasma sodium plotted against chloride from tank experiments conducted in July 1974 at 18 °C. Trout kept at pH 6.0 and trout exposed to pH 4.0 for 20–100 h. The pH was regulated by metered addition of sulphuric acid. The broken line indicates equimolar concentration for sodium and chloride. "Dying" animals have lost their ability for integrated bodily movements. The frame gives the range in concentration for "dying" animals. ●, pH 6.0; △, pH 4.0; diamond, pH 4.0 "dying".

Fish from a locality with high incidence of dead fish (station V) were transferred to tanks with running water of the same water quality, but neutralised to pH 6.0 by metered addition of dilute potassium hydroxide. After 2 weeks at this pH, the previously stressed fish had regained their normal sodium chloride levels. The change in plasma ions induced by varying only the pH indicates that high acidity is the dominating stress agent for fish in the river.

Brown trout from the wild stock population of the Tovdal River has been used in tank experiments at different times of the year. Fish kept in tanks with water acidified to pH 4.0 lose their ability to regulate plasma sodium and chloride concentrations (Fig. 3). The lowest sodium chloride levels were always found in animals so heavily stressed that the ability for integrated bodily movements had been lost.

Freshwater fish take up ions actively through the gill epithelium. Sodium is exchanged for hydrogen ions and chloride for bicarbonate<sup>8</sup>. Increased hydrogen ion activity in the surrounding medium will impede the active uptake of sodium<sup>9,10</sup>.

This study has shown that low plasma sodium chloride is associated with massive fish kills and with exposure to low pH in tank experiments and in the field. The plasma content of potassium, calcium and magnesium is not affected. It seems probable therefore that impairment of the active transport mechanism for sodium and/or chloride ions through the gill epithelium is the primary cause of fish death in acid waters. Severe ionic imbalance is known to affect fundamental physiological processes such as nervous conduction and enzymatic reactions. The pH below which fish populations are affected depends on several factors. There are differences between species—salmon is more sensitive than trout. Newly hatched fry are more sensitive than adult fish and lack of recruitment is common in acid lakes<sup>1,6</sup>.

It should be stressed that the lakes and rivers that have lost their fish populations contain small amounts of dissolved salts. Typical values for specific conductance is 10–30  $\mu\text{mho cm}^{-1}$ , total hardness is 0.9–6.0  $\text{mg l}^{-1}$  as  $\text{CaCO}_3$  and Na is 0.5–2  $\text{mg l}^{-1}$ . Not only are such waters poorly buffered but field surveys suggest that the fish population is affected at a higher pH in lakes with extremely low ion content. In the spring, pollutants released in the first phases of snow melt produce a pH shock in the rivers and surface

layers of lakes. The subsequent meltwater lowers the total ion content and thus reinforces the pH stress. The fish kill in the Tovdal River indicates that this is the most critical season for the fish populations.

## Chemical treatment of soil alleviates effects of soil compaction on pea seedling growth

HIGH mechanical resistance of soils, related to naturally occurring hard pans, or to compaction by machinery and untimely cultivation<sup>1–3</sup>, often reduces crop yields through poor development of root systems<sup>1,4–6</sup>. In the laboratory, progressive increases in mechanical resistance of the growth medium cause reduced root elongation<sup>7–9</sup>, stunting and thickening of root systems<sup>3,10</sup> and reduced shoot growth<sup>11</sup>. Loosening of subsoil in the field can reduce compaction, increase aeration and waterholding capacity of the soil and improve the distribution of available water<sup>1</sup>. Roots can then penetrate to greater depths and crop yields often increase<sup>1,12,13</sup>. White light also affects root growth, inhibiting axial extension in some species<sup>14–16</sup>. This effect can be counteracted in cross roots by 3,5-diiodo-4-hydroxybenzoic acid (DIHB)<sup>17–19</sup>. The fact that compacted soil and white light can both induce stunting and thickening of root systems suggested to us that similar growth control mechanisms might be involved. We have therefore investigated whether DIHB can improve root development in compacted soils; we have shown that this is the case.

The roots and shoots of pea seedlings grown in compacted control soil (moistened with water) in growth room conditions were found to be much shorter and had smaller dry weights than those of seedlings grown in loose control soil (Tables 1–3). Furthermore, the growth-inhibited roots were thickened and bent whereas the roots of seedlings grown in loose control soil were slender and straight. These responses of roots to adverse soil conditions are typical of those observed in various crop plants<sup>3,8,10,11</sup>.

Addition of  $10^{-4}$  M or  $10^{-6}$  M solutions of DIHB to soil followed by compaction, reduced the level of root growth inhibition, the overall lengths of unstraightened roots being 19% and 31% greater, respectively, than those of corresponding roots in the compacted control soil. When the roots were straightened the chemical was found to have induced increases of 19% and 24% (Table 1). Similar DIHB treatments applied to the loose soil had little detectable effect on root elongation at either  $10^{-4}$  M or  $10^{-6}$  M, root length in both cases being the same as in the loose control soil (Table 2). Clearly, therefore, DIHB enhanced root penetration in compacted soil and was ineffective in loose soil.

Straightening and measuring the roots of pea seedlings grown in  $10^{-4}$  M DIHB compacted soil or the compacted

**Table 1** Effect of DIHB solution or distilled water incorporated in a compacted silt loam soil on the length of pea seedling roots

DIHB concentration (M)	Length (mm)	Shoot % Increase over control	Length (mm)		Root % Increase over control	
			Unstraightened	Straightened	Unstraightened	Straightened
Control	14.12±0.78	—	16.90±0.91	23.97±1.07	—	—
10 <sup>-6</sup>	15.37±1.02	8.85	22.12±1.34	29.63±1.36	30.89	23.61
10 <sup>-4</sup>	15.04±0.91	6.51	20.06±0.95	28.56±1.12	18.70	19.14

Data are the means and standard errors from six samples each containing at least eight seedlings. Silt loam soil of the Wood Series was taken from the plough layer (0–22.5 cm), sieved (4 mm mesh) and air dried. Gravimetric moisture determinations were carried out so that the final soil moisture content could be adjusted to 20% (pF 3.6) by weight using distilled water or aqueous DIHB solution. Treated or control soil was placed in rigid plastic isodiametric pots (7.5 cm high, 10.2 cm inner diameter, Osma) in four layers of equal weight and each layer was compressed evenly using an air-operated piston. Each pot constructed in this way was filled to a depth of 6.5 cm. Applied pressure at the soil surface was 3.16 kg cm<sup>-2</sup> for compacted soil and 0.15 kg cm<sup>-2</sup> for 'loose' soil (read from a standard curve showing the relationship between soil bulk density and moisture content over a range of applied pressures for the Wood Series soil<sup>20</sup>), which gave dry bulk densities of 1.5 and 1.1 g cm<sup>-3</sup> respectively. Seeds of *Pisum sativum* L. cv. Meteor were soaked in flowing tap water for 4 h before germination between sheets of moistened Whatman No. 1 filter paper at 25±1 °C in darkness. After 22–24 h, seedlings with radicles 2 mm long were planted in the pots containing control or DIHB-treated soil. Radicles were embedded firmly in small holes made in the soil surface and the pots were filled to capacity with the appropriate soil, which was gently firmed by the piston at a pressure of 0.15 kg cm<sup>-2</sup>. Polythene sheet was used to cover the pots to prevent evaporation of water from the soil. After further incubation for 72 h at 20±2 °C, seedlings were removed from the soil and washed in tap water. Root length of seedlings grown in compacted soil was assessed as (a) the length of a straight line extending from the base of the root to the root tip, thereby not accounting for any deviations due to bending and (b) the entire length of the root after straightening. These two values, which are referred to as unstraightened and straightened lengths respectively, gave a guide to the amount of bending of the root induced by the soil conditions. Roots of seedlings grown in loose soil were free from such bending so only the length of the straight root was recorded.

control soil revealed a 42% increase in length; for roots grown in the 10<sup>-6</sup> M DIHB compacted soil treatment the increase was 34% (Table 1). Since a highly bent root would show a large increase in overall length on straightening and vice versa, it follows that the roots grown in the 10<sup>-6</sup> M DIHB compacted soil were less bent than those from either the 10<sup>-4</sup> M DIHB or the control compacted soils. Thus the concentration of DIHB which was most effective in enhancing root elongation through the compacted soil also reduced root bending in response to high mechanical resistance of the soil.

A trend was detected which indicated that small increases in shoot length occurred when seedlings were grown in compacted soil treated with 10<sup>-4</sup> M and 10<sup>-6</sup> M DIHB, but the chemical had little effect on shoot length in the loose soil treatments (Tables 1 and 2).

Seedling dry weights were not affected by inclusion of DIHB solution in the loose soil treatments, but increases in the weight of both shoots and roots were detected in the DIHB compacted soil treatments (Table 3). The greatest dry weight increase was found in seedlings subjected to the 10<sup>-6</sup> M DIHB compacted soil treatment, which, as we have already seen, was also the most effective treatment for enhancement of root and shoot elongation.

We have demonstrated, therefore, that incorporation of DIHB into compacted soil can produce substantial increases in overall root length of pea seedlings and small increases in shoot length and seedling dry weight. DIHB can thus reduce root growth inhibition induced by both compacted soil conditions and exposure to white light. This supports our initial idea that the two responses might have similar control mechanisms. Investigations in our laboratories have shown that DIHB may counteract effects of light on root

elongation by reducing ethylene-induced growth inhibition<sup>19,21</sup>. Ethylene can also cause swelling and bending of roots<sup>22,23</sup> and these distortions are similar to those observed in roots of seedlings growing in compacted soils<sup>3,10</sup>. Anaerobic conditions arising as a result of conditions prevailing in some compacted soils can stimulate the production of ethylene by soil microflora<sup>20,24,25</sup> and mechanical resistance can also induce endogenous production of ethylene by roots and shoots<sup>23,26</sup>. Thus, it is possible that DIHB acts by reducing the production and/or the inhibiting effects of ethylene derived from the soil or the plant tissue or both. Further research is required to assess the relative

**Table 3** Dry weights of root and shoot tissues of pea seedlings treated with DIHB

DIHB concentration (M)	Dry weight per seedling (mg)			
	Compacted		Loose	
	Shoot	Root	Shoot	Root
Control	8.41±0.72	5.54±0.52	9.77±0.45	7.66±0.31
10 <sup>-6</sup>	10.99±1.17	6.50±0.72	9.96±0.35	7.92±0.18
10 <sup>-4</sup>	9.55±0.86	6.03±0.53	10.14±0.15	7.87±0.08

Pea seedlings were grown for 72 h at 20 °C in 'loose' or compacted silt loam soil, treated with DIHB solution or distilled water (control) to give a 20% soil moisture content. Data for each treatment are the means ± s.e. from six samples, each consisting of at least eight seedlings.

importance of mechanical resistance, ethylene and anaerobic conditions in limiting seedling growth, and also to determine whether DIHB relieves growth inhibition due to one or more of these factors. The moisture content of the soil used in the present studies, however, was well below that at which pea seedling growth is limited through lack of aeration<sup>9,28</sup> and in view of the short growth periods involved it seems unlikely that anaerobic conditions would be established. Whatever the reason, the important aspect of our findings is that seedling growth can be improved by treating compacted soil with low concentrations of specific chemicals, an effect which is not apparent in non-compacted soil.

Intensive investigations are now in progress to determine the conditions necessary for optimum plant response to DIHB and the precise mode of action of the chemical and its analogues 3,5-Dichloro- and 3,5-dibromo-4-hydroxybenzoic acids, for example, have much the same effect on pea seedling growth in compacted soil as DIHB and the results of these studies will be published in full elsewhere.

**Table 2** Effect of DIHB solution or distilled water incorporated in a 'loose' silt loam soil on the elongation of pea roots and shoots

DIHB concentration (M)	Shoot		Root	
	Length (mm)	% Change over control	Length (mm)	% Change over control
Control	21.47±0.56	—	65.98±1.82	—
10 <sup>-6</sup>	21.37±0.46	-0.47	64.55±1.59	-2.17
10 <sup>-4</sup>	21.24±0.49	-1.07	67.04±1.44	+1.60

The density of the soil was 1.1 g cm<sup>-3</sup>, and its moisture level was 20%. Seedlings were grown for 72 h at 20 °C and the data for each treatment are the means ± s.e. from six samples each consisting of at least eight seedlings.

Clearly, these findings of enhanced seedling performance in adverse soil conditions could open exciting new possibilities in practical agriculture by helping to combat the effects of soil compaction on plant growth using chemical rather than mechanical means.

## Substance stimulating the differentiation of spores of the blue-green alga *Cylindrospermum licheniforme*

THE study of intercellular inductions in higher plants and animals is hindered by the complexity of the multicellular tissues involved. Sporulation of filamentous blue-green algae is a relatively simple process to study because these algae contain, in linear array, only three types of cells. There are vegetative cells, and heterocysts and spores which form by differentiation of vegetative cells. Wolk<sup>1,2</sup> showed that heterocysts of the blue-green alga *Anabaena cylindrica* Lemm. induce adjacent vegetative cells to differentiate into spores. We report here that a substance produced by the related alga, *Cylindrospermum licheniforme*, greatly stimulates sporulation of that same alga.

Stock cultures *C. licheniforme* Kutz. were grown axenically<sup>3</sup> in an eightfold dilution of the medium of Allen and Arnon<sup>4</sup> on a rotatory shaker at  $27 \pm 1^\circ \text{C}$ , illuminated with cool-white fluorescent light at an intensity of 2,200 lx. These cultures, subcultured 1% v/v weekly to maintain a density below  $2.5 \mu\text{g}$  chlorophyll per ml, contained no spores.

Phosphate deficiency stimulates sporulation of *Cylindrospermum*. Cultures of *C. licheniforme* sporulated in phosphate-free standard sporulation medium (SSM)<sup>1</sup> containing 5.7 mM *N*-tris(hydroxymethyl)methyl-2-aminoethane sulphonic acid (TES), pH 7.5, as buffer in place of DL-alanyl-glycine. Conditioned SSM was the centrifugal supernatant fluid from 50 ml 10–15-d-old cultures, and from 250 ml

15–20-d-old cultures. SSM and conditioned SSM were inoculated (2%, v/v) from 7-d-old stock cultures, and were cultured in the same conditions of temperature and light as were the stock cultures. In some experiments, conditioned SSM was supplemented with all the constituents of SSM, or was lyophilised and then made up to its original volume by addition of SSM or water.

In *C. licheniforme*, heterocysts normally develop at the ends of filaments, and spores differentiate first next to the heterocysts. The extent of sporulation was quantified as the percentage of heterocysts with an adjacent spore or spores. (Heterocysts can be caused to form at an intercalary position<sup>5</sup>, in which case spores form on both sides of these heterocysts, but intercalary heterocysts were not observed as part of our experiments.) Cells were considered to be heterocysts only if they contained the polar granule<sup>6</sup> characteristic of heterocysts, and were considered to be spores only if they were at least twice as long as a normal vegetative cell, and showed no sign of septation. Growth was measured as an increase in the chlorophyll content of a culture, as determined with methanolic extracts<sup>7</sup>.

Filaments grown in SSM show no acceleration of sporulation until the fifth day of culture, whereas the acceleration of sporulation of filaments grown in conditioned SSM starts essentially immediately (Fig. 1). The final percentage sporulation is approximately the same in the two cultures. Growth and sporulation of *C. licheniforme* in SSM therefore modifies (conditions) that medium in a way that makes it stimulatory to spore formation on reinoculation. No significant difference in growth accompanies the difference in sporulation. Therefore, stimulation of sporulation cannot be due to an effect on growth. Conditioning also had no significant effect on the pH of SSM.

Supplementation of conditioned SSM with all the constituents of SSM does not affect the sporulation-stimulation which results from conditioning (Table 1). Supplemented, conditioned SSM contains all of the components of SSM in concentrations equal to or greater than their concentration in SSM. The stimulation of sporulation which is effected by conditioning of SSM is not, therefore, the result of a depletion of the medium. Rather, the filaments produce a substance which is released into the medium and which stimulates the differentiation of spores in newly inoculated filaments. We conjecture that sporulation of the original inoculum results from an increasing concentration of this same substance.

A 1:19 dilution of conditioned SSM with SSM retains 50% of its sporulation-accelerating activity. Lyophilised samples retain activity after storage for at least 1 month at room temperature, reconstitution with water or SSM, and sterilisation by autoclaving.

Blue-green algae release a large amount of polypeptidic and other organic material into their medium<sup>8–12</sup>. The substance produced by *C. licheniforme* may function normally as an extracellular agent, an intrafilamentous agent, or both. As an extracellular agent, it might become more concentrated during stagnation or desiccation of a natural body of water, and thereby signal the need for

Table 1 Effect of supplementing conditioned medium with components of fresh sporulation medium

Medium	% Heterocysts with spores	
	A	B
Standard sporulation medium (SSM)	$6.4 \pm 2.7^*$	$5.8 \pm 2.6^*$
Conditioned SSM	$66.0 \pm 6.1$	$64.8 \pm 6.6$
Conditioned, supplemented SSM	$68.0 \pm 13.8$	$67.2 \pm 12.8$

In experiments A, constituents of SSM were added to liquid, conditioned SSM. In experiments B, liquid SSM was added to lyophilised, conditioned SSM.

\* Mean  $\pm$  s.e., from five experiments, each of which was assayed after 3 d of culture.

Fig. 1 Time course of sporulation of *C. licheniforme* in SSM (●) and in SSM conditioned by previous growth and sporulation of the alga (○).

*C. licheniforme* to sporulate so as to survive an impending period of dryness. Within filaments, the substance may be involved in the possible induction, by heterocysts, of the sporulation of adjacent vegetative cells<sup>13</sup>. Thus, if heterocysts induce adjacent vegetative cells to sporulate by producing this substance, and if some of it were to leak out, the exogenous supply could accelerate sporulation in a second inoculum by supplementing the supply, within vegetative cells, which comes from heterocysts. Alternatively, the juxtaposition of the first-formed spores to heterocysts may mean that the heterocysts control the entry of, activation of, or response to, the exogenous factor.

## Inference of the time of origin of some *Drosophila* species

MUCH attention has recently been paid to the interpretation of protein evolution through amino acid substitution. These events are under genetic control and seem, in certain well documented cases, to occur at a constant rate per site per

year for many species<sup>1,2</sup>. At the population level, arguments have been adduced that the observed allozymic variation may also have similar clock-like properties<sup>3</sup>. A further area of present interest is the existence of certain pairs of species which show only very slight genetic difference as measured by allozymes<sup>4–6</sup>. These cases may represent pairs of newly formed species. Thus, genetic similarity may serve as direct measure of the recency of the cladistic event which separated the two compared lines of descent. This note extends the 'protein clock' idea to a series of species endemic to a set of successively younger island volcanoes, for which ages are well documented.

The ages of each of the twelve volcanoes comprising the five largest Hawaiian Islands (Kauai, Oahu, Molokai, Maui and Hawaii; see inset, upper left, Fig. 1) are accurately known from potassium-argon and magnetic declination data<sup>7</sup>. According to a well-supported theory, each volcano has been formed in sequence from north-west to south-east. They have emerged above the ocean in the order listed above, as the Pacific crustal plate has drifted north-westwards over a fixed 'hot spot' in the Earth's mantle<sup>8</sup>. The ages of the oldest rocks of each volcano<sup>7</sup> can be read along the horizontal axis in Fig. 1.

Eight very closely related but morphologically distinct (that is, non-sibling) species of the *Drosophila planitibia* subgroup are found on these islands<sup>9,10</sup>. They show very narrow geographical distributions, being restricted to the volcanoes listed under each species name on Fig. 1. The island of Hawaii shows no lava flows older than 700,000 yr (ref. 11), so the two sympatric species endemic to the island of Hawaii must be relatively newly formed. These species, *D. heteroneura* and *silvestris*, are, moreover, virtually indistinguishable electrophoretically<sup>5</sup>. *D. heteroneura*, probably the newest species in the series, has been selected as a standard for pairwise comparisons with each of the other seven species. Genetic similarities based on allozymes (Rogers<sup>12</sup> coefficient *S*) have been used in these comparisons.

Along the ordinate in Fig. 1 is given the genetic distance, *D*, obtained in pairwise comparisons between *heteroneura* and each of the other seven species. Following Nei's<sup>13</sup> suggestion, *D* has been calculated as the negative natural logarithm of the similarity coefficient. Differences calculated from the data<sup>5</sup> have been plotted against time, measured by the age of the oldest known emergent rocks of each volcano or island. The time of each cladistic event (splitting) is indicated along a diagonal line, *A*, in Fig. 1. This line assumes allozymic identity at separation and then an accumulation of genetic difference directly proportional to the elapsed time since the cladistic event. Diagonal *A* assumes that genetic difference accumulates at a rate of 1% in 20,000 yr. These are large, slow-breeding flies of high, cool rain forests; there may be no more than two generations a year.

These assumptions fit the age of the islands, the endemic position of the species and the chromosomal phylogenies reasonably well. For example, the cladistic event separating *D. substenoptera* of Oahu from the line leading from *picticornis* of Kauai towards *heteroneura* would have occurred when Kauai and West Oahu (Waianae) were the only existing emergent volcanoes. *D. neopicta*, a pivotal ancestor common to the more advanced species in the chromosomal phylogeny<sup>10</sup>, would have been, as expected, the first of the series to colonise Molokai. At first glance, *hemipeza* seems, from the electrophoretic data alone, not to be old enough to have evolved ancestrally on Oahu. This is, however, in accord with earlier theories based on chromosomes<sup>9,10</sup>. Thus *hemipeza* has been considered a 'back-migrant', having colonised Oahu relatively recently from a Molokai ancestor.

Diagonal dashed lines *B* and *C* (Fig. 1) assumes a slower and faster rate of change respectively. *B* shows an accumu-

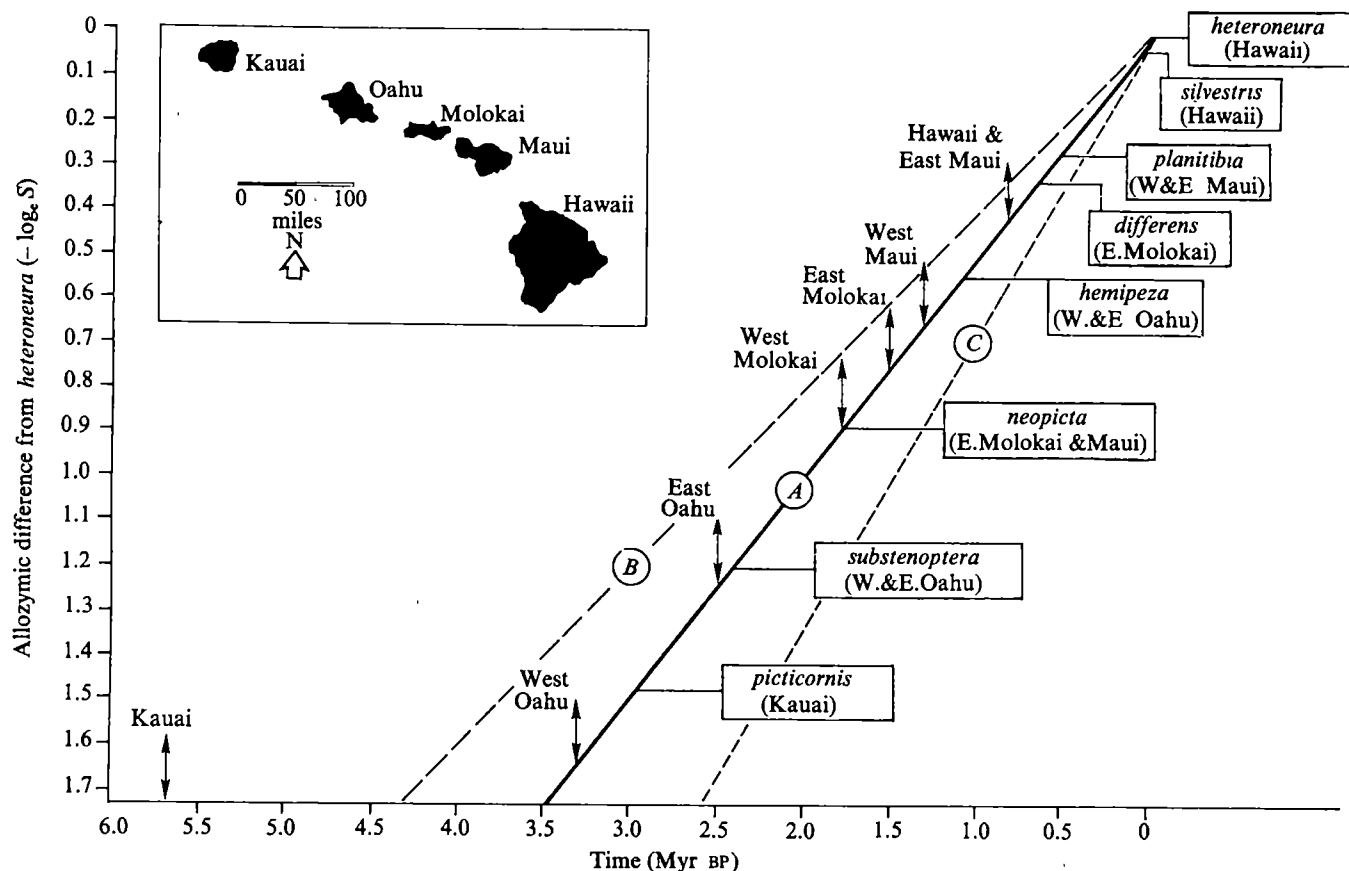

Fig. 1 Allozymic difference and time of species origin in eight species of Hawaiian *Drosophila* (*planitibia* subgroup).

lation genetic difference at the rate of 1% in 25,000 yr and C a rate of 1% in 15,000 yr. Both of these assumptions produce a less satisfactory fit of the data on differences to the geological, geographical and chromosomal data. The rate which fits best, suggests that a level of  $D=1.0$  may be attained after two million years of separation. This is about 15 times faster than the rate suggested by another well-documented case<sup>8</sup>.

Accordingly, the following cautious suggestion may be made. Accumulation of electrophoretically detected protein differences over geologic time may possibly serve as a useful clock mechanism, permitting details of the past evolutionary history of a species to be inferred from the biochemical state of the living forms.

## Positional signalling by mouse limb polarising region in the chick wing bud

THE development of the chick limb may be viewed in terms of positional information; that is, the spatial pattern of cellular differentiation results from the cells interpreting their position in a three-dimensional coordinate system<sup>1</sup>. We have presented evidence that positional information along the antero-posterior axis is specified by a signal from the zone of polarising activity (ZPA), which is at the posterior margin of the wing bud<sup>2,3</sup>. Grafts of ZPA to anterior regions of an early bud result in mirror image duplication between grafted ZPA and host ZPA which is particularly evident in the pattern of the digits. The three digits of the chick wing<sup>4</sup>, digits 2, 3, and 4 appear to be specified by their distance from the nearest ZPA, digit 4 being closest, then digit 3 and then digit 2. The ZPA from the leg can also specify additional wing digits when grafted into the wing which suggests that the positional information along the antero-posterior axis in leg and wing is similar, but that interpretation differs. We therefore wanted to know whether a ZPA was present in other classes of vertebrates, and if so whether the signal from it was also similar. We investigated this question by grafting tissue from embryonic mouse limbs into developing chick wing buds.

Arms and legs of mouse embryos aged 10 d (the day of the vaginal plug was taken as day 0) were used to provide tissue to graft into the chick wing. These limbs were chosen as, morphologically<sup>5</sup>, they resemble stages of the chick wing which have been shown to possess a ZPA. As far as we can judge from the work of Jurand<sup>6</sup>, the time taken to lay down the pattern of the forelimb is approximately the same for both chicks and mice. The arms and legs were cut off

**Fig. 1** Dorsal views of whole mounts of operated wings stained to show cartilage pattern. *a*, Wing resulting from a graft of a mouse arm ZPA showing a pattern of digits 32234. Note there is a small nodule of cartilage at the anterior margin of the wing, but not an identifiable digit 4. *b*, Wing resulting from a graft of a piece of tissue from the anterior margin of a mouse arm showing a normal pattern of digits, 234. The little hooks are the pins used to keep the grafts in place.

the mouse embryos, and regions from posterior margins of the limbs  $\sim 300\mu\text{m}$  from the tip were tested for ZPA activity. This region was taken because it would correspond to the ZPA of the chick limb bud. These small pieces of mouse limb tissue were pinned into holes cut into the anterior margins of embryonic chick wings (stage 20–22) opposite somite 16 in contact with the apical ectodermal ridge. (In this position with an implanted chick ZPA the pattern of digits in the resultant wing has been shown<sup>3</sup> to be 432234 or 43234.) In a few cases the graft was placed opposite somite 17. The host chick embryos were then incubated for a further 5 d at 37 °C; then they were killed and the pattern of the digits of the operated wing was examined. From 20 grafts of these regions from mouse limbs, we obtained 13 wings with extra digits; 5 wings with normal digits; and 2 wings with extra pieces of cartilage which could not be identified as particular digits. Of the 13 grafts which produced wings with extra digits, 6 wings had the digit pattern 2234 and the remaining 7 wings 32234 or 3234 or 334 (see Fig. 1*a*). Regions of both arms and legs of mouse embryos were used in these experiments, and there was no detectable difference in the ability of these to specify additional digits in the wing. As a control, we took equivalent pieces of tissue from the anterior margin of mouse legs and arms and grafted these into chick wings in the same way. All 7 of these wings were normal, with no extra digits (see Fig. 1*b*). In five additional grafts, more proximal pieces of tissue from the posterior margins of the mouse limbs were assayed and these operated wings were normal.

These results show that the embryonic mouse limb possesses a ZPA and its position is similar to that in the embryonic chick wing. Moreover, this mouse ZPA can specify additional digits in the chick wing. We would emphasise that the response to a grafted ZPA has thus far not been obtained by grafting any other tissue, even though a wide variety have been tested. Such test tissues include: tissues from other regions of the chick limb, other embryonic chick tissues such as liver and brain, and rat endocrine organs.

The pattern of digits specified by the mouse ZPA must be compared with that specified by a chick ZPA. There was no way of predicting the effect of the mouse ZPA in the chick limb, since we know neither the relative level of the signal, nor the threshold for specifying the various digits of the mouse. Whereas with a chick ZPA opposite somite 16 one almost always obtains a well formed digit 4 adjacent to the graft<sup>3</sup>, with the mouse ZPA this never occurred. There is reason to believe that the signal from the ZPA is graded, and falls off with distance<sup>3</sup>. Whenever we have effectively reduced the signal, by placing the chick

ZPA further away from competent tissue, or by interfering with its propagation by Nucleopore filters, digit 4 is not formed, but digits 3 and 2 may develop. Thus the inability of the mouse ZPA to specify digit 4 may be caused either by its specifying an intrinsically lower positional value, or by the transmission of the signal being impaired.

Slack (personal communication) has recently shown that there is a region similar to the ZPA in early amphibian embryos, and one may thus reasonably infer that a ZPA is present in all vertebrates with limbs. Our results suggest that the signal from it may be the same in all vertebrates, the differences along the antero-posterior axis being due to differences in interpretation. In this connection it is of interest that mouse dermis can interact with chick epidermis to produce feather buds from the epidermis<sup>7,8</sup>, and Waddington<sup>9</sup> showed that Hensen's node from a rabbit gave rise to a secondary neural tube when implanted into a chick host of the same developmental stage.

We thank Rodney Meredith for pregnant mice, and the Medical Research Council for support.

## Suppression of the incidence of death with spontaneous tumours in DBA/2 mice after *Corynebacterium parvum*-mediated rejection of syngeneic tumours

KILLED *Corynebacterium parvum* has been effective when administered into tumours or when included as a subcutaneous inoculum containing tumour cells (the subcutaneous site, unlike the intradermal site<sup>1</sup>, facilitates early

tumour cell dissemination)<sup>2-4</sup>. After tumour rejection, the augmented host resistance prevented progressive growth of potentially lethal metastases present at the time of therapy<sup>5</sup>. In addition, animals rejecting tumours formed from primary grafts of tumour cells admixed with killed *C. parvum* (compared with those rejecting tumours after intratumour therapy with *C. parvum*) exhibited an augmented tumour-specific protection against inoculation of large challenge cell doses<sup>6</sup>. Whitmire and Huebner<sup>7</sup> reported a significant decrease in incidence of 3-methylcholanthrene-induced malignancies in C57BL/Cum and BALB/c C<sub>v</sub> mice after preimmunisation with formalin-killed wild-type virus and Rauscher leukaemia virus vaccines administered with Freund's complete adjuvant. We have now found a considerable decrease in the incidence of spontaneous tumours in the high-incidence strain of DBA/2 mice after rejection of tumours formed from subcutaneous transplants of syngeneic mammary adenocarcinoma cells admixed with killed *C. parvum*.

DBA/2 female mice (4-6 weeks old, Jackson Laboratory) and the well differentiated syngeneic T1699 mammary adenocarcinoma (Jackson Laboratory) were used. Seven hundred and fifty previously unsensitised mice were separated into five equal groups and received subcutaneous injections as described in Table 1. We included 60 unsensitised mice which received 10<sup>6</sup> living tumour cells alone. The experiment was repeated 3 months after the start of the initial studies. In addition (Table 2) three groups of 50 unsensitised mice received subcutaneous injections as for groups 1, 4 and 5. They were evaluated for tumour-specific resistance.

Of the five groups (Table 1), mice receiving subcutaneous living tumour cells and killed *C. parvum* (group 5) developed tumours at the injection site. Tumours grew for 11 d (mean) followed by their rejection in all animals as previously described<sup>2</sup>. Only four of the 150 mice in group 5 developed spontaneous tumours (mammary adenocarcinomas) at 10-13 months of age. They exhibited minimal increase in tumour size (from the day of origin) for approximately 60 d (mean) followed by accelerated tumour growth and death with growing tumours and metastases (survival range from onset of tumour was 77-96 d). Mice given irradiated tumour cells mixed with *C. parvum* (group 4) exhibited no tumour growth at first but 49 developed spontaneous tumours at 9-13 months (with growth patterns

**Table 1** Incidence of death from spontaneous tumours in DBA/2 mice

Group (150 mice per group)	Deaths from spontaneous tumours	
	Experiment 1	Experiment 2
(1) 0.9% NaCl	105	117
(2) Killed <i>C. parvum</i> (200 µg) alone	96	107
(3) Irradiated T1699 cells (10 <sup>6</sup> ) alone	101	112
(4) Irradiated T1699 mixed with killed <i>C. parvum</i> (200 µg)	49	56
(5) 10 <sup>6</sup> Living T1699 cells mixed with killed <i>C. parvum</i> (200 µg)	4	9
10 <sup>6</sup> Living T1699* cells (60 mice)	60	60

\*All animals died with growing tumours and metastases after injection of tumour cells.

Effect of *C. parvum*-mediated rejection of T1699 mammary adenocarcinoma cells on death with spontaneously growing tumours in DBA/2 mice. Groups of DBA/2 mice (150 animals each) received subcutaneous injections (0.2 ml) of one of the following (1) 0.9% NaCl; (2) killed *C. parvum* (200 µg) and 0.9% NaCl; (3) 10<sup>6</sup> irradiated T1699 tumour cells (10,000 r.); (4) 10<sup>6</sup> irradiated T1699 cells with killed *C. parvum* (200 µg), and (5) 10<sup>6</sup> living T1699 cells with killed *C. parvum* (200 µg). A further 60 mice received 10<sup>6</sup> living T1699 cells alone. The animals were inspected weekly for 30 months or until death with or without growing tumours. All animals receiving living tumour cells mixed with killed *C. parvum* exhibited tumour growth (at injection site) for 11 d, followed by tumour rejection. Mice receiving tumour cells alone died with growing tumours and metastases.

**Table 2** Tumour-specific resistance in DBA/2 mice

Initial injection	Second injection (5 mice per group) Live 10 <sup>7</sup> tumour cells	Survival after second sub- cutaneous injection (%)
(1) NaCl (0.9%)	T1699 cells	0
	CAD <sub>2</sub> cells	0
(4) 10 <sup>6</sup> Irradiated T1699 tumour cells mixed with killed <i>C. parvum</i> (200 µg)	T1699 cells	100
	CAD <sub>2</sub> cells	100
(5) 10 <sup>6</sup> Live T1699 tumour cells mixed with killed <i>C. parvum</i>	T1699 cells	100
	CAD <sub>2</sub> cells	0

Tumour-specific protection in DBA/2 mice after *C. parvum*-mediated rejection of T1699 tumours. At 20 months, 10 surviving animals from each of the above three groups were separated into two subgroups of five mice each. They then received subcutaneous injections (0.2 ml) of either 10<sup>7</sup> T1699 or 10<sup>7</sup> CAD<sub>2</sub> cells.

similar to those in group 5) followed by death with growing tumours and metastases (range of survival after onset of tumour was 70-102 d). The remaining three groups had higher incidences of spontaneous tumours. Of these, 105 treated with 0.9% NaCl (group 1) developed tumours at 8-15 months and died with growing tumours and metastases (range of survival from onset of tumour was 40-60 d). The groups treated with killed *C. parvum* (group 2) or irradiated tumour cells (group 3) exhibited similar incidences of spontaneous tumours and survival after onset of tumour (range: *C. parvum*, 32-35 d; irradiated T1699 cells, 44-67 d). Findings were similar in experiment 2. Histological sections from random autopsies revealed that all tumours were mammary adenocarcinomas with various degrees of differentiation. The 60 mice receiving 10<sup>6</sup> living T1699 cells alone (in experiments 1 and 2) all died with growing tumours and metastases between 28 and 48 d after inoculation of tumour cells.

At 20 months of age, 10 surviving animals (Table 2) from each of the three groups (50 per group) given treatments approximate to groups 1, 4 and 5 were separated into two subgroups of five. All mice of a subgroup received subcutaneous injections of either 10<sup>7</sup> live T1699 or 10<sup>7</sup> CAD<sub>2</sub> cells. The CAD<sub>2</sub> mammary adenocarcinoma syngeneic to DBA/2 mice is antigenically different from the T1699 tumour. The characteristics of this tumour which originated spontaneously in a DBA/2 female have been described before<sup>8</sup>. The results (Table 2) show that the animals that did not develop spontaneous tumours (after rejection of tumours formed from grafts of T1699 cells admixed with *C. parvum*: group 5) were protected and did not develop tumours after reinjection of 10<sup>7</sup> live T1699 cells. Findings were similar when the surviving animals from group 4 received a second injection of T1699 cells. But, the subgroups of mice in groups 4 and 5 (Table 2) that received a second injection of 10<sup>7</sup> living CAD<sub>2</sub> cells were not protected and died with growing tumours and metastases as did the mice in group 1 which received either CAD<sub>2</sub> or T1699 cells. All surviving mice (experiments 1 and 2) were dead at the end of 30 months with no tumours.

Thus DBA/2 mice exhibited a 3-6% incidence of death from spontaneous tumours after rejection of tumours formed from grafts of syngeneic mammary adenocarcinoma cells mixed with killed *C. parvum*. Furthermore, mice given irradiated syngeneic tumour cells mixed with killed *C. parvum* exhibited a 50% reduction in that incidence of death with spontaneous tumours compared with the control groups. In addition, mice given either irradiated or living tumour cells mixed with killed *C. parvum* exhibited tumour-specific protection which was evident for 20 months suggesting that the conferred host resistance was of long duration.

These findings were probably associated with the immunostimulant adjuvant properties of *C. parvum*

administered in association with living tumour cells. Thereafter, the augmented response conferred as a result of rejection of a large mass of tumour may have been directed by both virus-specific and tumour-specific transplantation antigens associated with these tumour cells and continued to protect the host from death with spontaneously growing tumours, or perhaps prevented progressive growth of newly formed tumour cells *in vitro*. Evidence for this comes from the demonstration that pretreatment of experimental animals with these viral or tumour antigens protected the recipients against tumour growth from syngeneic cell grafts<sup>9-13</sup>. Considerably less protection was afforded the mice treated with irradiated tumour cells mixed with killed *C. parvum*, which may have reflected a weakened response towards a decreased tumour cell antigen mass, but may correlate with studies showing that optimal usefulness was observed in experimental animals when living tumour cells were used in specific active immunotherapy<sup>17,18</sup>.

The immunopotentiating properties of *C. parvum* in association with tumour cells also conferred augmented host resistance<sup>19</sup>. This vaccine when administered to experimental animals activated both the reticuloendothelial system and phagocytosis for long periods. In addition stem cells were stimulated to differentiate into macrophages in these animals; T and B cells were stimulated to proliferate and recruitment of lymphocytes was stimulated<sup>20-22</sup>. *C. parvum* also stimulated the primitive surveillance mechanisms that have been found to be effective in tumour rejection<sup>19,23,24</sup>.

These studies were funded partially by a grant from the National Cancer Institute.

## Immunosuppression by micromolecular fibrinogen degradation products in cancer

PATIENTS with advanced cancer and lymphoid malignancies often show impaired cellular and humoral immune responses, partly caused by serum factors inhibiting lymphocyte reactivity<sup>1-3</sup>, which, although not fully defined, are considered to be low molecular weight (poly)peptides.

Another frequent finding in malignant diseases is the appearance of circulating fibrin(ogen) degradation products (FDPs)<sup>4,5</sup>. Besides the commonly investigated breakdown products X, Y, D and E, plasmin liberates several small peptides from human fibrinogen, designated "micromolecular FDPs"<sup>6</sup>. These are dialysable, thermostable, have molecular weights between 15,000 and 500 (ref. 6) and have distinct physiological properties<sup>7-10</sup>. Since both the degree of impairment of lymphocyte function and the frequency of FDP formation are related to the extent of neoplastic spread<sup>11</sup>, we investigated the influence of micromolecular FDPs on cellular and humoral immune responses. A striking immunosuppressive activity was found, possibly responsible for impaired immunoresponsiveness in cancer patients. Terminal FDPs were obtained by prolonged digestion of human fibrinogen (Forschungsfibrinogen Kabi) with human plasmin (Forschungsplasmin Kabi) in aqueous solution, pH 7.4, and dialysed against distilled water at 4 °C for 24 h. The dialysate was concentrated by evaporation in a vacuum, reconstituted in physiological saline, sterilised by filtration and added to lymphocyte cultures using a microculture system<sup>11</sup>. As Fig. 1 shows, micromolecular FDPs caused a dose-dependent suppression of PHA-induced lymphocyte transformation, which was 98% at 1.1 mg ml<sup>-1</sup>. These concentrations did not affect cell viability as measured by Trypan blue exclusion. Plasmin dialysates alone, prepared in identical conditions, inhibited neither of the systems tested: separation of fibrinogen on Sephadex G-200 showed no evidence of pre-existing contaminants (Fig. 4).

To characterise the active components, micromolecular FDPs were separated on Sephadex G-25. All preparations revealed four peaks (1, 2, 3 and 4), the first appearing with the void volume (Fig. 2). Peaks were reduced to the initial volume of the sample and tested in the lymphocyte culture. A marked inhibitory activity was always found in peak 3; peaks 1 and 4 were slightly suppressive.

Additional experiments were designed to test the effect of micromolecular FDP on sheep red blood cell (SRBC)-specific primary immune responses in Swiss mice. Animals

Fig. 1 Dose-dependent suppression of PHA-induced <sup>3</sup>H-thymidine incorporation of human peripheral lymphocytes by increasing amounts of micromolecular FDPs. Protein concentrations were assayed according to Lowry *et al.*<sup>19</sup>. After purification on Ficoll-Hypaque 200,000 cells were cultured in 0.1 ml of Eagle's MEM with 10% pool human AB serum using 0.1 ml of PHA-P (Difco) as a stimulant (25 µg per ml culture fluid). Samples of 20 µl of FDP dilutions in saline were added; controls included saline instead of FDPs and MEM instead of PHA. Cultures were collected after 66 h.

Fig. 2 Inhibitory activity of micromolecular FDPs separated by Sephadex G-25 gel filtration on PHA-induced lymphocyte transformation. Chromatography was carried out using column K 16 (Pharmacia, void volume 65 ml) and distilled water as eluant. Peaks were concentrated by evaporation in a vacuum, reconstituted with saline in the original sample volume, and tested as described in Fig. 1. ○, c.p.m. of controls with saline; ●, c.p.m. of cell cultures with FDPs added (mean  $\pm$  s.d.).

were immunised intraperitoneally with  $4 \times 10^8$  SRBCs and simultaneously injected intravenously with various dilutions of FDP. The splenic content of SRBC-specific plaque-forming cells (anti-SRBC PFC) was determined according to Jerne and Nordin<sup>12</sup>. The mean number of anti-SRBC PFC per  $10^6$  spleen cells in primed controls was 1,820 (Fig. 3). Unprimed controls either treated with FDP ( $n=3$ ) or untreated ( $n=6$ ) produced only few "background-plaques" (6–12 PFC per  $10^6$  cells). Treatment with 100  $\mu$ g of FDPs did not alter significantly the SRBC-specific immune response, whereas administration of 130–160  $\mu$ g markedly inhibited PFC production (mean value of 998 PFC per  $10^6$  cells).

To test the effect of different timing on specific PFC production, this dose was administered at different times before and after primary immunisation. The most striking immunosuppression (about 80%) occurred in mice treated with 130–160  $\mu$ g of FDPs 24 h after priming, whereas PFC responses in animals treated with 100  $\mu$ g of FDPs were not significantly different from the control value (Fig. 3).

These findings clearly demonstrate a time-dependent and dose-dependent immunosuppressive action of micromolecular FDP. In this experimental model FDPs act predominantly in the early phase of clonal proliferation, that is 24 h after antigenic challenge. By this time, DNA synthesis will be activated, but significant antibody production is still lacking.

Since we suspected a relationship between immunosuppressive activity and circulating FDPs in the blood of cancer patients, we studied 19 donors with malignant diseases and three patients with hepatic cirrhosis to look

for a correlation between both findings. Because direct measurements of micromolecular FDP are not yet available, we determined the higher molecular weight FDPs in plasma by means of reptilase time, thrombin coagulase time and the ethanol gel test, and in serum using the Laurell technique after collecting blood with Aprotinin.

Serum samples were fractionated by Sephadex G-200 chromatography, and the fourth peak containing the peptide material<sup>1</sup> (Fig. 4) was further chromatographed, on Sephadex G-25 as described for FDP. Chromatography of some sera revealed a first peak (A) corresponding to peak 1 of FDP; in all sera except one, two further peaks appeared, one of which (B) corresponded to peak 3, the other (C)

Fig. 3 Dose-dependent and time-dependent suppression of splenic production of anti-SRBC PFC by micromolecular FDPs in Swiss mice. FDP dilutions were administered intravenously in a single injection at the intervals indicated with respect to intraperitoneal primary immunisation with  $4 \times 10^8$  SRBC. Data represent day-4 PFC responses per  $10^6$  spleen cells (vertical bars indicate s.d.) calculated for groups of six mice. Primed animals receiving no further treatment served as controls ( $n=22$ ). ○, Controls; ●, 130–160  $\mu$ g FDP; ×, 100  $\mu$ g FDP.

to peak 4 of micromolecular FDPs. In the peak 2 region of FDPs no material appeared. Peaks and sera were again added to lymphocyte cultures, and a significant immunosuppressive activity was defined as at least 40% inhibition of PHA-induced  $^3$ H-thymidine incorporation.

Representative experiments are shown in Table 1. The sera and/or Sephadex G-25 peaks of seven patients without signs of circulating FDPs (cases 1–7) revealed no immunosuppressive activity, whereas those of eleven patients with demonstrable FDP (cases 8–18) inhibited lymphocyte transformation markedly. In only four cases investigated so far

Table 1 Occurrence of FDP and of inhibitory plasmatic activity (representative cases)

Case	Reptilase time (s)	Thrombin coag time (s)	Ethanol gel test	FDP Laurell (mg%)	% Inhibition by serum or peaks of rechromatography			
					Serum	peak A	peak B	peak C
2	14.3	18.1	Neg.	0	15	—	—	28.5
5	11.5	16.8	Neg.	0	24.9	—	0	0
6	17.9	18.9	Neg.	0	32.6	—	32.4	32.6
12	27.3	26.0	Pos.	10.0	45.4	—	71.3	16.0
16	32.3	30.9	Pos.	19.0	68.5	—	99.6	68.4
18	21.4	19.8	N.D.	25.0	N.D.	—	98.6	11.9

Diagnosis of all patients investigated: Chronic lymphocytic leukaemia (1,4), anaplastic Ca unknown origin (2), chronic uraemia with Ca rectum (3), Ca kidney (5,14), Hodgkin's disease (6,10,15,20), metastatic Ca mamma (7), liver cirrhosis (8,9,21), metastatic adeno-Ca unknown origin (11), malignoma suspected (12), metastatic solid Ca unknown origin (13), Ca pancreas (16,17), Ca bronchus (18,19), adeno-Ca stomach (22). —, No peak eluted in this position N.D., not done. For normals reptilase time and thrombin coagulase time were 22–24 s; ethanol gel test was negative and FDP Laurell was not measurable.

Fig. 4 Elution patterns (Sephadex G-200) of a patient's serum (curve 1), fibrinogen Kabi before digestion (curve 2), plasmin-digested fibrinogen (curve 3), and the micromolecular FDP separated by dialysis (curve 4). Column K 16 (Pharmacia), 0.1 M Tris-buffer, pH 7.4 as eluant. The micromolecular immunosuppressive molecules appear during plasmin digestion of fibrinogen, the dialysable moiety of which is eluted in the identical position as serum peak 4.

(19–22) was no direct correlation between inhibitory serum factors and circulating FDP evident. The inhibitory activity was most frequently localised in peak B, corresponding to the maximal inhibitory region of FDP eluates. Certain cases—especially with evidence of high FDP values in plasma—showed additional or predominant inhibition in peak C.

Our preliminary results suggest that micromolecular FDP, which are known to inhibit thrombocyte aggregation<sup>7,9,10</sup> and to influence the tonus of smooth muscles<sup>8</sup>, also have immunosuppressive activity. According to separation characteristics on Sephadex G-25, their molecular weight ranges below 5,000. Whether these peptides are identical with other serum inhibitors, not yet characterised definitively, needs further investigation. Clearly, however, in most conditions for which the presence of immunosuppressive serum factors has been reported, fibrinogen degradation products do indeed occur—in carcinomas<sup>2,4</sup>, Hodgkin's diseases<sup>3,13</sup>, renal diseases<sup>14,15</sup>, pregnancy<sup>5,16</sup> and transplant rejection<sup>17,18</sup>. Furthermore, it seems remarkable that in two of our cases with a non-neoplastic disease (hepatic cirrhosis) FDP-containing sera markedly inhibited lymphocyte transformation.

## Correlation between specific cytotoxicity and expression of idiotypic receptors of allograft-infiltrating cells

REJECTION of an allograft is normally accompanied by infiltration of the graft by host cells. The origin, type and receptor specificity of these cells as well as their precise functions are largely unknown, primarily because of the extreme difficulties of quantitative recovery of the infiltrating cells. A promising experimental technique<sup>1</sup> has recently been developed: a spongy matrix tissue is infiltrated by strain A fibroblasts, transplanted into B animals and removed at various times thereafter. Mere physical compression of the 'sponge' releases virtually all of the infiltrating B cells whereas virtually none of the A fibroblasts will be released. The released B-strain cells are functionally intact.

It has been found possible to visualise and enumerate lymphoid cells with specific immune reactivity toward major histocompatibility locus-determined antigens<sup>2,3</sup>. Such visualisation is achieved by the use of specific anti-idiotypic antibodies selectively reacting with B and T lymphocytes carrying idiotypic receptors signifying reactivity against a certain alloantigen. We here describe the cytolytic capacity and idiotype expression of cells invading an *in vivo* sponge 'allograft'.

Fibroblasts were allowed to invade sponge matrix allografts by implantation into the peritoneal cavities of DA, Lewis or BN rats. These strains differ at the major histocompatibility locus<sup>4</sup>. Five days later the sponges were removed and transplanted subcutaneously into the neck of Lewis or DA rats. These rats were killed seven or eight days later (at peak killer activity in the graft (P. J. Roberts and P.H., unpublished)) and the sponges, as well as the draining (axillary-inguinal) and non-draining (popliteal) lymph nodes and the spleens were removed. Cell suspensions were prepared as described previously.

Table 1 Expression of anti-DA idiotypic receptors on graft-infiltrating cells, on draining and non-draining lymph node cells and on spleen cells seven days after grafting of a syngeneic or allogeneic sponge matrix graft

	Graft	Source of cells* Draining lymph nodes	Non-draining lymph nodes	Spleen
Lewis carrying DA graft	56.0	25.1	4.5	9.1
DA carrying Lewis graft	1.3	0.7	0.0	0.1
Lewis carrying Lewis graft	2.0	5.8	5.0	4.9
Lewis carrying BN graft	3.9	7.5	5.4	5.7
Normal Lewis rat	ND	ND	4.5	5.2
Normal DA rat	ND	ND	0.1	0.2

\*Figures refer to the percentages of cells stained by direct immunofluorescence with FITC-conjugated anti-(anti-DA) antiserum<sup>3</sup>. ND, not done.

The percentages of cells displaying idiotypic receptors of Lewis-anti-DA specificity in the various cell-suspensions were analysed using FITC-conjugated anti-Lewis-anti-DA IgG antibodies. As seen in Table 1, low 'background noise' staining was observed in the control DA rats (highest percentage 'positive' cells being 1.3% in the most macrophage-rich population). In contrast, the Lewis cells from normal rats, or from rats carrying BN grafts, were all within the previously found range of percentage<sup>3</sup> (2–7.5% idiotype positive cells). In Lewis cell populations from rats receiving DA sponges, a normal (4.5% anti-DA) idiotypic frequency in the non-draining nodes, a slight increase in the spleen, and highly significant increases in the draining node cells and particularly among the sponge-invading cells were recorded. Thus, a highly selective increase of cells expressing idiotypes signifying anti-DA reactivity were indeed found infiltrating DA grafts transplanted into Lewis rats. Two similar experiments yielded essentially similar results, with a variation in the data of  $\leq 20\%$ .

In a second series of experiments cells invading a sponge allograft (and cells from the various lymphoid organs) were

analysed for idiotype-positive cells, as well as for specific cytolytic activity *in vitro* against relevant target cells. To further define the participating effector cells in this system, an investigation was carried out to determine the percentage of phagocytic or IgG-coated, latex positive (bound on the surface) cells among the idiotype-positive and negative cells. The results of such experiments are shown in Table 2. A clearcut positive correlation between the occurrence of an increased percentage of cells with anti-DA idiotypes and specific anti-DA cytolytic capacity of the same cell suspension was observed (see the results obtained using cells from Lewis rats grafted with DA sponges). When the capacity to bind latex particles on the cell surface and/or phagocytic activity were investigated, striking differences were observed between idiotype-positive cell populations obtained from the various rats and organs.

Lewis-anti-DA idiotype-positive cells obtained from lymph nodes or spleens always contained a majority of latex negative cells irrespective of whether the Lewis rats had, or had not, received any BN or DA sponges. This is to be expected since Lewis-anti-DA idiotype-positive T cells

**Table 2** Percentage anti-DA idiotype carrying cells and cytolytic anti-DA activity seven days after grafting of syngeneic or allogeneic sponges. Distribution of receptors for Fc of Ig and phagocytosis in idiotype-positive and negative cells

\*Total number of anti-Id carrying cells in a given sample by direct immunofluorescence with FITC-conjugated anti-(anti-DA) antiserum.

†The cells were first incubated at 37 °C for 30 min with IgG-coated latex particles. After preparation of the cell smears, each cell was investigated for the presence/absence of surface immunofluorescence, for the presence/absence of latex particles attached on to the cell surface ('Fc-receptor' carrying cells) and for latex particles ingested inside the cell (phagocytic cells). All cells phagocytosing latex particles also attached latex particles on their surface.

‡The killer assay was run overnight in V-shaped microtitre plates using a killer-target cell ratio of 100:1 using <sup>51</sup>Cr-labelled PHA blasts as target cells, with the media and killer conditioned essentially as described before<sup>5</sup>.

normally outnumber B cells carrying the same idiotype by a factor of 5–7 (ref. 3). Graft-invasive idiotype-negative cells had, on average, a higher percentage of latex-positive, phagocytic cells than cell suspensions obtained from lymph nodes or spleens. The 'background' noise of false 'positive' anti-DA idiotype cells in the fluorescent antibody technique was caused by latex-positive, phagocytic cells (see, for instance, figures obtained using cells from DA rats receiving Lewis sponge). We interpret this false positive staining to arise from complexed FITC-IgG molecules being bound by way of Fc receptors. In the DA grafts transplanted into Lewis rats, however, a very high percentage of the total population of graft-invasive cells displayed anti-DA idiotypes as well as the capacity to bind latex particles on the cell surface and phagocytic activity (compare with composition of cells extracted from BN sponges). The exact nature of these latter idiotype-positive, latex-binding and phagocytic cells is unknown, but they may very likely be of macrophage origin. If so, the presence of idiotype-positive material on the surface of the DA sponge invading macrophages would still be obscure (whether from specific T cells<sup>6</sup> or from surface binding of complexes made up of Lewis-anti-DA alloantibodies and DA alloantigen). Also, it would remain to be established whether such idiotype-coated macrophages could act like specifically armed macrophages with regard to DA target cells. Fractionation of the various cell types with subsequent analysis for cytotoxic activity are under way to determine these questions.

In conclusion we can state that an allograft is invaded by a complex variety of cells carrying actively produced or passively adsorbed idiotype receptors on the surface with specific reactivity for the target alloantigens. A positive correlation could be found between the presence of increased numbers of such idiotype-positive cells and the specific cytolytic activity against the relevant alloantigen.

## Cytotoxicity of antibody-coated trypanosomes by normal human lymphoid cells

DESTRUCTION of antibody-coated mammalian target cells by normal human lymphocytes demonstrated by release of <sup>51</sup>Cr-chromate is a phenomenon characterised by its rapidity of action and by the very small amounts of antibody required. It seems unlikely that such a mechanism destroys solely mammalian target cells, and possibly it has a role in immunity to parasitic infections. Butterworth *et al.*<sup>1</sup> demonstrated that normal human blood cells destroy

Fig. 1 Time course of isotope release from *T. dionisii* culture forms. Circle and dot, isotope release from parasites incubated in the presence of antibody (1/100 dilution) and normal human lymphocytes; dot, parasites incubated in the presence of normal human lymphocytes alone; vertical line, incubated in medium alone. Statistical summary: analysis of variance—interaction of time with treatment (antibody, lymphocytes or medium) very significant ( $P < 0.05\%$ ;  $F = 5.5$ , d.f. 14 and 72; limiting value for  $F = 3.82$ ). Loge least significant differences for comparison of means up to 0.239, corresponding to a difference of 5.3% at 20% isotope release, 10.7% at 40% and 16% at 60%.

schistosomula coated with antibody from infected patients.

We present here evidence that normal human lymphoid cells in the presence of specific antibody can cause isotope release from culture forms of *Trypanosoma* (*Schizotrypanum*) *dionisii*, a parasite related to *T. cruzi* with an intracellular stage in its vertebrate host (bats).

Protozoa do not take up enough <sup>51</sup>Cr-chromate to make it possible to use this label in cytotoxicity experiments. Technetium (as <sup>99m</sup>Tc-pertechnetate) can be used as a label for target cells in cytotoxicity experiments if non-radioactive sodium chromate is present in the labelling mixture (unpublished results of D.F., B. Tayabali and P. O'Brien); the target cells are presumably labelled with some complex organometallic ion of chromium and technetium. The isotope is released when the cells are killed, is not reutilised and, like <sup>51</sup>Cr-chromate, gradually leaks out of target cells. Repeated freezing and thawing causes the release of about 70 or 80% of the isotope, and treatment of labelled protozoa with detergent Nonidet causes the release of all the isotope. In all respects, therefore, protozoa labelled with technetium in this way behave like mammalian cells labelled with either <sup>51</sup>Cr-chromate or <sup>99m</sup>Tc-pertechnetate.

Culture forms of *T. dionisii* were grown in a liquid medium (L4N (ref. 2) with the concentration of serum and erythrocyte lysate reduced by half). They were washed three times and incubated with about 1 mCi of sterile <sup>99m</sup>Tc-pertechnetate eluted from a generator (Radiochemical Centre). To this mixture was added 0.1 ml of a solution of sodium chromate ( $13.5 \mu\text{g ml}^{-1}$  in phosphate-buffered saline). After incubation at 37 °C for 1 h, the organisms were washed repeatedly (usually five times) until the count rate in the supernatant had reached an acceptable level (less than 5% of the label in the protozoa). The organisms were then made up to  $10^5$  per ml. Tissue culture Medium

**Table 1** Isotope release from  $^{99m}\text{Tc}$ -pertechnetate labelled *T. dionisii* in the presence of antibody and normal lymphoid cells

Experiment	Time (h)	Dilution of antibody			Lymphocytes alone	Medium alone
		1/10	1/100	1/1,000		
1	3	70.6	61.7	59.9	26.7	17.0
	6	76.9	73.9	67.5	35.0	17.0
2	3	59.7	59.9	48.8	17.8	12.3
	6	72.5	60.0	58.5	16.5	16.3
3	3	47.6	—	26.5	19.8	12.2
	6	49.9	—	26.8	18.2	17.0

Controls: normal rabbit serum alone and antiserum to *T. dionisii* alone gave isotope release not significantly different from that in the presence of medium. Normal rabbit serum with lymphoid cells gave isotope release not significantly different from that of lymphoid cells alone.

Summary of statistical analysis. Effect of antibody treatment very highly significant in all experiments ( $P < 0.05\%$ ). Experiments 1 and 2:  $F = 469$ , d.f. 4 and 90; limiting value for  $F = 5.6$ ; experiment 3:  $F = 83$ , d.f. 3 and 54; limiting value of  $F = 7.01$ . Log<sub>e</sub> least significant difference for comparison of means up to 0.128 for experiment 1 (corresponding to differences of 4% at 30% isotope release and 8.2% at 60%), up to 0.164 for experiment 2 (corresponding to 5.3% at 30% and 10.6% at 60%) and up to 0.174 for experiment 3 (corresponding to 3.8% at 20% and 9.5% at 50%).

199 with 10% foetal calf serum (previously heated at 56 °C for 2 h) was used throughout. Normal human peripheral blood lymphoid cells were prepared by the methocel/carbonyl iron method from defibrinated blood. Rabbit antiserum to *T. dionisii* prepared by three injections ( $10^7$  organisms in Freund's complete adjuvant intramuscularly, subcutaneously; and  $10^7$  sonicated organisms intravenously) at 14-d intervals, and collected 12 d after the last injection, was heated to 56 °C to destroy complement activity, and diluted in medium. Samples of 100  $\mu\text{l}$  of labelled *T. dionisii* ( $10^4$  organisms), 100  $\mu\text{l}$  of diluted rabbit antiserum and 100  $\mu\text{l}$  of human lymphoid cells ( $2 \times 10^5$  cells) were mixed in small plastic tubes and incubated at 37 °C for up to 6 h. After this time half of the supernatant was removed from the tube and counted in a sodium iodide crystal scintillation counter together with the tube containing the remainder of the supernatant and the remaining organisms, so that the percentage of isotope released could be calculated. All experiments were subjected to statistical analysis by analysis of variance, and differences between means of groups of tubes were tested for significance by Duncan's multiple range test.

Table 1 shows that normal human lymphocytes in the presence of dilutions of antibody as high as 1/1,000 cause considerable isotope release from the parasites. Lymphocytes alone cause more isotope release than the spontaneous leakage from organisms incubated in medium as also occurs when human target cells are incubated in the presence of human lymphoid cells, and its significance is not understood.

Figure 1 shows that significant isotope release occurs within 1 h and progresses to completion at about 6 h. Isotope release in the presence of lymphocytes alone also increases, though more slowly. Spontaneous leakage of isotope from organisms incubated in medium alone remains fairly constant between 1 and 6 h.

It would clearly be premature to claim that this demonstration of antibody-dependent lymphocyte-mediated cytotoxicity of *T. dionisii* establishes its role in immunity against protozoal parasites. Nevertheless, the requirements for very small amounts of antibody, its dependence on a ubiquitous normal cell, and the rapidity of its action at least make this form of cytotoxicity a candidate which may have an important role in limiting the spread of intracellular parasites from one cell to another.

## Preparation and characterisation of an antiserum to the mouse candidate for immunoglobulin D

ANALYSIS of mouse B-lymphocyte surface immunoglobulin (Ig) by isotopic labelling techniques reveals little, if any, IgA or IgG. Instead, the surface Ig consists of monomeric IgM and an Ig similar in physicochemical properties to human IgD<sup>1-3</sup>. In the absence of sequence comparison between human IgD and its assumed mouse counterpart, this assignment is tentative. With this proviso, however, and for the sake of clarity in presentation, we refer to this immunoglobulin as IgD. During development, IgM-bearing cells are the first to arise and the ratio of IgM-IgD determined with labelled adult lymphocytes is higher in the spleen than in lymph nodes or Peyer's patches<sup>1-4</sup>. These findings, however, give the total yield of the two Ig classes and not their distribution on individual lymphocytes. On the basis of the absence of immunoglobulins other than IgM or IgD on the surface of B lymphocytes, we indicated the presence of cells bearing IgM or IgD, or IgM and IgD in mouse spleen cell suspensions<sup>5,6</sup>. In these experiments, IgM was first capped with rhodamine-labelled anti- $\mu$  and subsequent ring staining with fluorescein-labelled anti-Fab in the presence of sodium azide was taken as evidence for the presence of IgD. We report here the preparation of an antibody specific for mouse IgD, and its use in the characterisation of mouse B-lymphocyte surface Ig.

Plasma cell membranes were prepared from the spleens of 1,750 BALB/c mice (wet weight 160 g) to yield 130 mg of protein. The membranes were dissolved in 25 ml of phosphate-buffered saline (PBS) containing 1% (w/v) Nonidet P-40 and 1 mM phenylmethylsulphonyl fluoride, centrifuged at  $10^5g$  for 3 h, and then passed successively through three columns of Sepharose 4B: (1) normal rabbit Ig (6.0 mg)-Sepharose (3.0 ml); (2) rabbit anti-mouse  $\mu$  (3.6 mg)-Sepharose (1.8 ml); (3) rabbit anti-mouse Fab (5 mg)-Sepharose (2.5 ml). The rabbit anti-mouse  $\mu$  was prepared by applying a specific rabbit anti- $\mu$  serum to IgM ( $\lambda^1$ ) (MOPC 104E)-Sepharose, and then eluting the antibody with molar acetic acid. Anti-Fab was prepared similarly and was a mixture of the following acid eluates: rabbit anti-whole IgG<sub>1</sub>(K)(MPC 21) retained by IgG<sub>2a</sub>(K)(Adj PC5)-Sepharose, rabbit anti-whole IgG<sub>2a</sub>(K)(Adj PC5) retained by IgG<sub>1</sub>(K)(MPC 21)-Sepharose and rabbit anti-whole IgM(K)(TEPC 183) retained by IgG<sub>2a</sub>(K)(Adj PC5)-Sepharose. Purified antibody was coupled to Sepharose<sup>8</sup> to give high capacity immunoabsorbants. After passage of the sample, the columns were washed with phosphate-buffered

**Fig. 1** Surface immunoglobulin of murine splenic lymphocytes. Spleen cell suspensions of 3–6-month-old, specific pathogen-free, female CBA mice were labelled with  $^{125}\text{I}$  by the lactoperoxidase-catalysed procedure<sup>18</sup>, washed once in ice-cold PBS and then lysed for 10 min at 0 °C in 1% (w/v) Nonidet P-40 in PBS containing 1 mM phenylmethylsulphonyl fluoride and 100 mM recrystallised iodoacetamide. The centrifuged lysate ( $30,000g \times 15$  min) was passed over Sephadex G-25 equilibrated with the solution used for lysis of the cells. Labelled IgD was precipitated at 0 °C by addition of rabbit antibody (10  $\mu\text{l}$ ) and a goat anti-rabbit Ig (100  $\mu\text{l}$ ). The precipitate was removed by precipitation and the supernatant was further reacted with rabbit anti-mouse  $\mu$  chain (10  $\mu\text{l}$ ) and goat anti-rabbit IgG (100  $\mu\text{l}$ ). Both precipitates were washed three times with ice cold 0.5% (w/v) Nonidet P-40 in PBS, once with 50 mM sodium phosphate, pH 7.0, and then dissolved in 50 mM sodium phosphate, pH 7.0, containing 2% (w/v) sodium dodecyl sulphate (SDS) and 1 mM dithiothreitol. The precipitates were heated at 100 °C for 10 min, and then iodoacetamide was added to 100 mM. Internal  $^{125}\text{I}$ -labelled<sup>19</sup> markers were added to the labelled cell surface Ig samples, which were then resolved by SDS-polyacrylamide gel electrophoresis<sup>1</sup>. After electrophoresis the gels were sliced into 1-mm segments and radioactivity was determined. Values were corrected for cross-channel spill and plotted with the top of the gel on the left hand side of the figure. Reduced cell surface Ig precipitated with the anti-IgD (a and c) and subsequently anti- $\mu$  (b and d) were electrophoresed on 7.5% (a and b) and 4.2% (c and d) polyacrylamide gels. —,  $^{125}\text{I}$  incorporated into cell surface Ig; . . . ,  $^{125}\text{I}$ -labelled internal marker.

1–4) A similar profile resulted when 100  $\mu\text{l}$  of normal mouse serum was incubated with 10  $\mu\text{l}$  of the rabbit antiserum (30 min room temperature) before addition of the radioactive sample. Thus circulating IgD is likely to be present in very small amounts in the mouse. Recovery of IgM was possible from the supernatant of the first precipitation by addition of anti- $\mu$  (Fig. 1b). The radioactive material which runs before and after the  $\mu$  and  $\delta$  chains also occurs in non-specific precipitates. Furthermore, the higher molecular weight material largely disappears when less concentrated polyacrylamide gels are used (Fig. 1c and d), and thus may represent an aggregation artefact. The disadvantage of the less concentrated polyacrylamide gels is that there is no resolution between the  $\mu$  and  $\delta$  chains. When unreduced samples of cell surface Ig were electrophoresed on 4.2% (w/v) polyacrylamide gels, the material then coincided with a disulphide-linked 7S IgM internal marker<sup>1</sup>.

On the basis of these results, we were therefore confident that our antiserum was specific for mouse IgD, and thus turned to studies using fluorescent reagents prepared by DEAE chromatography<sup>10</sup> to stain live cells<sup>11</sup>. With 1–2-week-old CBA mouse splenocytes, we were unable to find significant numbers of cells reacting with the anti-IgD, whereas anti-mouse  $\mu$  chain revealed 8–14% of the cells as positive. Cells bearing IgD were, however, readily apparent in the spleens of 6-week-old mice (~20% total lymphocytes). Absorption of the antiserum with foetal liver cells ( $3.6 \times 10^{10}$  cells per ml of serum) did not remove its capacity to react with spleen cells, whereas absorption with adult spleen cells did ( $1.9 \times 10^{10}$  cells per ml of serum). The finding that IgM precedes IgD in ontogeny<sup>1,3</sup> is therefore confirmed.

We next determined the distribution of IgM and IgD on lymphocytes from various lymphoid organs (Table 1). Single staining was done by the indirect procedure. Double staining was achieved by capping IgD with a fluorescein-labelled system followed by staining for IgM with a rhodamine-labelled rabbit anti-mouse  $\mu$  chain under non-capping conditions. From the single staining results it is immediately clear that IgD constitutes the major cell surface immunoglobulin of lymph nodes and Peyer's patches, as would be suggested by biochemical investigations<sup>1–4</sup>. Double staining of lymphocytes from these organs not surprisingly revealed most of the Ig-positive cells as having only IgD, although some doubles (IgM and IgD) and occasional cells positive for IgM alone were also present. In the spleen, however,

saline (PBS), emulsified in complete Freund's adjuvant and injected into rabbits<sup>9</sup>. Each column was divided between two rabbits. Serum from a rabbit receiving the third column, the anti-Fab, was passed over IgG<sub>2a</sub>(K)(Adj PC5)-Sephadex and then IgM(K)(TEPC 183)-Sephadex. The absorbed serum was tested by radioimmunoassay<sup>5</sup> and found to be unreactive with  $^{125}\text{I}$ -labelled IgM(K)(TEPC 183), IgM( $\lambda_1$ )(MOPC 104E), IgA( $\lambda_2$ )(MOPC 315), IgG<sub>1</sub>(K)(MPC 21), IgG<sub>2a</sub>(K)(Adj PC5), IgG<sub>2b</sub>(K)(MOPC 195), IgG<sub>3</sub>(FLOPC 21),  $\lambda$  chains (RPC 20), K chain (MOPC 41) and mouse  $\alpha_2$ -macroglobulin. The radioimmunoassay will detect less than 1  $\mu\text{g}$  of antibody in 1 ml of serum.

When used in conjunction with rhodamine-labelled goat anti-rabbit Ig (ref 10), the absorbed antiserum stained<sup>11</sup> about 20% of CBA strain spleen cells, but not thymocytes from CBA, C57BL, DBA/2, C3H, AKR and BALB/c mice. By this test, the antiserum was also negative for peripheral T cells prepared by the nylon wool method<sup>12</sup>.

We then evaluated the antiserum by testing with  $^{125}\text{I}$ -surface labelled spleen cells as described before<sup>1</sup>, and found the only Ig precipitated corresponded to IgD (Fig. 1a, refs

Table 1 Frequency of IgM and IgD-bearing cells in mouse lymphoid tissue

	Organ	Anti-Ig	Single staining		$\mu$	Double staining	
			Anti- $\mu$	Anti- $\delta$		$\mu+\delta$	$\delta$
Experiment 1	Peripheral nodes	14.9	3.1	10.5	0.7	1.5	8.1
	Mesenteric nodes	14.4	4.1	10.5	1.1	1.8	7.2
	Peyer's patches	23.1	8.5	26.8	1.6	8.5	19.3
	Spleen	35.6	19.1	23.8	12.1	13.8	12.6
Experiment 2	Peripheral nodes	15.6	3.1	9.1	0.5	2.7	11.1
	Mesenteric nodes	14.7	3.6	12.6	0.8	2.8	11.6
	Peyer's patches	23.2	9.4	22.5	0.8	8.2	14.0
	Spleen	32.2	17.8	25.9	8.7	11.9	14.3

Cell suspensions were prepared from 7-month-old, specific pathogen-free, female CBA mice by teasing the organs with veronal-buffered saline (Oxoid), containing bovine serum albumin (1 mg ml<sup>-1</sup>) (VBS-BSA), and the living cells were stained and prepared for examination as described by Raff<sup>11</sup>. Peripheral nodes collected were superficial cervicals, axillary, brachial and inguinal. For single staining the cells were incubated for 20 min at room temperature with rabbit antiserum, washed three times with VBS-BSA and then suspended in rhodamine-labelled goat anti-rabbit IgG (20 min, room temperature). Samples were washed, and then mounted in 50% (w/v) glycerol in (PBS)-0.03 M sodium azide. For double staining, cells were treated with anti-mouse IgD and fluorescein-labelled goat anti-rabbit IgG as described above. The two layers were essential to ensure capping of all the IgD positive cells. The cells were then incubated in the cold for 20 min with rhodamine-labelled rabbit anti-mouse  $\mu$  chain and with sodium azide at 0.03 M. After washing with cold VBS-BSA-0.03 M sodium azide the cells were mounted and examined under ultraviolet light with a Leitz Orthoplan research microscope fitted with Ploem illumination. At least 500 lymphocytes were assessed for staining and the results are given as percentages of total lymphoid cells observed. All reagents were centrifuged (50,000g, 60 min) on the day of use. On the basis of the double staining protocol, lymphocytes could be classified into three groups, those with green caps (IgD positive), those with peripheral red staining (IgM positive) and those with green caps and red rings (IgM and IgD positive). The rabbit anti-mouse Ig was prepared by immunisation of rabbits with the Fab portion of myeloma protein Adj PC5 ( $\gamma_{2a}$ K) (ref. 20) as described before<sup>9</sup> and was polyspecific, reacting against IgM, IgG<sub>1</sub>, IgG<sub>2a</sub>, IgG<sub>2b</sub>, IgG<sub>3</sub> and IgA (but not other serum proteins) on Ouchterlony analysis. Rabbit anti-mouse  $\mu$  chain was prepared by immunisation with myeloma protein MOPC 104E ( $\mu\lambda_1$ )<sup>9</sup> and absorbing the serum with a 7S fraction of normal mouse serum coupled to Sepharose 4-B. The resulting serum precipitated IgM on Ouchterlony analysis, but did not react with any other mouse Ig class when tested by radioimmunoassay against <sup>125</sup>I-labelled immunoglobulins (see the text and ref. 5). Preparation of rabbit anti-mouse IgD is described in the text. Fluorochrome conjugates were prepared using DEAE-purified Ig fractions, and conjugates with fluorochrome: protein ratios of 1.5–2.5 were selected by chromatography on DEAE<sup>10</sup>.

all three categories of cells were represented in similar proportions.

Our findings in the mouse therefore mirror those in the human<sup>13,14</sup>. In the mouse, there are fewer cells bearing both IgM and IgD, with correspondingly higher numbers of cells with exclusively IgM or IgD. These studies in the human, however, have been made with peripheral blood and so the comparison is not necessarily valid. The biological significance of these subpopulations of B cells should now be open to investigation. Since IgM precedes IgD in ontogeny, we favour the idea that in B-lymphocyte maturation there is differentiation from cells expressing only IgM to those expressing only IgD (ref. 5). An intervening cell type expresses both Ig classes. Thus the B lymphocytes of lymph nodes and Peyer's patches would in the main constitute a more mature population, possibly enriched with memory cells and precursors of cells destined to secrete IgG and IgA. The finding that IgA precursor cells of rabbit Peyer's patches are IgM and IgA negative, but certainly do have surface immunoglobulin<sup>15</sup>, suggests that these cells bear the rabbit equivalent of IgD.

The simultaneous expression of two Ig classes on the cell surface has implications for "switch" and V-C gene integration mechanisms. For example, the two constant region genes for  $\mu$  and  $\delta$  chains are known to share the same V region<sup>16</sup>, and if this reflects the simultaneous presence of two integrated genes (that is VH-C $\mu$  and VH-C $\delta$ ), then a copy-choice mechanism for V-C gene integration<sup>17</sup> is suggested.

## New evidence on the location of the saccharide-binding site of concanavalin A

THE biological activities<sup>1–4</sup> of the mitogenic lectin concanavalin A (con A) depend on the binding of the protein to receptors on the cell surface, and this binding can be inhibited by specific saccharides related to D-mannose and D-glucose<sup>5</sup>. Knowledge of the location and nature of the saccharide-binding site of con A would therefore contribute greatly to understanding the molecular basis of its biological activities. Although the complete amino acid sequence<sup>6–8</sup> and three-dimensional structure<sup>9–11</sup> of con A are known, there has been conflicting evidence on the location of the carbohydrate-binding site. Crystallographic studies with saccharides labelled with heavy atoms indicated that it was in a deep cavity in the molecule, more than 20 Å from the Mn<sup>2+</sup> and Ca<sup>2+</sup> ions<sup>9,12</sup> (Fig. 1). Subsequent magnetic resonance measurements<sup>13–15</sup> as well as crystallographic considerations<sup>16</sup> suggested that the site was 10–12 Å from the metals, and led to the hypothesis that the previously studied saccharides labelled with heavy atoms (for example, o-iodo-phenyl-β-D-glucopyranoside (β-IPG)) were bound by their hydrophobic aglycones, rather than by their saccharide moieties<sup>9,17</sup>.

High concentrations of inhibitory saccharides crack or dissolve con A crystals of the kind used in the structure determination, precluding crystallographic observation of the

**Fig. 1** Schematic representation of the con A tetramer. Each subunit is approximately  $42 \times 40 \times 39$  Å, and the tetrameric complex possesses exact 222 symmetry. The manganese and calcium sites are indicated by Mn and Ca, respectively. The saccharide-binding site near the metals is indicated by S and the  $\beta$ -IPG-binding site in the cavity by I.

carbohydrate-binding site. We have therefore adopted several different approaches to locate the site. We describe here the results of three such experiments: examination of the structure of an insolubilised crystalline con A-saccharide complex, investigation of the structure of demetallised inactive con A, and preparation of a new crystal form of con A containing bound saccharides.

Although specifically bound sugars disrupt con A crystals of the type used in the original structure determination, we have carried out diffraction studies of carbohydrate binding using these crystals. Con A crystals, prepared as described before<sup>9</sup>, were treated with 1% glutaraldehyde for 1 h at room temperature. Addition of specific saccharides to these cross-linked crystals caused considerable changes in the diffraction pattern and a reduction of the limiting resolution from 2 Å to 3.5 Å (Fig. 2). These changes were reversed by soaking the crystals in saccharide-free buffer, and non-binding carbohydrates, such as methyl- $\alpha$ -D-galactopyranoside, did not produce such changes, suggesting that the alteration of the diffraction is caused by non-covalently bound specific saccharide.

**Table 1** Comparison of locations of heavy-metal substituents in con A and its complex with 2-deoxy-2-iodo-methyl- $\alpha$ -D-mannopyranoside

Heavy-metal site*	Coordinates in native con A			Coordinates in the complex		
	x	y	z	x	y	z
Pb1	-13.67	-11.43	18.10	-14.19	-11.79	17.81
Pb2	-8.90	-22.59	11.16	-10.20	-22.10	11.37
Pt1	5.30	-0.35	3.66	5.57	1.04	4.42
Sm1	-13.58	-11.43	18.16	-13.36	-11.70	18.20
Sm3	-8.90	-23.29	11.67	-9.18	-23.05	12.41
II	0.45	-12.47	12.42	0.74	-12.91	13.32

\*Coordinates are in Å referred to an origin at the 222 point of each protein system. Overall figure of merit for the 2-iodo- $\alpha$ -methylmannoside-con A phasing calculation is 0.714 for 1,894 reflections. Heavy-metal sites are named as in ref. 9, except II refers to an iodophenol derivative of the saccharide complex.

To avoid potential nonspecific binding to a hydrophobic aglycone, 2-deoxy-2-iodo-methyl- $\alpha$ -D-mannopyranoside<sup>18</sup>, an inhibitor labelled with heavy atoms, was used to form a con A-saccharide complex. Attempts to solve the structure of this complex with phases from native con A produced electron density maps that we could not interpret. Accordingly, new phases were calculated by multiple isomorphous replacement methods, and refined by electron density modification<sup>19</sup>. The molecular packing is like that of native con A, as indicated by the close similarity of the heavy atom positions in the two proteins (Table 1). In addition, a rotation function<sup>20</sup> calculated between native and saccharide-treated con A has its highest maximum at nearly zero net rotation.

Nearly all the polypeptide chain can be traced in the electron density map, and preliminary interpretation suggests that significant local differences in conformation are induced by carbohydrate binding. The positions of chain segments 95-105 and 195-207 relative to the rest of the molecule are altered, resulting in a disruption of the  $\beta$ -structure in this region. The entire metal-binding region seems to have moved 4-6 Å with respect to the rest of the molecule (Fig. 3). Local changes in this region cannot yet be described in detail, but there seem to be related changes in residues 33-45 and the top two chains of the back  $\beta$ -structure<sup>9</sup>. To locate the bound sugar molecule, a difference map between the complexes with the iodo sugar and its chloro analogue was calculated. The highest peak in this map was approximately 13 Å from the Mn<sup>2+</sup> ion, at 0.74, 0.24, 0.42, which we interpret to be near to residues Gly 227 and Arg 228, in the metal-binding region of the molecule. Assuming that this peak represents the iodine of a bound saccharide molecule, the residues that may participate in con A-saccharide interactions are 14-16, 97-99, 168-169, 207-208, 224-228 and 235-237. These residues surround a shallow pocket near the top of the molecule (Figs 1 and 3)

**Fig. 2** A,  $hk0$  zone of the native con A diffraction pattern. Reflections at the edge of the circle correspond to Bragg spacings of 2.8 Å. The space group is I222 with  $a = 89.91$ ,  $b = 87.23$ ,  $c = 63.07$  Å. B,  $hk0$  zone of the cross-linked 2-iodo- $\alpha$ -methylmannoside complex of con A. Space group I222, with  $a = 92.76$ ,  $b = 86.66$ ,  $c = 64.99$  Å. C,  $hk0$  zone of triclinal con A crystallised from 20% saturated ammonium sulphate, pH 6.8. For comparison with D, a centred cell has been chosen, space group C1,  $a = 119.04$ ,  $b = 103.23$ ,  $c = 132.09$  Å,  $\alpha = 89^\circ 50'$ ,  $\beta = 94^\circ 17'$ ,  $\gamma = 85^\circ 03'$ . D,  $hk0$  zone of a con A crystal grown as in (C) and then treated with 50 mM  $\alpha$ -methyl-D-glucopyranoside in 50% saturated ammonium sulphate. Space group C222<sub>1</sub>, with  $a = 118.09$ ,  $b = 103.54$ ,  $c = 251.8$  Å.

**Fig. 3** *a*, Stereo drawing of the polypeptide backbone in the metal-binding region of native con A. ○, Alpha carbon atoms; ●, residues which serve as metal-binding ligands; CA and MN, calcium and manganese ions, respectively. *b*, The corresponding region of demetallised con A. The opening up of the polypeptide chain around the vacant metal-binding site is visible at the upper right.

and several of them participate in intermolecular interactions in the crystal. Disruption of these lattice interactions on saccharide binding may account for the difficulty of observing specifically bound saccharides in crystals of the type used in the original structure determination. The difference map shows no significantly large peak in the molecular cavity, suggesting that the binding site is elsewhere. This interpretation requires that the binding region in the cavity be a nonspecific site, active only in crystalline con A, inasmuch as in solution, hydrophobic sugars, such as  $\beta$ -IPG, are bound only at the specific site<sup>9</sup>.

The location of the site near the metal-binding region is supported by a study of the structure of demetallised con A. Removal of the bound  $Mn^{2+}$  and  $Ca^{2+}$  ions from native con A causes loss of saccharide-binding activity<sup>21-23</sup>, suggesting that the saccharide-binding site is associated with a part of the con A structure that changes significantly with demetallisation. Demetallised con A was prepared<sup>23,24</sup> and crystallised<sup>25</sup>, and diffraction data to a resolution of 2.8 Å were collected as before<sup>9</sup>. The native and demetallised structures were aligned using molecular replacement methods. In separate experiments, structure factors were calculated for a native con A monomer or dimer in a triclinic cell with the demetallised unit cell dimensions. Complete rotational<sup>20</sup> and translational<sup>26</sup> searches indicated that the demetallised molecule was related to the analogous native con A dimer by a rotation of 7.5° about an axis near  $x$ , in agreement with earlier results<sup>25</sup>, ( $\alpha = 273.8^\circ$ ,  $\beta = 7.5^\circ$ ,  $\gamma = 87.7^\circ$  using Crowther's notation<sup>20</sup>) and shifted slightly along  $z$  (translation = -0.0004, -0.0002, 0.0106 in the demetallised cell), the dimer moving as a single rigid body. (Details of the molecular replacement calculations will be published elsewhere.)

Structure factors calculated for this model, excluding residues in the metal binding region (residues 7-25), showed excellent agreement with the observed data for the demetallised molecule (conventional crystallographic  $R = 42.6\%$ , as compared with 40.4% for the final native con A structure). Difference maps

were calculated with coefficients

$$[(2|F_o| - |F_c|) \exp(i\alpha_c)]$$

and

$$[(|F_o| - |F_c|) \exp(i\alpha_c)]$$

where  $F_o$  are observed demetallised structure factors,  $F_c$  are model structure factors, and  $\alpha_c$  are model phases. Examination of these maps allowed construction of a model of the metal-binding region and comparison of the two structures. The largest differences between the two structures were confined to the metal-binding region, the most significant being an opening of the tightly folded loop (residues 11-23) above the metal atoms, and a rearrangement of the nearby chains involving residues 99, 209, 228 and 237 (Fig. 3). The remainder of the molecule seems to be very similar in the two structures, with most of the changes being small (<1 Å) motions of the backbone or rotations of side chains. In particular, the folding in the region of the molecular cavity is almost identical. This localisation of significant structural differences between active con A and inactive demetallised con A strongly supports the hypothesis that the saccharide-binding site is in the vicinity of the metal-binding residues, approximately 13 Å from the  $Mn^{2+}$  ion, and not in the deep cavity (Fig. 1).

Definitive crystallographic proof of the location of the saccharide-binding site and its detailed characterisation must await the determination at high resolution of the structure of a con A-saccharide complex. To this end, we have prepared a new crystal form of con A that can bind specific sugars without loss of the high resolution diffraction pattern (Fig. 2). The striking similarity between diffraction from this crystal form and that from native con A suggests that solution of the structure by molecular replacement methods will be feasible. It is likely that this determination will confirm the interpretation suggested by the experiments described here that the saccharide-binding site is directly associated with the metal-binding

region of con A. This close association allows a simple explanation of the dependence of saccharide-binding activity on the presence of the metal ions, as the metals may directly stabilise the saccharide-binding residues in their active conformation.

## Concanavalin A blocks desensitisation of glutamate receptors on insect muscle fibres

CONCAVALIN A (con A), a tetrameric lectin which binds to specific carbohydrate residues<sup>1</sup>, has been used in the purification of a glutamate-binding glycoprotein isolated from rat brain synaptosomes<sup>2</sup>, and has been shown to alter the isotherm describing the binding of  $\alpha$ -bungarotoxin to acetylcholine receptors on rat skeletal muscle<sup>3</sup>. Complementary electrophysiological studies on the effect of con A on intact receptor-bearing membranes are, as yet, lacking. We present here evidence that con A abolishes the desensitisation normally observed during repeated iontophoretic application of L-glutamate, the putative excitatory transmitter, to two populations of L-glutamate receptors on locust skeletal muscle fibres.

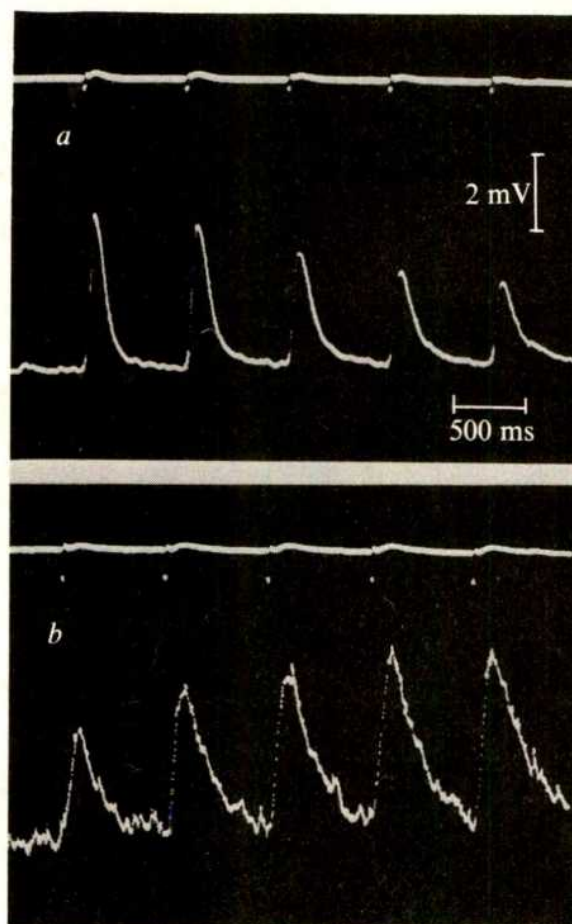

Iontophoresis of L-glutamate (pH 7.0, 1 M) through high resistance (120-300 M $\Omega$  micropipettes) is known to produce three types of response on innervated<sup>4,5</sup>, as opposed to denervated<sup>6</sup>, locust extensor tibiae muscle fibres. When the tip of the glutamate electrode is within a few micrometres of a neuromuscular junction, a rapid transient depolarisation of rise time 10-50 ms and peak sensitivity  $\sim 100$  mV nC<sup>-1</sup> is seen. This event is associated with the activation of excitatory junctional glutamate receptors<sup>4,5</sup>.

These receptors exhibit desensitisation at glutamate pulse repetition rates  $\geq 0.7$  Hz (ref. 5 and Fig. 1a).

Iontophoresis of 1-5 nC of glutamate on to the extrajunctional membrane of locust muscle fibres evokes a biphasic response due to simultaneous activation of two populations of receptors designated as D-type receptors and H-type receptors, which are associated with ionophores for cations (D) and ionophores for Cl<sup>-</sup> (H)<sup>7,8</sup>. The D and H receptors occur evenly over the entire extrajunctional membrane, their sensitivity to L-glutamate iontophoresis being 0.2-0.5 mV nC<sup>-1</sup> (ref. 6), and both types are very readily desensitised by repeated pulses of iontophoretically-applied glutamate (Fig. 2a, b). Indeed, the diffusion of glutamate which occurs from drug-filled micropipettes of resistance  $< 100$  M $\Omega$  is sufficient in itself to inactivate these receptors<sup>8</sup>.

Con A (Sigma, Grade IV), was dissolved in locust saline of composition 200 mM NaCl, 10 mM KCl, 2 mM CaCl<sub>2</sub>, 4 mM NaH<sub>2</sub>PO<sub>4</sub>, 6 mM Na<sub>2</sub>HPO<sub>4</sub>, pH 6.8, and applied topically to the preparations at a concentration of 10<sup>-7</sup> M. No change in membrane potential, input resistance or of frequency of spontaneous miniature potentials was observed. Within 0.5-1 h at 20-22 °C, the depolarising component of the biphasic extrajunctional response was no longer abolished by repeated pulses of glutamate. The H receptors, however, retained their normal rate of inactivation in these conditions (Fig. 3a-c). In sensitivity (0.2-0.5 mV nC<sup>-1</sup>), rise time (40-60 ms) and homogeneous distribution over the extrajunctional membrane, the glutamate-

Fig. 1 a, Iontophoresis of 1-nC glutamate pulses at 720 ms intervals on to an excitatory junction of a muscle bathed in 10<sup>-7</sup> M con A for 5 h. Responses showed desensitisation at a rate typical of junctional receptors in control fibres. b, Fibre exposed to 10<sup>-6</sup> M con A for 1 h. Responses now exhibited simultaneous potentiation and summation to 1-nC glutamate pulses delivered at the same frequency as in a. Note high frequency of spontaneous miniature end plate potentials.

Fig. 2 *a*, Biphasic (D-H) response (lower trace) evoked by iontophoresis of a 5-nC pulse (upper trace) of L-glutamate on to the extrajunctional membrane of a locust muscle fibre. *b*, A second pulse, delivered 4 s later, produced only a small hyperpolarisation, indicating that both D- and H-receptor populations had undergone marked desensitisation. Miniature excitatory potentials are seen on the lower traces.

induced depolarisation in the presence of con A resembled closely the normal D response elicited from control preparations. Bathing the nerve-muscle preparation in saline in which  $\text{Na}^+$  was substituted by choline reversibly abolished the D responses both in the presence and absence of con A.

The increased rate of application of an agonist is known to accelerate receptor desensitisation<sup>9</sup>. This phenomenon, also characteristic of both junctional and extrajunctional D receptors in control fibres of locust muscle, was not observed when glutamate was iontophored on to the extrajunctional membrane following exposure to  $10^{-7}$  M con A. When the frequency of glutamate pulses was raised, potentiation of the D potentials occurred (Fig. 4*a*), while at still higher frequencies a summated form of response appeared (Fig. 4*b*), the amplitude of which was stable for pulse trains of  $< 20$  s. This summated D response decayed rapidly to zero on switching off the iontophoretic current. The rise time of the summated D response in con A saline was reduced with increased rate of glutamate application (that is, increased pulse amplitude or frequency), while the amplitude and decay time were elevated by this procedure. Lateral movement of the glutamate electrode had no significant effect on the quantitative or qualitative aspects of this summated depolarisation, thus confirming its extrajunctional origin. The desensitisation of junctional glutamate receptors was not blocked by  $10^{-7}$  M con A. On increasing the concentration of con A to  $10^{-6}$  M, however, iontophoresis of glutamate on to excitatory synaptic sites evoked responses qualitatively similar to those seen on the extrajunctional membrane but of higher sensitivity and circumscribed origin (Fig. 1*b*). Since this concentration of con A also produced a significant rise in miniature potential frequency (see Fig. 1*b*), it is probable that the threshold concentration differential between D and junctional receptors reflects the presence of protective mechanisms at synaptic sites rather than a difference in the susceptibility of the two receptor groups to con A. The effects of con A on both junctional and D-receptor desensitisation could not be reversed by prolonged washing in con A-free saline.

Con A blocks the aggregation of  $\beta$ -lymphocyte immunoglobulin molecules which normally follows on their exposure to specific divalent antibodies<sup>10-12</sup>. This inhibition is believed to be mediated by a submembranous microtubular array which forms as a consequence of the binding of con A to its own glycoprotein receptors<sup>13</sup>. We find it difficult to apply a mechanism of this nature to our observations in view of the normal desensitisation rate of the H receptors in the presence of con A. The H receptor is thought to possess structural features absent from the junctional and D-receptor populations. These presumably account for its activation by DL-isotonic acid<sup>7,8</sup>, a conformationally restricted glutamate analogue, and possibly its association with a  $\text{Cl}^-$  ionophore<sup>14</sup> whose conductance is blocked by picrotoxin. Con A may act by binding directly to junctional and D-receptor molecules, thereby preventing the conformational changes thought necessary for desensitisation to occur<sup>15-17</sup>, but leaving the initial molecular processes, associated with receptor activation and ionophore opening, unaffected. The structural features peculiar

Fig. 3 Iontophoresis of 5-nC pulses of L-glutamate on to the extrajunctional membrane of a fibre bathed in saline containing  $10^{-7}$  M con A for 40 min. *a*, The first pulse elicited a biphasic response; the second and third pulses (*b*, *c*) delivered at 4-s intervals, showed progressive reduction in the hyperpolarising component due to desensitisation of the H receptors. There was no evidence for desensitisation for the D receptors in these conditions.

**Fig. 4** Effect of glutamate iontophoresis, at various pulse intervals, on the response of the extrajunctional membrane after treatment with  $10^{-7}$  M con A. On this fibre, there was no H-response present because of the equivalence of  $E_{Cl}$  and  $E_M$ . *a*, Two 8-nC pulses, delivered 650 ms apart, resulted in D responses of almost equal amplitude. After a further delay of 220 ms, a third pulse elicited a D response of potentiated amplitude. The fourth and fifth pulses, each occurring after a delay of 200 ms, produced less marked response potentiation. Summation is seen following the third and succeeding glutamate pulses. *b*, A prolonged train of 3-nC pulses, delivered at intervals of 240 ms, evoked a train of extrajunctional D responses. These depolarisations initially showed simultaneous potentiation and summation, leading to the formation of a stable, summated depolarisation which decayed rapidly on cessation of glutamate ejection.

to the H receptor may prevent the con A binding step.

It is likely that there are several glycoproteins on the surface of locust muscle membranes to which con A might bind. Perhaps the glutamate receptors on this membrane, like the putative glutamate receptors isolated from rat brain<sup>7</sup>, are glycoproteins although this has not yet been established<sup>18</sup>. It is of interest that the binding of con A to rat brain glycoprotein cannot be reversed on simple washing, a feature shared with the desensitisation characteristics of locust muscle glutamate receptors that we observed. If the receptors on locust muscle are not glycoproteins, then the restriction of the conformational change which possibly leads to desensitisation of these receptors could be the result of con A binding to membrane glycoproteins closely associated with the receptors. Whatever the explanation for the action of con A on insect muscle, this substance will probably prove of great value in the further biochemical characterisation of glutamate receptors from both vertebrate and invertebrate sources. The drug may also provide a means of dissecting the molecular mechanisms underlying receptor desensitisation.

## Lithium inhibition of adrenaline-stimulated adenylylase in humans

LITHIUM is an effective therapeutic agent in the treatment and prevention of the manic phase of manic-depression<sup>1</sup>, and although known to influence many physiological systems, no specific mechanism has been identified for its efficacy in this illness<sup>2</sup>. One postulated primary site of Li action is as an inhibitor of hormone-stimulated adenylylase<sup>3</sup>. Li inhibits the ADH-sensitive adenylylase in kidney<sup>4,5</sup>, the TSH-sensitive adenylylase in thyroid<sup>6,7</sup>, the prostaglandin-sensitive adenylylase in human platelets<sup>8,9</sup>, and the noradrenaline-sensitive adenylylase in rat brain<sup>10,11</sup>.

It is therefore possible that therapeutic concentrations of Li in man inhibit adenylylase activity. Ball *et al.*<sup>12</sup> have shown that administration of  $\beta$ -adrenergic agonists in

**Fig. 1** The effect of Li on plasma cyclic AMP response to adrenaline administration. Subjects received 0.5 mg adrenaline subcutaneously at time 0 and blood was drawn every 10 min using an indwelling catheter in the antecubital vein. (Subcutaneous adrenaline injection was chosen rather than intravenous injection for greater clinical safety, in spite of the possibility of increased variability.) Samples were collected in plastic test tubes containing heparin and theophylline. Cyclic AMP was determined by the protein binding method of Brown *et al.*<sup>19</sup> as modified for plasma by Lattner and Prudhoe<sup>20</sup>. Bars indicate s.e.m. All subjects were physically healthy consenting adults. The lithium subjects (6 males, 3 females, ●) had a mean age of  $38 \pm 3.6$ . Mean plasma lithium level<sup>21</sup> was  $0.71 \text{ mEq l}^{-1}$  with a range  $0.32\text{--}1.15 \text{ mEq l}^{-1}$ . The no-lithium control subjects (7 males, 1 female, ○) had a mean age of  $34 \pm 3.6$ . The lithium subjects included four manic-depressive patients and one unipolar depressive patient, all in euthymic states; a hypomanic manic-depressive patient; an euthymic schizo-affective patient; and two normal individuals. The no-lithium subjects included one euthymic manic-depressive patient; one depressed unipolar patient; one agitated schizo-affective patient; one hypomanic manic-depressive patient and five normal individuals. Comparison (not shown) of the response of normal individuals without lithium to the response of patients without lithium does not suggest any effect of diagnosis or clinical state on the plasma cyclic AMP response to adrenaline. \* $P < 0.05$ ; \*\* $P < 0.01$ .

healthy volunteers leads to a rise in plasma cyclic AMP. Plasma cyclic AMP is derived from intracellular cyclic AMP of several tissues including liver, muscle and adipose tissue, but the rise in plasma cyclic AMP after  $\beta$ -adrenergic stimulation seems to result largely from stimulation of  $\beta$  receptors other than those in the liver or adipose tissue<sup>13</sup>. We have measured the rise in plasma cyclic AMP induced by adrenaline in subjects on and off Li therapy, and have found that therapeutic doses of the drug block this effect.

The effect of adrenaline on plasma cyclic AMP levels for a group of Li-treated and control subjects is shown in Fig. 1. In the control subjects there was a mean rise in plasma cyclic AMP levels which commenced at 10 min after adrenaline injection, peaked at 40 min, and by 70 min had almost returned to base levels. Li-treated subjects showed no mean increase in plasma cyclic AMP levels after adrenaline administration. Examination of individual responses (not shown) reveals that each of the no-lithium subjects showed a rise in plasma cyclic AMP levels after adrenaline injection, the magnitude of the maximum response ranging from 38 to 221%. In contrast, five of nine Li-treated subjects showed no rise in plasma cyclic AMP levels and the remaining four only a small increase (29–

39%). It should be noted that there seems to be no effect of Li on basal adenylate cyclase activity, but only on the activation of this enzyme by the hormone. Similar results have been reported for the ADH-sensitive adenylate cyclase in the kidney<sup>4</sup>. Figure 2 shows that two normal individuals (R.E. and H.B.) who respond to adrenaline with a rise in plasma cyclic AMP levels ceased to show a response when the test was repeated after 3 d of Li treatment. This suggests that the effect of Li on adrenaline-stimulated adenylate cyclase is a pharmacological effect of the drug and is not dependent on pre-existing pathology.

In addition to a direct effect of Li on adenylate cyclase, it has been proposed that this drug may also act at a site more distal to the synthesis of cyclic AMP<sup>14,15</sup>. Our results, however, suggest that a more distal action of Li need not be postulated to explain the effect of Li on the adrenergic system. Li's marked effect on  $\beta$ -adrenergic adenylate cyclase contrasts with the paucity of reports of Li effects on the peripheral cardiovascular system<sup>16</sup>. Intracellular levels of cyclic AMP after receptor stimulation are probably many times greater than those occurring in extracellular fluid<sup>12</sup>. It is possible that intracellular cyclic AMP responses, even after Li administration, are adequate to maintain homeostatic integrity. Fann *et al.*<sup>17</sup> have shown, however, that Li does decrease the pressor response to infused noradrenaline in man by 22%.

The catecholamine hypothesis of affective disorders postulates that mania is characterised by a functional excess of noradrenaline at a site in the central nervous system<sup>18</sup>. We have shown that in man, therapeutic doses of Li inhibit the peripheral  $\beta$ -adrenergic-stimulated adenylate cyclase. The brain adenylate cyclase stimulated by noradrenaline and the peripheral  $\beta$ -adrenergic-stimulated adenylate cyclase may be related, since both synthesise cyclic AMP after

**Fig. 2** The response of plasma cyclic AMP to adrenaline before (○) and after (●) Li in two normal subjects. After initially testing the response of plasma cyclic AMP to adrenaline in the absence of Li, both subjects were given Li for 3 d until a blood level of  $0.60 \text{ mEq l}^{-1}$  (R.E.) and  $0.66 \text{ mEq l}^{-1}$  (H.B.) was attained. The test was then repeated. The experimental procedure is the same as described in the legend to Fig. 1. a, Patient R.E.; b, patient H.B.

hormonal stimulation. This is in contrast to stimulation of the peripheral  $\alpha$ -adrenergic receptors, by either adrenaline or noradrenaline, which leads to a rise in cyclic GMP levels in plasma<sup>12</sup>. If Li inhibits human brain adenylate cyclase stimulated by noradrenaline, its antimanic efficacy could be understood.

We thank Kirsten Ebbesen for technical assistance. These studies were supported by a grant from the Israel Center for Psychobiology.

## Antagonism between channels for pattern and movement in human vision

MACKEY<sup>1</sup> rediscovered a striking experimentally produced visual hallucination. After inspection of stationary black-and-white stripes, a uniform test field is apparently filled with particles in chaotic streaming motion at right angles to the orientation of the stripes<sup>2</sup>. A great deal has since been discovered about pattern-analysing channels in the human brain, and much of this information has been gained from the study of visual illusions and after-effects. The streaming hallucination, however, has never been properly explained<sup>3</sup>, and is now not much more than a curiosity in the textbooks. In this paper an explicit model of the streaming after-effect is proposed, and from it some new subjective after-effects are derived.

Physiological<sup>4</sup> and psychophysical<sup>5</sup> results imply that the visual system is organised into parallel subsystems of 'sustained' and 'transient' channels which have complementary roles in visual processing. Sustained channels code information about spatial form, pattern and contour, whereas transient channels primarily carry information about temporal change, flicker and movement. Sustained channels have higher spatial acuity, and selectivity<sup>4</sup>, whereas transient channels have higher temporal acuity, and in man are probably always direction selective<sup>6</sup>.

In the visual cortex, cells tuned for a particular contour orientation are grouped together in slab-shaped columns, along with cells whose 'preferred' direction of movement is

at right angles to that orientation<sup>7</sup>. Neighbouring columns have adjacent preferred orientations, producing a complete array of orientation columns<sup>8</sup>. We also know that mutual inhibition between neurones in a particular neighbourhood is a prime feature of cortical organisation<sup>9</sup>.

Suppose that, within a column, sustained (pattern) channels selectively inhibit movement channels and vice versa, as shown schematically in Fig. 1. It has frequently been suggested that to explain the motion after-effect ('waterfall illusion') opponent pairs of movement analysers are required<sup>10-12</sup>, so that in one sense the triplet model of Fig. 1 may be seen as an outgrowth of that idea. If the output of one channel is reduced by adaptation, then the resting level of the other two channels must rise since they are released from inhibition. Therefore, after adaptation to stationary vertical stripes there is a temporary increase in the outputs of the horizontal movement channels and horizontal streaming movements are seen. After inspection of moving stripes one of the movement channels is also adapted; only the opposite movement channel is released from inhibition, and streaming is seen in that direction only<sup>2</sup>.

Pattern channel

Movement channels

**Fig. 1** Model of antagonism between cortical channels extracting components of pattern and movement in retinal image. There is mutual inhibition between a pattern channel selective for vertical contours and movement channels sensitive to left or right movements. The three channels illustrated can be expected to lie within a single cortical orientation column. Other orientations would be handled by similar triplets in neighbouring columns. A single inhibitory interneurone is shown (black disk) but other ways of producing the interaction are possible (for example, an interneurone for each pair of channels) without altering the basic idea. The model can explain the streaming after-effect<sup>1-2</sup>, and predict some new phenomena (see text).

From the symmetry of the model two predictions can be made. Adapting to left and right movements without contours should release the corresponding pattern channel. Hallucinated stationary stripes at right angles to the movement should be seen as an after-effect. If adaptation was to only one direction of movement, then the hallucinated stripes should appear to drift in the opposite (unadapted) direction.

These predictions were tested on human observers by adapting to rotating dot patterns without coherent contours. Such a procedure should produce adaptation of movement channels with little corresponding pattern adaptation. Since the motion was circular, the predicted effect must be one of radial lines, at right angles to the adapting motion.

Two coarsely textured disks were seen superimposed by a half-silvered mirror close to the observer's eyes. Both disks rotated at 66 r.p.m. either in the same direction (clockwise) or in opposite directions. These conditions will be called single and double rotation respectively. After fixating the centre of this display for 1 min, the subject then gazed at the centre of a sheet of smooth white paper to observe any after-effects. His descriptions were recorded on tape and he also made drawings wherever possible. Each subject made two observations in each condition of rotation, and

these conditions were presented alternately. Half the subjects began with single rotation and half with double rotation.

After inspection of irregularly patterned disks rotating in the same or opposite directions most subjects spontaneously reported seeing complex patterns of radial lines or curves. There were also reports of fields of moving dots, or of no pattern at all. The taped reports were therefore analysed according to a fivefold classification: (1) stationary radial pattern, (2) moving radial, (3) stationary granular, (4) moving granular, (5) no pattern. After double rotation most reports were of stationary radial contours (50%) or of no pattern at all (Fig. 2). Two subjects reported patterns with some anticlockwise movement, but this was almost certainly a residual effect from the preceding trial of single rotation.

After single rotation half the reports were again of radial contours, but rotating anticlockwise, in the opposite

direction to the adapting motion. All but one of the remaining reports were of a field of dots in anticlockwise motion. In 80% of cases, the two observations in each pair fell into the same category of report; in the remaining cases, the first report was of no pattern or of moving dots, but the second report was of radial contours.

These results strongly support the proposed model of a mutual antagonism between three types of channel contained in each individual orientation column of the visual cortex. Adapting out one or two channels produces an 'hallucinated' after-effect based on the disinhibited or rebound response(s) of the remaining channel(s). Adapting to movement produces orthogonal contours (and vice versa, as MacKay's work<sup>1</sup> showed).

That a rotating field of dots (rather than contours) could be evoked suggests that sometimes only one of a disinhibited pair of channels may actually exceed the perceptual threshold. In this case it seems that the movement channel exceeded threshold but the pattern channel did not. As in the 'streaming after-effect' this seems to be characterised by the perception of moving granules. This interpretation is also consistent with the fact that some subjects continued to see movement for some time after the contours had faded.

Usually the after-effect would last only a few seconds, but during that time it could appear remarkably clear and vivid. Some of the subjects' drawings are reproduced in Fig. 2. Like subject 10, I see the lines as straight after double rotation but curved after single rotation. This difference was reported by several other subjects, but quite often curved lines were described even after double rotation. Following single rotation the apparent rotation of the hallucinated lines is about an order of magnitude faster than the conventional motion after-effect. In all cases the lines are confined to the adapted region of the visual field, and follow Emmert's law of apparent size when 'projected' on to a uniform field at different distances.

I have experimented less formally with dichoptic adapting conditions. Using a Dove prism, it was easy to adapt one eye to clockwise rotation while the other eye adapted to anticlockwise. Testing each eye separately I saw a pattern of radial curves rotating in a direction opposite to the adapting direction seen by that eye. That is, the adaptation seemed to be eye specific. Viewing the test field binocularly, however, I saw a stationary pattern of straight radial lines, just as obtained with binocular adaptation to double rotation. These observations were confirmed many times. Furthermore, as with the streaming after-effect, these contoured hallucinations did not transfer between the eyes, if one eye was adapted and the other was tested.

These observations with dichoptic adaptation can be understood if channels in the human brain have varying degrees of ocular dominance, as found for cells in cat and monkey cortex<sup>2</sup>. Testing the after-effect with one eye revealed the activity of monocularly dominated channels adapted to only one direction and thus adaptation seemed to be eye specific. If the tested eye had not been adapted, then no effect was seen, again implying eye-specific adaptation. Binocular testing did not give the sum or mixture of the two monocular percepts, but instead revealed the activity of binocular channels adapted to both directions. Thus the after-effect was stationary just as with ordinary binocular adaptation.

The subjective patterns and streaming movements generated by adaptation are therefore anything but a textbook curiosity. We can apparently use them to probe the columnar organisation and within-column interactions in the human visual cortex. There is considerable evidence for a more widespread inhibitory interaction between columns in the cortex, and this too shows up in the 'hallucinated' after-effects. Adapting to a sinusoidal grating gives rise to subjective patterns of other orientations and

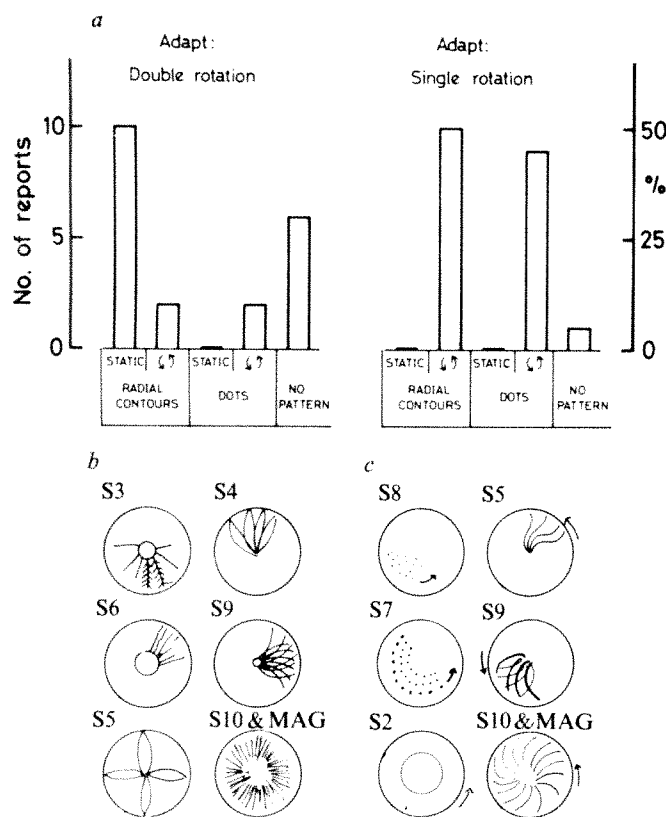

Fig. 2 *a*, Reports obtained from 10 naive observers after inspection of two superimposed dot patterns rotating clockwise (single rotation) or in opposite directions (double rotation) at 66 r.p.m. Disks subtended 12° at a viewing distance of 109 cm. Each disk bore a pattern of roughly circular dark spots on a white background. Each spot was about 0.5° across, drawn by hand in a quasi-random distribution, and separated by 0.5–1.5°. The contrast of each spot was about 0.4, relative to the combined background luminance ( $L_{max}$ ) of 26 cd m<sup>-2</sup>. (Contrast in this situation is defined as  $(L_{max} - L_{min})/L_{max}$ , where  $L_{min}$  is the luminance of the spot.) Patterns of smaller dots, or random visual noise were found to produce similar effects. *b* and *c*, Representative sample of subjects' sketches (redrawn). Where the lines fill only one quadrant of the drawing the observer invariably indicated that the whole region was filled with the same pattern. *b*, Adapting to double rotation produced stationary radial contours as an after-effect. *c*, Adapting to clockwise rotation produced radial contours (or a field of dots) rotating anti-clockwise. Appearance of curved lines (or cross hatching) as well as straight radial lines suggests that several near-radial orientations may be simultaneously disinhibited. The fact that the adapting speed increased with radial position on the disk might also have influenced the forms observed.

spatial frequencies<sup>13</sup>. These phenomena will be discussed in detail in a later paper.

## Effects of ethanol injections on morphine consumption in morphine-preferring rats

If there is a connection between the systems influencing morphine and ethanol consumption as suggested by the results of refs 1–4, then injections of ethanol should affect the intake of morphine. We have tried to determine if alcohol would cause a depression in morphine consumption in morphine-preferring rats similar to the results reported with ethanol consumption and morphine injections<sup>5</sup>. The results show no such connection to exist.

The subjects were 17 male Hooded rats (Canadian Breeding Farms) weighing between 250–325 g at the start of the experiment. All rats were housed individually in stainless steel cages. Purina Lab Chow was available *ad libitum*.

In the first phase of the experiment, a preference for morphine solutions over tap water was established. Since oral intake of morphine is limited by the reluctance of animals to ingest opiates presumably because of their aversive taste<sup>6,7</sup>, we developed two procedures where non-nutritive saccharin was used to mask the taste of morphine. Eight rats were provided with a free choice between water and a morphine solution (0.1 g ml<sup>-1</sup>) adulterated with 0.5 mg ml<sup>-1</sup> sodium saccharin, both of which were continuously available. The criterion used for morphine preference was arbitrarily set at persistent consumption of 60% or more of the total fluid intake as morphine. If this level was achieved, the morphine concentration was increased to 0.2 g ml<sup>-1</sup>, whereas the saccharin concentration remained constant. If the rat continued to drink the morphine solution, its concentration was increased in steps of 0.1 g ml<sup>-1</sup> until a cutoff concentration of 0.5 g ml<sup>-1</sup> was attained. The 5 rats which developed a morphine preference comprised group 1. An additional 10 rats were provided with a free choice between tap water and a morphine solution (0.5 g ml<sup>-1</sup>) adulterated with 0.1 g ml<sup>-1</sup> of sodium saccharin. If the rats failed to drink 60% or more of their total fluid intake from the morphine/saccharin tube, the saccharin concentration was increased in steps of 0.1 g ml<sup>-1</sup> until the criterion for preference was attained, or until the arbitrary cutoff concentration of 0.65 g ml<sup>-1</sup> of saccharin was reached. The morphine concentration was kept constant throughout. Four animals developed a preference for the morphine/saccharin solution and subsequently made up group 2. Group 3 (*N*=8), a control group, was given a free choice between tap water and a 0.5 g ml<sup>-1</sup> solution of sodium saccharin.

Seven days after group 1 and group 2 developed a preference for the saccharin-adulterated morphine at their

Fig. 1 Effect of ethanol injections on morphine intake over days. ●, Group 1; ▲, group 2; ■, group 3. The arrow represents injection of ethanol.

respective cutoff concentrations, the rats were injected intraperitoneally with 4 ml kg<sup>-1</sup> of 20% ethanol. Group 3 was given intraperitoneal injections of 20% ethanol (4 ml kg<sup>-1</sup>) after having consumed 60% or more of their fluid intake from the saccharin tube for seven days. Fluid intake was recorded for six days following the injection for all groups. Food intake for the groups was recorded seven days preceding injection of ethanol and for a 6-d postinjection period. Fluid and food intake were monitored daily the same time throughout the experiment.

Seven days preceding injection of ethanol group 1 drank a mean of 60.38 ml of saccharin-adulterated morphine. The mean consumption of the saccharin-adulterated morphine for 6 d after the injection was 62.76 ml. A Wilcoxon-signed ranks pairs test indicated that there was no significant difference in morphine/saccharin intake between the preinjection and postinjection periods (*T*=3, *P*>0.05). Similarly, food and water were not affected by the injection (*T*=5.6, *P*>0.05; *T*=5, *P*>0.05, respectively). In the 7-d preinjection period, group 2 drank from the morphine/saccharin tube a mean of 33.95 ml. The mean saccharin-adulterated morphine consumption for the 6-d postinjection period was 41.0 ml. Again, there were no significant differences in morphine/saccharin consumption between pre- and postinjection periods (*T*=3, *P*>0.05), and food and water intake were not affected by the ethanol injection (*T*=0.8, *P*>0.05; *T*=2.0, *P*>0.55 respectively).

Control group 3 drank a mean of 37.25 ml from the saccharin tube in the 7-d preinjection period although their mean saccharin consumption in the 6-d period after the injection was 41.3 ml. Ethanol did not affect their saccharin consumption (*T*=10, *P*>0.05), food consumption (*T*=5.6, *P*>0.05) or water consumption (*T*=17, *P*>0.05) (see Fig. 1).

The results of this study suggest that ethanol does not influence the oral consumption of saccharin-adulterated morphine. The assumption that a common connection exists between the systems influencing the consumption of morphine and alcohol does not seem to be supported by these results. Perhaps if the rats were exposed to the morphine solutions for longer periods of time, the alcohol effect would become manifest. In the present study rats were exposed to morphine solutions for about 40 d; Sinclair's subjects were exposed to alcohol for 141 d. Length of

exposure to a drug could conceivably be an important factor to consider in studies of this nature, and may explain the dichotomy between these findings and those of Sinclair. Furthermore, it is possible that a such commonality does exist, but that it is not a simple symmetric relationship.

## Production of human chorionic gonadotropin in HeLa cell cultures

THE ectopic synthesis of placental proteins in human cancer is of special interest because of similarities between neoplastic and embryonic cells. Moreover, the inappropriate synthesis of biologically active proteins and polypeptide hormones which are normally produced only in specialised tissues (endocrine glands) or at a particular stage of development may provide information on the control of gene activity. Ectopic production of human placental chorionic gonadotropin (HCG) has been reported in some patients with neoplasms<sup>1,2</sup>. A cell line (Cha Go) established from an HCG-producing pulmonary carcinoma was shown to continue synthesis of the gonadotropin in culture<sup>3,4</sup>. We have now found that HeLa<sub>65</sub> cells<sup>5,7</sup> produce the  $\beta$  subunit of HCG as measured by a specific radioimmunoassay and that sodium butyrate enhances production.

**Fig. 1** Production of HCG- $\beta$  by HeLa<sub>65</sub> cells grown for 120 h in the presence of different concentrations of sodium butyrate. ●, Intracellular HCG- $\beta$  (mIU per  $10^6$  cells); ▲, HCG- $\beta$  (mIU) secreted in 100 ml medium per  $10^6$  cells. HCG- $\beta$  was determined by radioimmunoassay using polyethylene glycol as a precipitant for <sup>125</sup>I-labelled antigen-antibody complex. Radioactive complexes were measured as outlined in Table 1 by counting in a Nuclear-Chicago Gamma-Counter.

**Table 1** Production of HCG- $\beta$  by HeLa<sub>65</sub> cells

Addition to medium	Intracellular HCG- $\beta$ (mIU per $10^6$ cells)		HCG- $\beta$ secreted in medium (mIU per $10^6$ cell)	
	Mean	Range	Mean	Range
None	0.07	0.06-0.08	0.06	0.059-0.061
1 mM sodium butyrate	2.18	2.15-2.21	62.3	59.3-65.3
3 $\mu$ M prednisolone	0.14	0.136-0.144	0.10	0.099-0.101

Replicate flasks of HeLa<sub>65</sub> cells were grown for 120 h in Waymouth's medium containing 10% foetal calf serum and antibiotics (penicillin, 50 U, streptomycin 50  $\mu$ g and kanamycin 30  $\mu$ g ml<sup>-1</sup>). The medium was decanted, freed from suspended cells by centrifugation and stored at -20 °C until assayed. The cells were removed from the glass surfaces with 0.02% EDTA and 0.05% trypsin (1:300 Grand Island Biological) in Puck's saline A. The cells were counted in a haemocytometer, washed by centrifugation in 0.15 M saline and frozen at -20 °C. Before assay the thawed cell pellet was suspended in 0.15 M saline and disrupted by sonification using Model W 185 Sonifier Cell Disrupter (Heat System—Ultrasonics).  $\beta$  subunits of human chorionic gonadotropin (HCG- $\beta$ ) were measured by a specific radioimmunoassay that exhibits less than 1% cross reaction with luteinising hormone (LH). Antiserum against the beta chain of HCG was used to ensure the specificity of the immunological reaction. Radioactive <sup>125</sup>I-HCG- $\beta$  antigen-antibody complexes<sup>16</sup> were precipitated with either anti-gammaglobulin serum or polyethylene glycol (molecular weight 6,000). The radioactive precipitate was collected by centrifugation at 4,000g in a refrigerated (4 °C) centrifuge and counted in a Picker Nuclear Autowell II Gamma-Counter. The concentration of HCG- $\beta$  in ultrasonicates of washed HeLa cells and in medium were calculated from a standard calibration curve. The standard curve was obtained by plotting %<sup>125</sup>I-HCG- $\beta$  bound to HCG- $\beta$  antibody against known concentrations of unlabelled highly purified HCG- $\beta$ . Standards were run concurrently with unknowns in each experiment. Purified HCG- $\beta$  (molecular weight 22,000) and purified HCG- $\beta$  labelled with <sup>125</sup>I and antibody against HCG- $\beta$  were supplied by Serono Laboratories, and also by the Institute of Bio-endocrinology, Montreal. Values are the means and ranges of duplicate assays carried out on two replicate flasks.

HCG is a heteropolymer composed of two dissimilar subunits; an alpha subunit that is common to follicle-stimulating hormone, luteinising hormone, thyroid-stimulating hormone and HCG and a  $\beta$  subunit unique for each hormone that confers biological specificity<sup>8</sup>. Table 1 shows that HeLa<sub>65</sub> cells produce low levels of HCG- $\beta$  and secrete it into medium. Growth of cells in medium containing sodium butyrate markedly increases HCG- $\beta$  production both intracellularly and in medium (Table 1). Similar striking effects were observed in ten additional experiments. The amount of HCG- $\beta$  produced by HeLa<sub>65</sub> cells depends on the concentration of sodium butyrate in the medium (Fig. 1). Sodium butyrate (0.1-10 mM), when added to the assay mixture, does not interfere with the radioimmune measurement of HCG- $\beta$ . Another well characterised HeLa subline designated HeLa<sub>71</sub> (ref. 6) also produced HCG- $\beta$  which was increased by growth in medium with sodium butyrate. On the other hand, the cortisol analogue, prednisolone, increases HCG- $\beta$  only slightly. In four other experiments, prednisolone slightly increased the gonadotropin levels in one but was without significant effect in the other three. In baby hamster kidney BHK/C<sub>13</sub> cultures<sup>8</sup> and adult human lung fibroblasts gonadotropin could not be detected nor could HCG- $\beta$  be induced by growing these cells in medium with either sodium butyrate or prednisolone (data not shown).

It is interesting that the heteroploid HeLa cell line after many years in culture produces several proteins normally found only during embryonic development or synthesised by specialised cells. For example, these cells produce the placental form of alkaline phosphatase with electrophoretic characteristics similar to the isozymes of the heterozygous FS phenotype<sup>9</sup>. The addition of iron to culture media mediates the synthesis by HeLa cells of an apoferitin with properties different from the adult form of this protein<sup>10</sup>. HeLa cells are agglutinated by concanavalin A, a property shared by tumour and embryonic cells (our unpublished

results). The production of HCG- $\beta$  by HeLa cells, as measured by a specific radioimmunoassay, provides additional evidence for the putative derepression of an element of the genome with the synthesis of a protein normally produced only by the specialised trophoblastic cells.

Cortisol<sup>11,12</sup> and more recently sodium butyrate<sup>13-15</sup> have been reported to modulate the shape and to alter the activities of several enzymes in HeLa cells. Short chain fatty acids such as butyrate increase the activity of HeLa alkaline phosphatase<sup>14</sup> and sialyltransferase<sup>15</sup>. The accumulation of HCG- $\beta$  in HeLa cell cultures is enhanced markedly by growth in medium containing sodium butyrate. Since this peptide hormone is not degraded in cell cultures<sup>4</sup>, it seems that the synthesis of HCG is increased by butyrate.

## Loss of a non-histone chromatin protein parallels *in vitro* differentiation of cartilage

SEVERAL lines of evidence have implicated the proteins associated with the nuclear DNA of eukaryotic cells in the control of differential gene expression<sup>1-6</sup>. In contrast to the histones of eukaryotic chromatin which are relatively conserved in both primary structure and distribution across cell types within an organism, and from species to species<sup>4</sup>, the non-histone chromosomal proteins are very variable in size and distribution. This lends weight to the presumption that they are the specific regulators of transcription<sup>5,6</sup>.

Although there have been studies of tissue-specific<sup>5-8</sup>, developmental stage-specific<sup>9-11</sup> and cell-cycle phase-specific<sup>12-14</sup> variations in the complement of non-histone chromatin proteins, the causal association of specific alterations in chromosomal proteins with a particular transformation of one cell type into another can best be established with a homogeneous population of precursor cells able to differentiate in isolation into a homogeneous population of a recognisable cell type. In particular, differences in the chromosomal proteins of cell types which are adjacent in a developmental lineage would be more amenable to analysis than the larger number of differences likely to be encountered among cell types more widely diversified during development. Here we report a change in the complement of non-histone, chromosomal proteins in an *in vitro* system that closely approaches this situation.

Fig. 1 Gels prepared from chromatin proteins from nuclei of freshly explanted (left) and 3-d cultured (right) sub-apical ridge mesoderm from Hamilton-Hamburger stage 25 chick wing buds. Tissue was pooled from 370 White Leghorn embryos; nuclei were isolated from half the material immediately and half after 3 d in culture (see text). In each case intact pieces of tissue were suspended in a buffer consisting of 0.32 M sucrose, 0.001 M MgCl<sub>2</sub>, 0.3% Triton N-101 and 0.001 M phosphate buffer, pH 6.8. Tissue was homogenised with two strokes of a Teflon pestle in a Potter-Elvehjem homogeniser. Nuclei were collected at 1,000g and resuspended in 3 ml of the same buffer, washed in 80 mM NaCl, 20 mM EDTA, pH 7.2, and then in 0.15 M NaCl, 0.05 M Tris pH 7.5. The resulting pellet was dissolved in 2% sodium dodecyl sulphate (SDS) in 0.01 M Tris and 10% glycerol and boiled, after which 1 mM phenylmethylsulphonyl fluoride<sup>21,22</sup> was added. The mixture was then dialysed against 0.1% SDS, 0.01 M Tris, 0.3 M glycine, and run on Tris-glycine 10% polyacrylamide SDS gels using the gel and buffer systems of Laemmli<sup>23</sup>. Approximately 150  $\mu$ g of protein was applied to each gel. Gels were stained with Coomassie brilliant blue. The protein characteristic of the prechondrocyte preparation is indicated by the arrow.

As described<sup>15</sup>, the mesenchyme subjacent to the apical ectodermal ridge<sup>15</sup> of the stage 25 (5-d) chick wing bud consists of cells which are not chondrocytes according to several criteria. The dissociated cells cannot clone for cartilage in conditions which support cartilage colony formation by authentic chondrocytes<sup>17</sup>; sectioned subridge mesoderm does not stain metachromatically with toluidine blue, a test which is diagnostic for the sulphated mucopolysaccharides of cartilage matrix<sup>18</sup>; and most definitively, the collagen produced by the subridge mesoderm is of a level (1.5-2.5% of total newly synthesised protein when grown in ascorbate), and species (type I-like) uncharacteristic of cartilage (ref. 19 and R. Mayne, unpublished results). Nonetheless, after 3 d in organ culture, explanted subridge mesoderm attains the cartilage phenotype by the following criteria: dissociated cells clone for cartilage; sectioned explants stain metachromatically with toluidine blue, and the level (14-16% of newly synthesised protein) and species (type II-like) of collagen indicate that the tissue has virtually completely chondrified. At the histological level the transition proceeds uniformly during the 3 d, with moderate DNA synthesis at all stages (determined autoradiographically) and no overt necrosis. No myotubes are ever seen in these explants, suggesting that while the freshly explanted material is not yet committed to a chondrogenic programme, it has nevertheless passed the stage in the mesodermal lineage when it can 'choose' to be myogenic<sup>20</sup>.

It is significant with regard to the possible mechanisms involved in this transition during development, that the individual  $\alpha$ -helical chains comprising chick type I collagen (found in skin, tendon, bone and various other tissues) differ in their primary structure from the  $\alpha$ -helical chains comprising chick type II collagen (found only in cartilage)<sup>19</sup>. The appearance of a new gene product in the subridge mesodermal cells or their descendants during

the 3d in culture suggested reprogramming at the chromosome level and led us to look for corresponding changes in the nuclear proteins of these cells.

Tissue was isolated from the sub-apical ridge region of 370 stage 25 chick wing buds by transection of the limb tip 0.2–0.3 mm from the apex. No attempt was made surgically to remove the ectoderm which we estimate contributed less than 10% of total cells to the newly isolated material. Also, as sheets of ectoderm were lost during the early steps of nuclear isolation, the contribution of ectodermal nuclei to the final chromatin protein sample was probably a few per cent. Nuclei were isolated immediately from half the tissue, and from these chromatin was prepared and stored in a denaturing buffer containing phenylmethylsulphonyl fluoride, an inhibitor of proteolysis<sup>21,22</sup>, at  $-20^{\circ}\text{C}$ .

The other half of the tissue was cultured on 1.2% agar containing Ham's F-10 medium supplemented with 10% foetal calf serum and 1% bovine serum albumin. After 3 d in culture, nuclei were isolated from this tissue by the same procedure, chromatin was prepared, and the two preparations were run simultaneously on 25 cm 10% polyacrylamide gels containing 0.1% sodium dodecyl sulphate. The stained gels and the corresponding visible light spectrophotometer scans in Figs 1 and 2 were made from the preparation described, in which the freshly explanted and cultured material was taken from the same group of randomised embryonic limbs. Replicate analyses were done from separately prepared fresh and cultured tissue, yielding gels virtually identical to those pictured.

**Fig. 2** Optical scans of the gels in Fig. 1 done at 563 nm on a Gilford spectrophotometer (a). Preparation from freshly explanted material. b, Preparation from cultured material. Tracing of prechondrocyte distinctive band is indicated by the line. The histone region may also contain some non-histone proteins.

In view of the phenotypic behaviour of the material analysed, we emphasise the following features of our electrophoretic data. First, we note the essential similarity between the two gels with respect to most of their stainable bands. While there are quantitative variations between some of the corresponding bands, this similarity appears greater than that usually found when different tissues or organs from a single individual or species are compared<sup>2-14</sup>. Second, the presence of a heavily staining band of low mobility (molecular weight between 125,000 and 150,000, estimated from markers in separate gels) in the freshly explanted, but not cultured material, is quite striking. This band is not present in similar gels of material prepared from cultured embryonic chick vertebral chondrocytes, fibroblasts or myogenic populations, though a low intensity band of similar mobility appears in chromatin preparations from primitive series chick erythrocytes (unpublished results of J.B., G.C.T.Y., and H. Holtzer). We do not exclude the possibility that the phenotypic differences between our freshly explanted and cultured material could be partly or entirely controlled by chromatin-associated molecules outside the limits of detection of our electrophoresis, staining, and scanning techniques. But we emphasise that our two preparations represented cell types which are adjacent in a developmental lineage and that the distinguishing protein (or class of proteins) was prominent against a relatively constant background, suggesting a role for this component in nuclear reprogramming. The all-or-none character of its disappearance (or loss of affinity for the stain) during the change from prechondrocyte to chondrocyte in culture recommends this system for *in vitro* studies of the mechanisms of cell differentiation.

We thank Dr H. Holtzer for facilities. This work was supported by grants from the National Institute of Health and the American Cancer Society to H. Holtzer. G.C.T.Y. is a recipient of a C.J. Martin Overseas Postdoctoral Fellowship from the National Health and Medical Research Council of Australia.

## Expression of parental histone genes in the intergeneric hybrid *Triticale hexaploide*

*Triticale hexaploide*, the intergeneric hybrid resulting from the cross of diploid rye (*Secale cereale*) and tetraploid wheat (*Triticum durum*), offers a unique opportunity for the study of the expression of genes which are derived from two dissimilar organisms but exist together in the same cells. I have investigated the expression of histone genes in triticale because the histones are an extensively studied class of proteins with individual components which range from being highly conservative in an evolutionary sense to being probably species specific. For example, the sequence of histone F2a1 from peas and cows differs in only two of 102 amino acids<sup>1</sup>, whereas different species of sea urchin have F1 histones of different electrophoretic mobilities<sup>2</sup>. I

have found that in wheat, rye and triticale the evolutionarily conservative histones seem to be identical. There are, however, differences in the F1 histones of wheat and rye, and the gene for one of the wheat F1 histones is not expressed in the hybrid triticale.

Histones were extracted from dark-grown coleoptiles of triticale and from the rye and wheat parents as previously described<sup>1</sup>, and were analysed electrophoretically on short and long one-dimensional gels by the method of Panyim and Chalkley<sup>4</sup> and on a new two-dimensional electrophoretic system.

Not surprisingly, considering the relatively close phylogenetic positions of wheat and rye, the highly evolutionarily conservative histones (F2a1 and F3) and the moderately conservative histones (F2b and F2a2) from all three organisms appeared identical on both one and two-dimensional gels (Figs 1 and 2). The only differences were in the F1 (lysine-rich) histones.

On short gels wheat F1 histones were resolved into four distinct bands, F1a, b, c and d. Long gels further resolved

wheat F1a into two electrophoretic bands, the slower of which I have called F1a'. This heterogeneity of wheat F1 histone is not due to phosphorylation since treatment of the isolated F1 fraction with alkaline phosphatase by the procedure of Sherod *et al.*<sup>7</sup> did not affect the electrophoretic mobilities of the subfractions. Rye has only three F1 histones as resolved on both long and short gels. These have identical electrophoretic mobilities (as shown by electrophoresis of mixed samples of wheat and rye on long gels) to histones F1a, b and d (that is, rye histones are the same as wheat histones except that F1c and F1a' are lacking).

In the hybrid triticale the genes for histones F1a, b and d are expressed as is the gene for the wheat-specific F1a'. Even greatly overloaded gels, however, show no trace of the wheat-specific F1c histone.

The reason for the lack of expression of the wheat F1c gene is unknown, although it is not due to the loss of any whole chromosomes. Root tip squashes reveal the entire  $2n$  complement of 28 chromosomes derived from wheat and 14 derived from rye, in the hybrid.

**Fig. 1** *a*, Electrophoresis of wheat, rye and triticale whole histones on short gels by the method of Panyim and Chalkley<sup>4</sup>. The 10-cm gels were run for 4 h at room temperature, 2 mA per gel, then stained with amido black and destained by diffusion. All three species have histones F1a, b and d. The wheat-specific F1c is not expressed in the hybrid. The remaining histone fractions appear to be identical in all three plants. They have been named according to the nomenclature of Johns<sup>3</sup> and identified by their fractionation properties, susceptibility to ferric chloride destaining and comparative mobility in one- and two-dimensional electrophoresis (manuscript in preparation). In this electrophoretic system the plant F2b and F2a2 histones have lower electrophoretic mobilities than histone F3 whereas histones F2b and F2a2 of mammals have greater electrophoretic mobility than histone F3 (ref. 3). *b*, Electrophoresis of wheat, rye and triticale F1 histones on long gels. The gels are of the same composition as the short gels in *a*, but are 20 cm long and were run at 0.75 mA per gel for 50 h at 2 °C. Other histone fractions have run off the gel, and only the portion of the gel containing the F1 histones is shown. Rye histones appear the same as in short gels but are separated further. F1a has been resolved into two bands in wheat and triticale, the slower of which has been labelled F1a'. The wheat-specific F1c is not expressed in the hybrid.

**Fig. 2** Two-dimensional gel of triticate whole histone. Separation in the first dimension (right to left) was on acetic acid-urea gels according to Panyim and Chalkley<sup>4</sup>. The second dimension (top to bottom) was of the same composition but included 1% Triton X-100. The patterns for rye and wheat are identical except for the F1 histones. The rapidly moving, arrowed but unlabelled spots are probably histones which have not bound the Triton<sup>6</sup>.

## Transbilayer movement of cholesterol in dipalmitoyllecithin-cholesterol vesicles

THE movement of cholesterol across biological membranes is an important process for many cellular functions, but the mechanisms by which it occurs are not known. The movement of lipid molecules between the two halves of a bilayer, a process which has come to be known as flip flop, was first demonstrated to occur in films of stearate<sup>1</sup>. Subsequently, several workers have reported flip-flop times for phospholipids in model systems, the values obtained varying between several hours and many days depending on the system studied and the techniques used<sup>2-5</sup>.

Lipid flip flop provides a possible mechanism for the translocation of cholesterol across membranes. To our knowledge only one study has been carried out to estimate the rate at which such a process could occur. Smith and Green<sup>6</sup> reported a half time of 70 min at 30 °C for the flip flop of the fluorescent cholesterol analogue, sterophenol, in liposomes. We have carried out experiments to measure the flip flop of cholesterol itself in sonicated dipalmitoyllecithin-cholesterol vesicles, a

well known system<sup>7</sup>. On the basis of two kinds of experiments using different strategies, we conclude that cholesterol flip flop in this system is a very slow process if it occurs at all.

Lipid vesicles were made by sonication of dipalmitoyllecithin (DPL) (Sigma) and cholesterol in the mol ratio of 1:0.9 at 4 °C for 1 h under nitrogen, followed by centrifugation at 20,000g for 45 min at 4 °C. The purity of the DPL was checked by thin-layer chromatography before and after sonication, and there was no evidence of impurities or chemical degradation. Red-cell ghosts were prepared using the technique of Dodge<sup>8</sup>. The ghosts were used in excess as an acceptor membrane and no attempt was made to measure their leakiness. Red cells were labelled with <sup>14</sup>C-cholesterol by incubating them in plasma containing <sup>14</sup>C-cholesterol<sup>9</sup>. Lipids were extracted from red cells<sup>8</sup> and from ghosts<sup>10</sup>, and cholesterol was determined by digitonin precipitation<sup>11</sup> and assayed by the method of Parekh and Jung<sup>12</sup>.

In the first set of experiments DPL-cholesterol vesicles containing <sup>3</sup>H-cholesterol and <sup>14</sup>C-DPL were incubated at a cholesterol concentration of 10<sup>-5</sup> M with red-cell ghosts at a cholesterol concentration of 4.2 × 10<sup>-4</sup> M. This represented a 42-fold excess of ghost membranes, so that back exchange of the tritiated cholesterol would be insignificant. The ghosts and vesicles were incubated at pH 7.4 in a phosphate buffer (1.2 mM MgCl<sub>2</sub>, 2.4 mM CaCl<sub>2</sub>, 4.2 mM NaH<sub>2</sub>PO<sub>4</sub>, 1.7 mM Na<sub>2</sub>HPO<sub>4</sub>, 5.0 mM KCl, 13.5 mM Na<sub>2</sub>CO<sub>3</sub>, 117.8 mM NaCl, 10.0 mM glucose) at 37 °C. At various times aliquots were taken, the ghosts separated from the vesicles by centrifugation, and both the supernatant and pellet assayed for <sup>3</sup>H and <sup>14</sup>C. To prevent sticking of the vesicles to the ghosts, 10<sup>-6</sup> M bovine serum albumin was added to the incubation medium. Figure 1a indicates that the exchange phenomenon saturates after 73% of the <sup>3</sup>H-cholesterol has been removed from the vesicles, in ~ 24 h. No additional cholesterol could be removed from the

**Fig. 1** *a*, Exchange of <sup>3</sup>H-cholesterol from DPL-<sup>3</sup>H-cholesterol vesicles into erythrocyte ghosts where the labelled cholesterol was introduced into the original sonicated mixture. % cholesterol exchange refers to the amount of vesicle cholesterol transferred to the acceptor membrane. Correction (never exceeding 7%) was made for vesicles sticking to ghosts at each time point. *b*, Exchange of <sup>3</sup>H-cholesterol from DPL-cholesterol vesicles into erythrocyte ghosts where the labelled cholesterol was introduced into the vesicles by a previous incubation with intact red cells containing <sup>3</sup>H-cholesterol. The vesicles were stored at 37 °C for 48 h before being added to the ghosts preparation. The incubation medium contained streptomycin sulphate as an antibacterial agent and 10<sup>-6</sup> M bovine serum albumin to reduce sticking of the vesicles to the ghosts. <sup>14</sup>C-DPL was used as a control to monitor the degree of sticking and the concentration of phospholipid in the supernatant containing vesicles. The disappearance of labelled cholesterol from the vesicles corresponds with the appearance of label in the ghost fraction.

Table 1 Ratio of  $^3\text{H}$  to  $^{14}\text{C}$  decays

Experiment	$\Delta t$ (h)	$R_1$ (ratio in vesicles)	$R_2$ (ratio in red cells)	$R_2/R_1$
1	0	120	80	0.67
2	0	69	48	0.69
3	0	68	51	0.75
1	20	120	87	0.72
2	20	69	52	0.75
4	20	240	163	0.68
2	43	69	50	0.72
Mean = $0.71 \pm .03$				

The third column gives this ratio ( $R_1$ ) for the vesicles at the end of the first incubation. The fourth column gives this ratio ( $R_2$ ) for the red cells at the end of a 2-h second incubation, which followed the first incubation after a delay  $\Delta t$ . See the text for experimental details. Ratios of  $^3\text{H}$  to  $^{14}\text{C}$  decays measured in red cell lipids and vesicles were determined in triplicate to within 5%. Error caused by the sticking of vesicles to red cells was determined separately and was found to be insignificant in our experimental conditions.

vesicles over a 120-h incubation period. Between 0 and 60 h the specific activity of the  $^3\text{H}$ -cholesterol in the vesicle decreases from  $14.9 \times 10^5$  d.p.m. per mg cholesterol to  $4.3 \times 10^5$  d.p.m. per mg cholesterol representing a 71% loss in labelled cholesterol. The specific activity of the ghost cholesterol increases from zero to  $0.3 \times 10^5$  d.p.m. per mg cholesterol, which is indicative of the large excess of cholesterol in the acceptor membrane. This 71% exchangeable and 29% non-exchangeable cholesterol pool in the vesicles correlates well with the evidence of Huang<sup>7</sup> that 70% of the total membrane cholesterol is located on the outer half of the vesicle bilayer, and suggests that the cholesterol on the inner half of the bilayer is not accessible for exchange. The possibility that the non-exchangeable cholesterol observed in these experiments indicated the presence of inner bilayers in the vesicles is excluded, since quantitatively similar results were obtained using sized vesicles that had been chromatographed on a Sepharose 4B column by the method of Huang, and are homogeneous by established criteria. A tentative conclusion is that cholesterol does not flip from the inner half of the bilayer to the outer half within the time of the experiment.

In a further experiment, 1:0.9 DPL-cholesterol vesicles containing  $^{14}\text{C}$ -lecithin but no  $^3\text{H}$ -cholesterol were incubated for 8 h with red blood cells containing  $^3\text{H}$ -cholesterol. The vesicles were then separated from the red cells and incubated with an excess of ghosts in the same manner as the previous experiment. Figure 1b shows that all of the  $^3\text{H}$ -cholesterol can be exchanged from the vesicles in 24 h. This is consistent with the conclusion that the cholesterol exchanged into the vesicles from the red cells did not flip to the inner surface and therefore remained on the outside available for exchange with the acceptor membrane.

In a different set of experiments designed to compare the size of the exchangeable pool with the total cholesterol pool, vesicles were made with DPL and  $^3\text{H}$ -cholesterol, and then  $^{14}\text{C}$ -cholesterol was exchanged into the vesicles by incubating them with red cells containing  $^{14}\text{C}$ -cholesterol for 4–5 h (first incubation). By introducing labelled cholesterol in these two ways, the  $^3\text{H}$ -cholesterol will be found throughout the vesicle, whereas the  $^{14}\text{C}$ -cholesterol will have been introduced only into regions of the vesicle reached by the exchange process. Following the first incubation the vesicles were isolated for a period  $\Delta t$ , after which the vesicles were incubated with unlabelled red cells to facilitate the exchange of cholesterol between the two systems (second incubation). The proportion of  $^3\text{H}$  and  $^{14}\text{C}$  present in the vesicles at the end of the first incubation and the proportion of the isotopes found in the red cells at the end of the second incubation were measured. The results of these experiments are given in Table 1. The ratio of  $^3\text{H}$  to  $^{14}\text{C}$  measured in the red cells was the same at the end of a second incubation of either one or two hours. Furthermore, this proportion was independent of  $\Delta t$  for values of this delay up to 43 h,

the longest time tested. It was found that the ratio of  $^3\text{H}$  to  $^{14}\text{C}$  had a value in the red cells which was  $0.71 \pm 0.03$  of its value in the vesicles.

The finding that the ratio of  $^3\text{H}$  to  $^{14}\text{C}$  in the red cells was different from that in the vesicles means that the exchange process does not sample vesicle cholesterol uniformly, or that all of the vesicle cholesterol is not available for exchange. The time independence of the results indicates that the pool of cholesterol molecules which exchange with red cell cholesterol constitutes an isolated subpopulation of the total cholesterol in the vesicle. If this exchangeable pool represents the outer layer of molecules, then the isolation of this pool from the rest of the vesicle cholesterol would imply that there is no translocation of cholesterol between the two surfaces of the vesicle.

Let us denote the number of  $^3\text{H}$  molecules in the exchangeable and non-exchangeable pools at the end of the first incubation by  $N_{H1}$  and  $N_{H2}$  respectively. All of the  $^{14}\text{C}$ -cholesterol in the vesicles will be in the exchangeable pool, and we denote their number by  $N_{C1}$ . The measured ratio of  $^3\text{H}$  to  $^{14}\text{C}$  decays in the vesicles at the end of the first incubation is:  $R_1 = (N_{H1} + N_{H2}) / N_{C1}$ . The cholesterol exchanged into the red cells during the second incubation came from the vesicle exchange pool and the ratio of  $^3\text{H}$  to  $^{14}\text{C}$  decays in the red cell is therefore:  $R_2 = N_{H1} / N_{C1}$ . Algebraic manipulation yields  $N_{H2} / N_{H1} = (R_1 - R_2) / R_2$  or  $N_{H1} / (N_{H1} + N_{H2}) = R_2 / R_1 = 0.71 \pm 0.03$ .

In these experiments, the number of  $^{14}\text{C}$ -cholesterol molecules in the vesicles was negligible compared with the number of  $^3\text{H}$ -cholesterol molecules and therefore the value of 0.71 gives the fraction of vesicle cholesterol molecules which are accessible for exchange. As remarked before, this number is in good agreement with published values<sup>7</sup> for the fraction of cholesterol molecules located at the outer surface of the DPL vesicle, and we conclude therefore that the exchangeable pool is the outer surface of the vesicle. That the exchangeable pool is isolated from the rest of the cholesterol in the vesicle is then the statement that cholesterol flip flop is extremely slow. Within the accuracy of our measurements, we can determine a lower bound for the half time to be 6 d. This lower bound was arrived at by taking values of 0.67 and 0.75 for the ratio  $R_2/R_1$  for time delays of 0 and 20 h respectively, to fit an exponential process. This gives an extremely conservative estimate for the half time of flip flop. Similar rates of flip flop have been observed for phosphatidylcholine<sup>3,4</sup>.

Slow cholesterol flip flop could have interesting implications for biological membranes. The slow rates observed for this process in vesicles may also occur in biological membranes which would explain the finding of some authors<sup>14</sup> that there exists a pool of erythrocyte membrane cholesterol which is not exchangeable.

## Identification of $\beta$ carbolines isolated from fluorescent human lens proteins

WITH ageing, a number of significant changes occur in the chemistry of the human lens. In the central region of the organ there is a slow transformation of protein to high molecular weight (HMW) aggregates greater than  $50 \times 10^6$  (refs 1 and 2). It has been suggested that the relatively high concentration of such protein species in older lenses may cause significant light scattering<sup>3,4</sup> and may be a contributing factor in the development of senile cataract characterised by central sclerosis and opacification<sup>1</sup>. An age-dependent increase in the insoluble protein fraction has also been observed<sup>5-8</sup> and recent experiments indicate that the HMW species is an intermediate in the formation of this material<sup>15</sup>. Marked changes in the polypeptide chains of human lens proteins probably largely attributable to post-translational transformation, have also been observed<sup>16</sup>.

A yellowing of lens with age is also observed and its generation has been correlated with a concomitant increase in a protein bound non-tryptophan fluorescence<sup>8</sup>. This fluorescence is found primarily in the insoluble protein<sup>8,9</sup> fraction of the nuclear region as well as with the HMW components of the soluble protein fraction<sup>8</sup>. It also has been shown that this fluorescence is associated with a 43,000 molecular weight polypeptide found in a number of HMW species and the insoluble fraction<sup>8</sup>. This polypeptide seems to increase in concentration with age and is not present in very young lens.

Alkaline degradation of either the insoluble fraction or HMW fractions in 4 N barium hydroxide at 110 °C for 24 h results in the release of a number of fluorescent components which have been separated and partially purified by preparative paper electrophoresis at pH 1.9. The principle fluorescent compound obtained by this procedure was designated 'C<sub>1</sub>'. We report here the structure of this component and consider its relationship to the fluorescent material present in the lens proteins.

Approximately 1–2 g insoluble protein fraction obtained from 50–100 cataractous lenses were hydrolysed by 4 N barium hydroxide and C<sub>1</sub> was isolated by preparative paper electrophoresis at pH 1.9. Examination of C<sub>1</sub> by high pressure liquid chromatography using poragel PN in ethanol–water indicates that it contains considerable contamination and that only small amounts of it are present in the initial electrophoretically isolated preparations. C<sub>1</sub> has a yellow fluorescence when observed by long wavelength ultraviolet light (maximum 360 nm), is unstable and decomposes to two components characterised by a blue fluorescence designated Ia and Ib. These decomposition products have a much higher mobility towards the negative pole at pH 1.9 than their precursor C<sub>1</sub> and they are formed in all conditions including storage at –80 °C in the dry state. Oxidation of C<sub>1</sub> by potassium dichromate<sup>10</sup> yields only two components which are the same as Ia and Ib on the basis of electrophoresis and fluorescent colour. Thin-layer chromatography (silica gel–EtOAc) indicated that Ia (r.f. = 0.20) was present in much greater amounts than Ib (r.f. = 0.25). Oxidation of the barium hydroxide hydrolysate of the insoluble protein yields two components which are the same as the products obtained from oxidation of C<sub>1</sub> on the basis of electrophoresis, thin-layer chromatography and fluorescence. Much higher yields of Ia and Ib are obtained by this procedure than through isolation and oxidation of C<sub>1</sub>. This is undoubtedly attributable to the decomposition of C<sub>1</sub> which occurs during the hydrolysis and isolation procedures. A third fluorescent component was also observed. The origin, structure and significance of this third component are under investigation.

Studies on well characterised tryptophan-containing proteins such as bovine serum albumin failed to reveal the generation of any fluorescent components by alkaline hydrolysis<sup>10</sup> using the methods described above. Furthermore, with such methodology, essentially no fluorescent components were found with either

very young human lens proteins or calf lens protein. (Note that C<sub>1</sub> has been obtained by proteolytic digestion of succinylated, reduced and carboxymethylated protein from old human cataractous lenses<sup>8</sup>. Such protein is poorly digested and this approach is therefore not suitable for isolation and characterisation studies.) Hydrolysis of the above preparations in constant boiling hydrochloric acid<sup>11</sup>, however, revealed significant amounts of components comparable with C<sub>1</sub>. The amount of presumptive C<sub>1</sub> could be decreased but not eliminated by the presence of a reducing agent such as thioglycolic acid during the hydrolysis. Such observations suggest that C<sub>1</sub> was an alkaline hydrolysis product of precursors present in the insoluble lens protein and HMW fractions. In acid conditions, however, it was generated from normal tryptophan-containing proteins during the course of hydrolysis. The properties of C<sub>1</sub> and a consideration of the chemistry involved suggested that it might be a mixture of tryptophan derivatives, namely the 3,4-dihydro- $\beta$ -carboline-3-carboxylic acids IIa and IIb (Fig. 1) and that Ia and Ib were fully aromatic  $\beta$ -carbolines. Synthesis<sup>10,12,13</sup> of authentic Ia, Ib, IIa and IIb confirmed this hypothesis.

The following chromatographic and spectral data were obtained from both synthetic and natural Ia (about 15  $\mu$ g per 750 mg insoluble protein): thin-layer chromatography (silica gel–EtOAc), r.f. = 0.20; ultraviolet (in EtOH), 348, 335, 320s, 305, 287, 282, 267 and 250 nm; fluorescence (uncorrected, in EtOH), excitation at 350, 338, 290 and 257 nm, emission at 385 nm; mass spectrum, 182 (100%, M<sup>+</sup>), 181 (33%, M<sup>+</sup>–H), 154 (33%, M<sup>+</sup>–H–HCN), 127 (14%, M<sup>+</sup>–H–2HCN).

For synthetic and natural Ib (about 7  $\mu$ g for 750 mg insoluble protein) the following chromatographic and spectral data were obtained: thin-layer chromatography (silica gel–EtOAc), r.f. = 0.25; ultraviolet (in MeOH), 349, 335, 288, 282, 250s nm; fluorescence (uncorrected, in EtOH) excitation at 350, 338, 290 and 257 nm, emission at 385 nm; mass spectrum, 168 (100% M<sup>+</sup>), 167 (10%, M<sup>+</sup>–H), 140 (35%, M<sup>+</sup>–H–HCN), 114 (18%, M<sup>+</sup>–2HCN), 113 (14%, M<sup>+</sup>–H–2HCN).

As stated earlier C<sub>1</sub> is unstable and furthermore, since the amount of C<sub>1</sub> isolated from the lens is very small, direct spectral studies of this material were very difficult. Comparisons of electrophoretic and chromatographic data of C<sub>1</sub> with those of a mixture of authentic 1-methyl-3,4-dihydro- $\beta$ -carboline-3-carboxylic acid (IIa) and 3,4-dihydro- $\beta$ -carboline-3-carboxylic

Fig. 1  $\beta$ -carboline structures. I, Unsaturated  $\beta$ -carbolines; II, 3,4-dihydro- $\beta$ -carboline-3-carboxylic acid, III, 1,2,3,4-tetrahydro- $\beta$ -carboline-1,3-dicarboxylic acid. In the a form R = H; in the b form R = CH<sub>3</sub>.

Fig. 2 *a*, Thin-layer chromatography comparison of (1)  $C_1$  and (2) a mixture of Ila and Iib (cellulose-0.01%  $NH_4OH$ ). *b*, Electrophoretic comparison of (1)  $C_1$ , (2) a mixture of Ila and Iib and (3) tryptophan (pH 1.9, 2,500 V, 25 min). *c*, Thin-layer chromatography comparison of methyl esters of (1)  $C_1$  and (2) Ila (silica gel-EtOAc). *d*, Electrophoretic comparison of (1)  $C_1$  methyl ester, (2) Ila methyl ester and (3) tryptophan (pH 1.9, 2,500 V, 25 min).

acid (Iib) demonstrated that they consisted of the same components (Fig. 2*a* and *b*). Note that the oxidation of  $C_1$  yields Ia and Ib, which are also obtained by oxidation of Ila and Iib, respectively. Ila and Iib on standing also decomposes to Ia and Ib with Iib being much less stable than Ila. Thus there is a disproportionate loss of Iib during the isolation of  $C_1$ , which consequently explains the small amounts of Ib obtained from the oxidation of  $C_1$ .  $C_1$  and Ila had the same fluorescent characteristics (excitation at 335 nm, emission at 495 nm; uncorrected in 0.01%  $NH_4OH$ ) and their methyl esters showed the same mobility on thin-layer chromatography and electrophoresis (Fig. 2*c* and *d*).

$C_1$  is probably a degradation product formed during the alkaline hydrolysis process. Therefore, three questions remain to be answered: Does the  $\beta$ -carboline ring structure exist *in vivo* in the lens protein? If so, in what oxidation state does it exist, and how is it linked to the lens proteins? We do not have direct evidence pertaining to the first question at this time, but the following experiment is suggestive. Protein from various sources were hydrolysed with base, oxidised with potassium dichromate, neutralised, extracted with ether and spotted on thin-layer chromatography. Protein obtained from 45- and 77-yr-old normal human lenses contained Ia and Ib. But significantly, essentially none of these components was detected in the protein of young human and calf lenses or bovine serum albumin. This suggests that there is an age-dependent formation of the  $\beta$ -carboline skeleton in human lenses. The second and third questions are more difficult to answer; however, preliminary experiments suggest that the *in vivo* precursor to the 3,4- $\beta$ -carboline-3-carboxylic acids Ila and Iib are 1-methyl-1,2,3,4-tetrahydro- $\beta$ -carboline-1,3-dicarboxylic acid (IIIa) and 1,2,3,4-tetrahydro- $\beta$ -carboline, 1,3-dicarboxylic acid (IIIb) (Fig. 1).

Base hydrolyses of synthetic IIIa (ref. 12) indeed gave the 3,4-dihydro- $\beta$ -carboline-3-carboxylic acid (IIa). These dicarboxylic acid structures are particularly attractive since they can act as a cross link between two polypeptide chains. Studies on the fluorescent 43,000 molecular weight polypeptide support this hypothesis. There is essentially no protein synthesis in the central region of the lens<sup>14</sup>. Thus the age-dependent appearance of the 43,000 molecular weight fluorescent polypeptide in this region must be attributable to the cross linking of two or more lower molecular weight components.

The mechanism by which the  $\beta$ -carbolines are formed in the lens is not understood at present. It is probable, however, that tryptophan is the precursor reacting with an unknown compound to form the  $\beta$ -carboline structure. This problem is now under investigation.

## Light-induced fast conformational change in all-trans-retinal at low temperature

AN understanding of the excited state properties of retinal is essential for the elucidation of the mechanism of the visual process, because the photochemistry of the visual chromophore accounts to a large extent for the early bleaching stages of rhodospin<sup>1</sup>. All-trans-retinal has some unusual optical properties. It exhibits a dependence of its fluorescence quantum yield on the exciting wavelength<sup>2,3</sup> as well as an anomalous heavy atom effect<sup>4</sup>. In addition, the nature of its emitting state has not been determined; there is evidence<sup>5-7</sup>, however, for the presence of a low lying, weakly allowed <sup>1</sup>A<sub>g</sub> state in some other polyenes.

I report here the nanosecond fluorescence properties of all-trans-retinal in a non-polar matrix at 100 K. Two samples of all-trans-retinal (Sigma and Eastman Kodak) were used with identical results. The purity of the samples was ascertained by thin-layer chromatography<sup>4</sup>. A nanosecond fluorometer with a boxcar averager<sup>8,9</sup> was used. A 7-60 Corning filter was used for excitation; the fluorescence quantum yield is constant<sup>2</sup> when exciting in the spectral region in which the filter transmits (maximum transmission is at ~360 nm).

Nanosecond time-resolved fluorescence spectra in a mixture of 1:1 by volume of isopentane and methylcyclohexane at 100 K are shown in Fig. 1. A broadening of the spectrum with time in the nanosecond range is observed. The full width to half maximum (FWHM) of the spectrum obtained at 10 ns after the peak of the exciting light pulse is 127 nm; that of the spectrum obtained at 1.5 ns before the peak of the exciting light pulse is 113 nm. But the spectral maximum as well as the long wavelength portion of the spectrum are invariant with time.

Figure 2 shows a strong dependence of the form of the decay on the emission wavelength. At 460 nm the decay is non-exponential; there is a long component corresponding to a decay time of about 3 ns at long times (small values of  $W(t)$ ) and a much shorter component corresponding to a decay time of about 0.3 ns at short times. As the emission wavelength increases, the decay becomes faster but it continues to be non-exponential up to about 510 nm. At

**Fig. 1** Normalised time-resolved fluorescence spectra of a  $10^{-6}$  M solution of all-*trans*-retinal in a mixture of 1:1 by volume of isopentane and methylcyclohexane at 100 K. The spectra were taken at the following times relative to the peak of the exciting light pulse (taken as zero time): (1) -1.5 ns; (2) +4 ns; (3) +10 ns. FWHM of the exciting light pulse  $\approx 4$  ns. A 7-60 Corning filter was used for excitation. The emission was analysed using a high intensity Bausch and Lomb scanning monochromator at a bandwidth of 19 nm. The spectra were not corrected for the variation of the photomultiplier-monochromator sensitivity with wavelength.

longer wavelengths the decay is virtually single exponential and independent of the emission wavelength; a decay time of about 0.1 ns is obtained in this wavelength region. It is significant that the variation of the form of the fluorescence decay with the emission wavelength occurs in the wavelength region for which the fluorescence spectrum is time dependent; this suggests that these two phenomena have a common origin. It should be noted that a decay time of

**Fig. 2** Phase-plane plots for the fluorescence decay of a  $10^{-6}$  M solution of all-*trans*-retinal in a mixture of 1:1 by volume of isopentane and methylcyclohexane at 100 K for the following emission wavelengths:  $\bullet$ , 460 nm;  $\blacksquare$ , 480 nm;  $\blacktriangle$ , 500 nm;  $\blacklozenge$ , 560 nm. The data were deconvoluted according to the method of Demas and Adamson<sup>12</sup>. Long times correspond to small values of  $W(t)$ . For a single exponential decay a phase-plane plot yields a straight line of negative slope equal to the decay time. A 7-60 Corning filter was used for excitation. The emission wavelengths were selected by using a high intensity Bausch and Lomb monochromator at a bandwidth of 19 nm.

$\sim 0.6$  ns has been reported<sup>4</sup> in absolute ethanol at 77 K; this value apparently refers to the long wavelength region.

Calculations<sup>10</sup> have shown that, as a result of electronic delocalisation brought about by excitation, the excited state-equilibrium torsional angle  $\phi_{6-7}$  between the cyclohexene ring and the polyene chain of all-*trans*-retinal is very different from that in the ground state. I infer then, that immediately after light absorption, relaxation will occur from the Franck-Condon electronic state, which is associated with the ground-state conformation, to an equilibrium excited state associated with a modified conformation. I therefore attribute the time and emission wavelength-dependent phenomena reported here to a relaxation process in the excited state resulting from rotation of the polyene chain about the C6-C7 bond. The relaxation time for this process depends of course on the microviscosity of the molecular environment. The spectral broadening observed in the nanosecond range implies that, under my experimental conditions, the relaxation process competes efficiently with the deactivation of the excited state by radiative and radiationless processes.

The results of a picosecond study<sup>11</sup> indicated that the formation of prelumirhodopsin when rhodopsin is irradiated probably involves a restricted change in the geometry of retinal rather than a complete isomerisation. The light-induced conformational change reported here may well be important in this first event of the visual process.

This work was supported in part by a biomedical sciences grant from the National Institutes of Health. I thank Dr P.-S. Song for access to his data before publication.

## Algal sexuality

CAVALIER-SMITH<sup>1</sup> raises many interesting points on the origin of the eukaryotic cell and its organelles. I find myself in general agreement with him and with others<sup>2-4</sup> who have provided an alternative to the widely held theory that eukaryotic organelles were originally acquired by endosymbiosis. I wish to comment, however, on one aspect of his evolutionary scheme (see ref. 1, Fig. 5), namely, the assertion that sex is absent in the Dinophyceae, Euglenophyceae, and Cryptophyceae. In fact, there have been several reports<sup>5-7</sup> of sexuality in the Dinophyceae. Beam and Himes<sup>8</sup> have observed pairing between cells of *Cryptothecodinium cohnii* and their fusion into a single cell, followed by nuclear fusion. Furthermore, those workers<sup>8</sup> and others<sup>9</sup> have demonstrated genetic recombination in *C. cohnii*. Although there has been no such conclusive demonstration of sexuality in the Euglenophyceae, it is necessary to approach this negative evidence cautiously—especially since there is evidence of a meiotic process in two genera of this group<sup>10,11</sup>. One can only repeat Leedale's careful conclusion that "It seems probable that there is no sexuality in the majority of euglenoids, but it remains a possibility that the process does occur as a rare phenomenon; this can never be disproved". Finally, there is a dearth of information on the Cryptophyceae, and consequently it is premature to conclude that sexuality is absent in that group.

These observations do not detract from Cavalier-Smith's main arguments. If anything they strengthen his evolutionary scheme since, if sex does exist in the Dinophyceae, Euglenophyceae, and Cryptophyceae, one could move those groups from their isolated position on Fig. 5 of ref. 1 to a position among the other algae and speculate on their interrelationships. (For example, how are the Dinophyceae and Cryptophyceae related to other algae whose chloroplasts contain chlorophylls *a* and *c*?)

## Irradiation and DNA breaks

JOHANSEN and Boye<sup>1</sup> reported their findings on the controversial question of whether the initial number of breaks induced by ionising radiation in DNA in oxic and anoxic conditions are identical, or whether less breaks occur in nitrogen than in oxygen. Their conclusion supports the latter.

They found<sup>1</sup> the difference in the yield of breaks in cellular DNA when *Escherichia coli* was irradiated in oxic and anoxic atmospheres and to minimise rapid repair<sup>2</sup> as far as possible, the time from irradiation to lysis of the cells was, according to those authors, "a fraction of a second". They assumed that cellular repair enzymes would not rejoin breaks in this short time and on the basis of some theoretical extrapolations on the correlation between the yield of breaks at a given dose and the rate of rejoining by cellular enzymes, they believed that the differences in yield of breaks due to rapid repair was an erroneous conclusion. They assumed that rejoining of breaks would not have occurred and if so, that the initial yield of breaks in oxic irradiation was at least three times more than that in anoxic conditions. I wish here to analyse the status of this controversy and I disagree with Johansen and Boye<sup>1</sup>.

The subject has long been a matter of debate and Dean *et al.*<sup>3</sup> were the first to suggest that anoxic breaks were subject to rapid enzymatic repair, showing that in experimental conditions which inhibited rejoining of strand breaks, nearly identical yields were obtained following oxic and anoxic irradiation.

The isolation of a DNA polymerase I mutant<sup>4</sup> and the study of the kinetics of single-strand break repair in *polA1* mutant<sup>2</sup> led to the recognition of a rapid repair system occurring in *E. coli*. The work on cellular DNA involved complications because repair probably

works very fast, rejoining breaks during irradiation and up to the moment of lysis. Town *et al.*<sup>5</sup> attempted to overcome the problem by preinactivating the cells at 52 °C for 10 min before irradiation and they obtained identical yields of breaks. Heat treatment, however, induces single-strand breaks in DNA<sup>6</sup> and release of sulphhydryl compounds in the medium<sup>1</sup>.

Another approach<sup>7</sup> was to irradiate bacteriophage  $\lambda$  extracellularly in oxic and anoxic atmospheres. Contrary to the situation for cellular DNA, any change in phage DNA would thus remain unmodified and beyond the influence of cellular repair as long as the DNA was not injected into a host. DNA could safely be extracted and layered on an alkaline sucrose gradient<sup>7</sup>. Identical yields of DNA breaks were obtained in oxic and anoxic extracellular irradiation<sup>7</sup>. When  $\lambda$  DNA was irradiated intracellularly in a *polA1* host, the decrease in molecular weight of  $\lambda$  DNA was identical in both oxic and anoxic conditions and equalled that obtained after extracellular irradiation. Intracellular anoxic irradiation of  $\lambda$  DNA to the same dose in wild-type bacteria, yielded no breaks<sup>7</sup>. This demonstrates that there is no difference in the initial number of breaks and that a rapid repair system, involving DNA polymerase I, rejoins breaks very rapidly. Similarly, there are data<sup>8,9</sup> on the equal number of breaks in oxic and anoxic conditions with phage T3 and T7 irradiated extracellularly.

Wild-type bacteria were injected for 10 min with  $\lambda$  DNA which had been irradiated extracellularly with 50 krad in oxic and anoxic conditions.  $\lambda$  DNA was immediately analysed for single-strand breaks.  $\lambda$  DNA irradiated anoxically had no breaks, but a few could be seen in DNA irradiated in oxygen. Since the initial yields of breaks were identical<sup>7</sup>, the difference in molecular weight after infection is attributable to cellular repair.

Sulphydryl compounds may have a function in the radiation sensitivity of *E. coli*<sup>1</sup> but I feel that the experiments described (ref. 7 and above), supported by other results<sup>2,5,8,9</sup> should leave no doubt that: (1) initially the number of DNA breaks are identical in oxic and anoxic irradiation and (2) rapid repair, involving DNA polymerase I and probably ligase, does exist in cells and preferentially rejoins anoxic-type breaks. This could explain the differ-

JOHANSEN AND BOYE REPLY—We believe Srivastava's conclusions<sup>1</sup> are based on misinterpretations of circumstantial evidence. First, it has long been known that when bacteriophages are irradiated extracellularly the survival of their plaque-forming ability is identical in oxygen and in nitrogen. When irradiated in the presence of sulphhydryls, however, the survival in nitrogen is increased, and becomes higher than in the presence of oxygen<sup>2</sup>. This suggests the importance of sulphhydryl compounds in anoxic protection. The finding that the yield of DNA strand breaks is similar in oxic and anoxic conditions when phage  $\lambda$  is irradiated extracellularly in the absence of sulphhydryls<sup>3</sup> is as expected, and within the framework of classical radiation biology.

Second, when irradiated intracellularly, in normal physiological condi-

bacteria heat shocked before irradiation<sup>4</sup>; (3) bacteria kept at pH 8.6 (ref. 8). During these treatments, the cells become leaky and considerable amounts of sulphhydryls are lost into the suspending medium<sup>5</sup>; (4) Srivastava's own experiment with intracellular phage  $\lambda$  (ref. 3). We noticed that in this experiment the bacteria were suspended in 0.01 M  $\text{MgSO}_4$  before irradiation, and wondered whether this hypotonic treatment had any effect on the level of endogenous sulphhydryls in the bacteria. As can be seen from Table 1, suspending bacteria in 0.01 M  $\text{MgSO}_4$  leads to a loss of a considerable amount of sulphhydryls from the cells. Small contaminating amounts of oxygen—if present—will increase the 'anoxic' yield of radiation-induced DNA strand breaks in these cells.

Third, experiments in which phage  $\lambda$  is irradiated extracellularly in oxygen or in nitrogen in the absence of sulphhydryls, and the DNA analysed 10 min after infection of a repair-proficient strain are very complex, and interpretation is not unambiguous. In conclusion, recent experiments<sup>4,5</sup> tend to support the view that the oxygen effect in radiation-induced DNA strand breakage is due to radiochemical reactions, rather than to preferential enzymic repair.

Table 1 Effect of hypotonic treatment on cellular sulphhydryls

Treatment*	Sulphhydryls in cell-free supernatant (mM)	Sulphhydryls in TCA extract (mM)
Phosphate buffer, pH 6.8	<0.05	2.04
0.01 M $\text{MgSO}_4$	1.15	1.12

\*Cells of *E. coli* K12, strain AB 1157, from a 100-ml log-phase suspension were collected by centrifugation and washed in phosphate buffer<sup>1</sup> at pH 6.8. The cells were resuspended in 0.3 ml of the same buffer or in 0.3 ml 0.01 M  $\text{MgSO}_4$ , kept for 10 min at room temperature and the concentration of sulphhydryls measured in the cell-free supernatant<sup>5</sup>. The bacteria were suspended in 0.3 ml trichloroacetic acid (TCA) at 0.3 M, kept at room temperature for 10 min and the concentration of acid soluble sulphhydryls measured in the cell-free extract.

tions, a higher yield of strand breaks is generally found in oxic than in anoxic conditions, both for chromosomal and phage DNA. This is true even when the experiments are performed so fast that the ligase could rejoin, at the most, one of a hundred DNA strand breaks formed<sup>4,5</sup>. We are aware of four types of experiment where the anoxic yield of DNA strand breaks is increased to—or nearly to—the oxic yield: (1) bacteria treated with the sulphhydryl-binding agent *N*-ethyl-maleimide (NEM) before irradiation<sup>6</sup>. This sensitisation is reversed by strict anoxia<sup>7</sup> and is believed to be caused by increased sensitivity to small contaminating amounts of oxygen in cells with low levels of endogenous sulphhydryls<sup>8</sup>; (2)

size or development...". Chang *et al.*<sup>2</sup> investigated the well-known asymmetry of the scrotum in man and showed that in right-handed subjects the right testis tended to be higher, whereas the converse applied in left-handed subjects. To investigate whether this was simply due to the greater weight of the left testis in right-handed subjects they measured the weight and volume of the testes in (presumably mainly right-handed) cadavers and found, paradoxically, that the right (that is, the higher) testicle was also the heavier and of greater volume, a result in accord with Mittwoch and Kirk's foetal data<sup>1</sup>.

Interest in testicular asymmetry may however be traced back much further. Winckelmann<sup>3</sup> in 1764 commented that: "Even the private parts have their appropriate beauty. The left testicle is always the larger, as it is in nature;". He went on, however, "so likewise it has been observed that the sight of the left eye is keener than the right", an observation which, to my knowledge, has not been confirmed.

To test Winckelmann's claim, I observed the scrotal asymmetry of 107 sculptures, either of antique origin or Renaissance copies, in a number of Italian museums and galleries. Table 1 shows that although the ancient artists were correct in tending to place the right testicle higher, they were wrong in so far as they also tended to make the lower testicle the larger: we may postulate that they were also using the common-sense view that the heavier ought to be lower. Although Winckelmann's observations of antique sculpture were correct, his observations of nature are clearly in error.

The reason for the artists placing the right testicle higher than the left is not clear. It may reflect the true observed state of things, but it may also be a function of Greek left/right symbolism, in which right and male, and left and female were regarded as equivalent, and thus for instance, the male child was presumed to come from the right (and thus higher?) testis, and vice versa for the female child<sup>4</sup>.

## Optimum strategy for perpetuating genes?

ANY textbook on behaviour which attempts to go beyond the single topic monograph, presents its author with formidable problems concerning the selection and organisation of material. Behavioural studies may have their origins in fields as far separated as neurophysiology and ecology. Brown's book\* has evolution as a unifying theme, and indeed behaviour itself is not always its main focus, for it contains a great deal of material pertinent to the mechanisms of evolution which would not normally be found in a behavioural text. It is very much a product of the new sociobiology school, and none the worse for that. We have certainly gained many fresh insights into animal behaviour from a consideration of the selective forces which operate on individuals with respect to their interactions with others of their species.

Brown operates very skilfully on the borderlines between ethology, population biology and genetics, and he is highly competent in all of them. His selection of literature is good and experimental results are described, and often illustrated, in sufficient detail for the reader to understand their significance fully. On those topics where I am competent to judge the adequacy with which a controversy is being discussed, Brown misses very few of the points and this is a rare quality in textbooks.

There are some penalties to be paid for being so comprehensive. The book is very long and the choice of more purely behavioural topics for inclusion seems rather arbitrary. Brown begins with a brief prologue which I found rather odd. He lays stress on diversity between species and constancy within species without once mentioning change. Indeed almost at the outset he states that species "... tend to persist

From Lorenz and Tinbergen, 1937

*Classic example of inherited behaviour patterns: a greylag goose rolling an egg back into its nest. The goose invariably attempts to roll the egg back using its bill in the manner shown, rather than using its foot, wing or bill in some other way.*

virtually the same for generation after generation." True, but not an idea I would choose to emphasise at the start of a book on evolution. The changes which natural selection can elicit from populations form the bulk of the book which follows.

The book is organised into six sections of very diverse proportions. Thus the first two on phylogeny and genetic basis of behaviour have but single chapters. The former is a brief but fresh survey of the possibilities for analyses of the phyletic descent of behaviour within and between groups. The genetics chapter is less satisfactory, although it provides a reasonable review of the different approaches in behaviour genetics (with however, no reference to the quantitative analysis of the genetic architecture of behavioural traits). Nevertheless this chapter seems very isolated from the rest of the book because our knowledge of the inheritance of behaviour does not yet match up to some of the questions which evolutionary studies force us to ask.

The book's real qualities emerge in sections 3 and 4 on social organisation and communication. Brown gives an excellent account of the modern sociobiological approach to animals in groups. He deals with the factors which determine the nature and size of groups and goes on to discuss mating systems and aid-giving behaviour of all

types. He presents most of the arguments very clearly in depth and I find it the more strange that Wynne-Edwards' ideas on group selection and the origins of social behaviour are given such brief treatment. They seem to me of great importance not because they are right (I think they clearly are not) but because of the effect they had on the course of sociobiology. The controversy which surrounded Wynne-Edwards' theories led to a great deal more attention being focused on the individuals within the group. This was vital in the development of the modern synthesis of behavioural and evolutionary concepts.

Will all social behaviour, including that which gives aid to others, turn out to be an optimum strategy for perpetuating one's genes? Certainly we need to know as much as possible about the genetic relationships within groups. Brown provides a very good review of the evolution of behaviour in relation to kin selection. He manages to retain clarity on some complex issues without oversimplifying.

The section on communication is more purely behavioural but the material provides some of the classic stories in the evolution of behaviour. Just as did Marler and Hamilton in their 1967 textbook, so Brown by skilful choice of examples manages to make the whole subject fresh. There is also a

\**The Evolution of Behaviour*. By Jeram L. Brown. Pp. xix+761. (W. W. Norton: New York, 1975.) \$15.95.

## Good but expensive fare

*Introduction to Physiology.* By Hugh Davson and M. B. Segal. Volume 1: Basic Mechanisms, Part 1. Pp. xii+561. Volume 2: Basic Mechanisms, Part 2. Pp. xi+481. (Academic: London and New York, June 1975.) £6.80 each part.

THESE two volumes are the first to appear in a series of five. A reviewer thus faces a similar dilemma to a diner passing judgement on a complete meal after sampling only the soup and fish. In this instance, however, the renown of the chef de cuisine, Dr Hugh Davson, is such that it is only necessary to decide for what type of clientele he is catering to predict what is in store. It turns out that, along with his co-author, Dr Segal, he is providing good, solid and easily digestible fare without too many sophisticated trimmings but also without succumbing to the hazards of oversimplification.

Volume 1 deals, in the opening chapters, with cellular physiology and includes a good deal of material usually classed as biochemistry—for example, the tricarboxylic acid cycle and protein synthesis. Such fundamental topics in general physiology as osmosis and the genesis of bioelectric potentials are also covered and up-to-date descriptions of ultrastructural findings related to cellular function and interactions are provided. Some elementary thermodynamics is also included but, although simple equations are used, the approach is essentially descriptive. The concept of chemical potential, although it receives a passing mention, is not seriously developed and the section on

entropy is one of the few instances in which the exposition is a trifle confusing, if not actually misleading. The remaining chapters are devoted to haemodynamics, respiratory exchange, in testinal absorption and renal function, all of which are treated in considerable detail. The second volume is concerned with the nervous system (chiefly the peripheral and spinal divisions), hormonal control (discussed in rather general terms), the effector systems (muscles and glands), defence mechanisms (mainly haematology and immunology) and reproduction (including some 20 pages on lactation).

The overall presentation is clear and commendably free from errors, although an occasional slip such as the heading "carbonate" over a section evidently devoted to carbamate could be tiresome to a beginner. The illustrations are of high quality and generally well chosen, but it seems odd to reproduce a typical Gamble diagram and attribute it to a recent review, and to opt for an oxygen dissociation curve published in 1958 which adds little to the one published by Bohr and Krogh in 1904. Students with hardly more scientific preparation than a nodding acquaintance with chemical formulae and graphs, should find these books comprehensible. After mastering the five volumes (if the succeeding ones resemble the first two) such students will be not only introduced to but thoroughly at home in physiology. Some, however, may find this protracted initiation and the entrance fee (presumably in five instalments of £6.80 each), which goes with it, too disheartening and will feel tempted to seek another portal of entry to the subject.

R. V. Coxon

very good account of the evolution of display movements although the motivational analysis of displays which has played such a large part in the development of this area of ethology, and which has strong evolutionary implications, is mentioned only in brief.

For the final sections of his book Brown chooses some topics on what he calls "the physiological basis of species constancy and species diversity in behaviour." The chapters on reflexes and fixed action patterns do fit the plan, but he goes on to deal with sensory systems, migration and circadian rhythms. They are all good, modern accounts, but I fail to see where they fit into Brown's evolutionary scheme. I have similar problems with the contents of the final section on development, in which the behaviour of embryos is covered in detail, but there is no mention of learning. The concluding chapter on bird song, however, does provide an opportunity to discuss the evolution of

development itself. The birds provide such a good range of ecological and social variants which we can now begin to correlate with the manner in which their song develops.

So this review ends as it began, quibbling about the selection of material. Brown's evolutionary theme has sufficient strength to give a solid backbone to his chapters even though all of us would leave some things out and include others. I think this is a distinguished textbook. In Britain it is probably too long for most undergraduate courses, but it can nevertheless unhesitatingly be commended as a book for students to consult. I defy anyone to browse in the central chapters without having their attention riveted by some elegant and fascinating example of the manner in which their behaviour has come to equip animals for survival and I can pay Brown no higher compliment.

Aubrey Manning

## Cryogenics

*Heat Transfer at Low Temperatures.* (The International Cryogenics Monograph Series.) Edited by Walter Frost. Pp. xiv+382. (Plenum: New York and London, 1975.) \$42.00.

THIS book "is intended to enhance the knowledge of the thermal design engineer faced with solving heat transfer and fluid flow problems at low temperatures." The temperature range which is covered lies, in effect, between room temperature and 1K: thermal transfer problems peculiar to lower temperatures than this are not described at all. The book consists of 15 chapters, in reality separate articles prepared by 20 different contributors.

The first two chapters deal effectively with 'classical' thermal transfer through conduction and convection. The second, and main, part of the book consists of ten chapters devoted entirely to two-phase phenomena of various sorts. Topics such as nucleate pool boiling, film boiling, two-phase flow, and the condensation of gases on cryogenic surfaces are treated in considerable detail. The third part consists of two chapters on topics which, presumably, did not seem to the editor to fit in conveniently anywhere else: one on radiative heating, with particular reference to the influence of cryodeposits on the cold surface; and a final chapter on thermal transfer to HeII.

No attempt has been made to standardise nomenclature or units between the different chapters: pounds and feet coexist uneasily with kilograms and centimeters; BTU with ergs and joules; and Kelvins with degrees Centigrade and even Fahrenheit. The remark on the dustcover about "surveying the literature to date . . ." was no doubt accurate at the time of writing. While three or more years may perhaps be a fairly normal publishers' gestation period these days, it seems rather a pity that more could not have been done to update the book at the proof stage: this would, at least, have enabled some modification of the amusingly anachronistic remark in the final chapter to the effect that liquid 'He and the superconducting electron gas are the only known superfluids.

The book does contain a great deal of information, however, so that, in spite of these minor shortcomings, it should certainly be useful to aspiring designers of rockets, space simulators, superconducting generators and other large scale cryogenic machines involving the flow or storage of liquified gases.

P. V. E. McClintock

## Molecular rearrangements

*Isotopes in Organic Chemistry*. Volume 1: Isotopes in Molecular Rearrangements. Edited by E. Buncl and C. C. Lee. Pp. xvi+301. (Elsevier Scientific: Amsterdam, Oxford and New York, 1975.) Dfl.100; \$41.75.

LABELLING experiments have often been crucial to the development and understanding of modern organic chemistry and few will question after reading this book that many mechanistic studies would be considerably harder, if not impossible, without the availability of isotopic techniques. Nonetheless, good texts and reviews of this field have been thin on the ground; this series, of which the pre-

sent volume is the first, should fill an important gap in the chemical literature.

Both carbonium ion (26 pages) and carbanion (105 pages) rearrangements are given another airing by N. C. Deno and D. H. Hunter, respectively, and pericyclic reactions (33 pages) are reviewed by W. R. Dolbier. J. S. Swenton's contribution concerns photochemically initiated rearrangements (51 pages) and J. L. Holmes deals with rearrangements occurring alongside mass spectral fragmentations (73 pages). As one might expect from these particular authors, of whom all have made significant contributions to their specialised topics, their articles are well-written from an authoritative standpoint, and all seem to cover the literature up to 1973. Generally, the

authors have written a fairly descriptive text of the kind usually appreciated by organic chemists and have attempted (with varying success) to relate the isotopic results to other mechanistic criteria. The editors have avoided the obvious pitfall of allowing repetitious theoretical introductions to each chapter, so the amount of worthwhile information is high.

This book (and probably the series, too) is written for the specialist with a deep interest in organic mechanistic studies. Elsevier might seriously have considered making each chapter available separately, particularly as the contents of the present volume span such a wide range of interests. Nonetheless, I strongly recommend the text as a valuable addition to any chemical library.

## Neoplastic development

*Neoplastic Development*. Volume 2. By Leslie Foulds. Pp. xiv+729. (Academic London and New York, August 1975). £16.80; \$43.50.

LESLIE FOULDS spent most of his working life in experimental cancer research, but his interest in cancer extended beyond the laboratory. His object in writing this book is perhaps best given in his own words:

In any branch of science it is important to confront inferences from laboratory experiments with the stark realities of natural phenomena... It is especially important... when the growing estrangement between clinical practice and laboratory research is leading to grave doubts about the ability of laboratory research, as now conducted, to make any substantial contribution to the alleviation of human suffering attributable to neoplastic disease. Writing from the standpoint of a medically qualified experimental pathologist with a long-standing interest

in both developmental biology and medical practice but with no direct participation in either, I hope to illustrate in this volume (Volume 2) the complimentary and essential, but diverse contributions, of biological theory, laboratory analysis and clinical experience of human disease...

Volume 1 provided a general theory, basically that neoplasia is a developmental process akin to normal development but differing from it in some important respects, still to be defined. In Volume 2, he considers special cases of neoplastic development in man, and animals, and discusses the biological and medical implications. After a brief general introduction, there are large sections on neoplasia of the skin, mammary neoplasia in laboratory animals and human breast cancer. Shorter sections deal with cancer of uterine cervix, urinary tract, lungs, liver and some endocrine glands, and there are two brief sections on neoplasia of unknown pathogenesis and virus tumours. The section on skin is the most extensive and is used to establish general

principle concerned with the initiation-promotion theory and with tumour progression. The latter is illustrated by descriptions of the disease process in man and in the experimental animal, and a discussion on aetiology. A similar approach is used in the other sections.

Like its predecessor it is a valuable work and few of those interested in cancer in general or in one of the special fields discussed will fail to learn something of value. It will teach the clinician something of experimental cancer research and the research worker a little about human cancer, but in a major objective—a more rational approach to the clinical management of the patient—it must be regarded as a gallant failure, not through a fault of the author but through our ignorance. It is sad that the author should have died from cancer shortly before the book was published, and before he completed the final chapter summarising his views and general conclusions.

L. M. Franks

## Bold perspective

*Ion-selective Electrodes.* (Cambridge Monographs in Physical Chemistry Volume 2.) By Jiri Koryta. Pp. 207. (Cambridge University: Cambridge and London, August 1975.) £10.50.

THE development and application of ion-selective electrodes (ISEs) based on membrane electrochemical principles have been, with comparable activity in liquid chromatography, the two most rapidly advancing areas in chemical analysis and continuous monitoring. Since 1965 improved or new measurements have become possible which have not only given impetus to analytical potentiometry, but have a broad impact in diverse areas as environmental science, physiology, clinical chemistry and biophysics. In fact one difficulty in following progress in the field is the widespread use of ISEs

and the large number of specialist journals in which results appear. ISEs are serving the fundamental purposes of making analytical chemistry visible in other branches of chemistry, physics, medical and health sciences and the converse effect of broadening the interests of analytical chemists in interdisciplinary problems and projects.

To write a book at midstream in a rapidly moving field requires courage, and to achieve a sense of perspective on the past and possible future developments is most unusual. Koryta's new volume is well organised and executed, and contains clearly presented fundamentals and applications drawn from all fields touched by ISEs. Jiri Koryta is a well known electrochemist, a major disciple of Nobel Laureate J. Heyrovsky and an exponent of the polarographic method. His outstanding contributions to theory and practice of coupled, homogeneous-heterogeneous electrode processes, complex ion equilibria and adsorption effects make him an ideal commentator on the field of ISEs and membrane processes. The primary strength of the book is the mature overview given on the topics of diffusion-migration and the interfacial processes which underlie the potential sources for fixed site, mobile site and neutral carrier classes of membrane electrodes. At the same time practical, analytical methods are tabulated and current topics such as continuous monitoring and use of computer-controlled titrations are described.

Only on hindsight can one determine key, definitive volumes on a given speciality area. Because of the continuing growth in this field, all previous books, although useful for reference, are clearly premature. This new book unfortunately must suffer from the same limitations: new fundamental studies on response mechanisms, time-dependence of responses and applications are still appearing in current literature at a rapid rate. This volume contains literature citations only as recent as 1973 and is an expansion of Koryta's excellent 1972 review article. Nevertheless, this book is the finest, comprehensive work published to date.

**Richard P. Buck**

## Climatic change

*Ice Ages: Ancient and Modern.* (Proceedings of the 21st Inter-University Congress, January 1974.) Edited by A. E. Wright and F. Mosley. Pp. 320. (Seel House: Liverpool, 1975.) £12.00; \$33.00.

THIS book is advertised as suitable for geology and geography students "from sixth form to final year undergraduate level"; but unless the sixth formers of

today are markedly more able than those of my generation it would seem better suited to students of Earth sciences at a rather later stage of their academic careers, including those active in research. For such people, the book will be of most value to those who have had a less formal education in geography and geology at an earlier stage. It provides a good quick guide to geology and timescales, to processes of sedimentation and to glacial tectonic structures, before moving on to discuss climate and climatic change in more detail.

There is one exceptionable statement early in the first section ("Introduction to the Quaternary") in which F. W. Shotton refers to ice ages occurring when "... snowlines extend outwards from the poles, ice sheets expand, mountain glaciers push forward ..." and makes no reference to the recent work which suggests strongly that ice ages can occur much more quickly than this older picture suggests, with snow and ice cover building up over a wide area of the northern hemisphere in a few years or decades. Otherwise, the various contributions (which are based on lectures given at Birmingham University in January 1974) provide a good overview of how geological and other evidence (pollen analysis, studies of fossil beetles and so on) provides an indication of how climate has fluctuated.

But the discussion of the causes of such changes is less satisfactory, and the volume also suffers from being almost entirely concerned with events in north-western Europe, particularly Britain. It is inexcusable, in a book of this length, to dismiss variations caused by changes in the Earth's orbit and inclination in less than a page and by volcanic dust in three lines. There is a preponderance of geological jargon in some of the contributions, and most of the contributors share the geologists' preference for talking in terms of the named geological periods of time, rather than in years b.p. These deficiencies are balanced to some extent by the copious references and by a summary from the editors putting the various contributions into perspective. In this case, the summary is particularly valuable and does not become bogged down by attempts at verbatim reporting of question and answer sessions. The importance of this kind of research, and the slightly parochial inclination of this book, are highlighted by one titbit from the summary: "even today it would only require an average temperature of 2 °C to [produce] glaciers on Ben Nevis".

Those searching for more answers in the study of climatic changes will be stimulated by this volume.

**John Gribbin**

## Nuclear structure

*Structure of the Nucleus.* By M. A. Preston and R. K. Bhaduri. Pp. xiv+693. (Addison-Wesley: Reading, Massachusetts and London, August 1975.) Cloth \$29.50; Paper \$19.50.

FOR more than a decade Preston's *Physics of the Nucleus* has been used by nuclear physicists as a comprehensive and reliable reference book. Its essential theme is the attempt to derive the properties of the nucleus from our knowledge of the nucleon-nucleon forces. This can be done to some extent, but in many respects we still have to rely on phenomenological models. The years since 1962 have seen many important advances, and while progress has been made in some areas the problem is now seen to be more complicated than was previously thought, particularly because of the importance of many-body forces. To deal with this situation Professor Preston, now joined by Dr. Bhaduri, has thoroughly revised and re-written the chapters dealing with nuclear structure, and since this is already as long as the whole book before revision the chapters on nuclear reactions have been omitted. The plan is very similar and successive chapters deal with the constituents of nuclei, internucleon forces, nuclear moments, nuclear shapes and sizes, and nuclear binding energies. The second part is devoted to nuclear models, correlation in nuclear matter, collective nuclear motion, and Hartree-Fock and particle-hole calculations. The final part covers  $\alpha$  radioactivity and fission. The standard of the original volume is amply maintained, and the new version will be a valuable and much-used text for years to come. **P. E. Hodgson**

## Human tumour lines

*Human Tumour Cells in Vitro*. Edited by Jørgen Fogh. Pp. xix+557. (Plenum: New York and London, 1975.) \$44.50.

THIS book, a collection of 16 papers on human tumour cell culture, has appeared at an appropriate time. Belatedly research laboratories are beginning to show an increasing interest in cancer in man and at the same time there is an increasing, if somewhat misguided, pressure from society to limit suffering in laboratory animals, particularly since it cannot or will not limit suffering among men. Consequently *in vitro* systems, especially those using human tissue, are becoming increasingly popular. As in any branch of science the value of a particular technique depends on the questions it is being used to answer. If cell cultures are being used for virus production or cytotoxicity testing (for example), the nature of the cells is unimportant provided they serve the purpose of the experiment. If the experiments are concerned with the nature and behaviour of the cells themselves a more critical approach is required.

It is important to know the precise origin of the cells and the variations in structure and function which they may have developed as a consequence of establishment *in vitro*. This was well known to the early practitioners of the art of cell culture—all of whom were biologists or physicians accustomed to studying the whole individual—but with the expansion of cell and molecular biology, concerned principally with isolated cells, and an era when living cells could be ordered and supplied 'off the shelf' by laboratory supply houses, these basic facts were often forgotten. Although the whole universe may be contained in a grain of sand the whole of biology is not contained in a HeLa or BHK cell. Why for example is it possible to maintain such a small proportion of tumour cells in culture as permanently established cell lines? How can tumour cells *in vitro* be identified with certainty and distinguished from mesenchymal cells arising from the non-malignant stroma of the tumour? *Human Tumour Cells in Vitro* considers some of these problems.

Apart from a valuable description of 31 new human tumour lines by the editor and Dr Trempe, most of the information is available elsewhere to those with access to a good library but for the others it provides a useful survey of methods and media which have been used for the establishment of human tumour cell lines *in vitro*. There are also sections on cytological characterisation, chromosome abnormalities and

ultrastructure and on the search for viruses in human cancer cells.

L. M. Franks

## Pineal physiology

*Frontiers of Pineal Physiology*. Edited by Mark D. Altschule. Pp. xii+269. (MIT: Cambridge, Massachusetts and London, 1975.) £8.75.

It would be a pity if this book were read as an entrée to the new and exciting realm of pineal physiology; its title stakes a claim which is wholly unjustified by its contents, a collection of papers (some reviews, others research reports, yet others an uneasy mixture of the two) uneven both in length and quality. Five years have passed since the conference on which it is based was held, and this latent period is all too obvious in places.

The intense enzymatic activity of the pineal, and the way this is changed by either natural or experimental lighting are characteristic features. Three chapters survey this area, with varying degrees of thoroughness. A firmer editorial hand might have improved the organisation of this part of the book, and reduced the considerable overlap between individual chapters; much of these have also appeared in other reviews by the same authors.

Although studies on pineal function are still dominated by the discovery of melatonin, increasing attention is now being given to pineal polypeptides, some of which seem to resemble those found in the hypothalamus and pituitary; two research reports deal with these substances. P. H. Sampson contributes a brief survey on the way the pineal may be involved in various categories of behaviour, most of which is a lengthy report of an experiment showing that pinealectomy somewhat reduced maternal behaviour. We are left wondering what this might mean in terms of pineal function, for no interpretation is offered.

The most intriguing, and inevitably the most controversial, part of the book explores the possible association between malfunction of the pineal and schizophrenia. The large amount of 5-hydroxytryptamine in the pineal and the suspicion that this monoamine is involved in schizophrenia make the link tempting (although drugs ameliorating this condition are generally dopamine blockers) M. D. Altschule contributes a chapter which is too brief either to inform adequately or to convince in which it is said that administering pineal extracts improves abnormalities in carbohydrate metabolism in schizophrenics, although how these are related to the disease is unclear. L. B. Bigelow describes the results of a trial in which schizo-

phrenics were given daily injections of melatonin-free pineal extract. In spite of a curious method of measuring the patient's mental state, an uneven baseline and coincident changes in phenothiazines, the results of at least one case suggest the need for a more comprehensive study. Dr Bigelow quotes the isolation from the pineal of a substance inhibiting the formation of dimethyltryptamines, long known to be hallucinogenic. What a pity his study didn't concentrate specifically on these symptoms.

This book represents the frontiers of our knowledge indistinctly, and the signposts to the future are hard to discern from reading it. J. Herbert

## Xylem strategy

*Ecological Strategies of Xylem Evolution*. By Sherwin Carlquist. Pp. xi+259. (University of California: Berkeley, Los Angeles and London, August 1975.) £6.85.

THIS book is profoundly disappointing. The subject matter does have general interest. Do such features as the lengths of tracheids and vessel elements, the shapes and sizes of these cells in transverse section and the shapes and sizes of the pits between these cells have any significance in the adaptation of plants to their habitats? Is the disposition of parenchyma and fibres within and around the xylem of adaptive significance? Any satisfying book would have to start from a statement of theory regarding the functional effects of these features, together with such experimental evidence as is available. The author offers no such opening statement, although relevant comments are scattered through the book. He considers each major vascular group in turn, seeking an exact harmony between certain arbitrarily chosen xylem features and the habitat of the plant. The whole account is riddled with unsupported statements, special pleading and illogical handling of facts and ideas. The author never deals adequately with the phenotypic as opposed to genotypic differences between plants; slower-growing individuals generally have shorter, narrower xylem elements, but is this feature necessarily adaptive? There are some suggestive correlations of habitat with xylem cell form, but in respect of most of the detailed differences in xylem type one is bound to agree that "the logical conclusion to be drawn is that a variety of peculiar types are functionally quite effective" (p23). This book should have been condensed into a review article.

P. J. Grubb

*Nuclear Quadrupole Resonance in Chemistry* By G. K. Semin, T. A. Babushkima and G. C. Yakobson. Pp. X+517. (Halsted, Wiley: New York and London; Israel Program for Scientific Translations: Jerusalem, October 1975.) £24.75.

THIS is a reasonably quick translation of an original published in the Russian in 1972. It does, however, have an inordinate price, considering that it has not even been set in normal print, but rather is the product of an electric typewriter. It is greatly to the credit of the authors that notwithstanding these shortcomings one is able to recommend it unreservedly to researchers in nuclear quadrupole resonance (NQR) spectroscopy, who will find 300 pages of data compilation invaluable (particularly because they contain so much from the Russian literature). The greatest emphasis is on the application of the technique to chemical problems and although the expert is so well catered for the authors have provided an adequate introduction to the technique and to the basic features of its theory. Any chemist reading the chapters which precede the data tables would acquire a sound feeling for the possible applications of NQR in his own field of research. What is not dealt with in detail, deliberately, is the quantum-mechanical calculation of coupling constants but this is no real shortcoming in a book which describes the chemical applications uniquely well.

The outstanding Russian contribution to this field of research is presented with modesty in a fascinating book.

**K. A. McLaughlan**

*The Living Ocean: Marine Microbiology.* (Biology and Environment) By E. J. Ferguson-Wood. Pp. 146. (Croom Helm: London, September 1975.) £5.50.

I ENJOYED reading this book which is about the structure, ecology and economics of marine prokaryotes and protists. It was intended as a personal and selective account and has been rescued from an early draft prepared shortly before the author's death. It is therefore obviously open to some criticisms of approach and incompleteness. Ferguson-Wood's enthusiasm and involvement, however, are evident from the text which may be of most use as an infectious introduction to the subject. The book can be recommended to the beginner or layman, but cannot be regarded as an alternative to other accounts of microbiology, including the author's previous books, for more serious

students. Rather few references are given (in the guise of notes at the end of each chapter), some of these are rather trivial and more obvious important ones are omitted. The short title given on the cover and binding does not fairly indicate the book's content otherwise it is quite well produced with few minor errors —although some of the diagrams are poorly prepared. Professor Ferguson-Wood certainly contributed to the main course of marine microbiology; this book is a rather expensive aperitif.

**P. J. S. Boaden**

## Books brief

*Physiology of Physical Stress: A Selective Bibliography, 1500–1964.* By Carleton B. Chapman and Elinor C. Reinmiller. Pp. vii+369. (Harvard University: Cambridge, Massachusetts and London, 1975.) £8.25.

THE compilers of this bibliography have selected 2,800 references concerned with some aspect of the physiology of physical stress. Physical stress seems to mean physical exercise or physical activity, to judge from the preface. References dealing with 'basic physiological work on physical stress' are included but 'extensions were made into clinical areas that had basic implications'.

The word 'stress' is notoriously difficult to define, and for that reason is best avoided whenever possible. The title might well have been 'The physiology of physical exercise'. It is difficult to determine why the authors include particular papers but not others. The word 'basic' is used five times in the third paragraph of the preface where an account is given of the identification of 'basic' articles. No doubt there would be considerable individual differences in the interpretation of 'basic' and thus decisions to include or reject must be to some extent arbitrary. All the same, I was surprised at the omission of Marius Nielsen's famous paper on the regulation of body temperature during physical exercise, and no reference is made to Adolph and *Physiology of Man in the Desert*. There are some other equally surprising gaps and some curious inclusions.

Nevertheless, one must applaud the determination required to prepare a bibliography which, in spite of some reservations, I have found useful.

**O. G. Edholm**

*Electrode Kinetics* (Oxford Chemistry Series.) By John Albery. Pp. xii+184. (Clarendon: Oxford; Oxford University: London, June 1975.) £5 00.

ELECTRODE kinetics is a difficult subject, especially for the beginner, and so a new book setting down the fundamental ideas in a clear, lively and occasionally humorous manner is welcome. Many will also see this particular book as an original contribution to the subject. It is suitable for specialist first degree courses in electrode kinetics but especially for new research workers in the field. There is also much to interest the expert, with many new angles on old problems. The subject is presented in a way which should be intelligible to the beginner. Even so, the amount of detail is considerable and many of the finer points are discussed. Inevitably there is much mathematics, but the reader is helped through this by numerous sketches of the important functions. The choice of much of the material reflects the author's own interests. There is an excellent chapter on the double layer and an illuminating one on the theory of electron transfer which should interest a wider audience.

**D. R. Whitehouse**

*Enzyme Induction.* (Basic Life Sciences, Vol. 6.) Edited by D. V. Parke. Pp. xii+328. (Plenum: London and New York, 1975.) \$32.50. THE title of this interesting book, which covers a Colloquium held at the University of Surrey in June 1972, is rather deceiving. "Enzyme induction" has been coined for a phenomenon involving *de novo* synthesis of a specific protein in response to a specific signal in the environment, such as the synthesis of  $\beta$ -galactosidase or tryptophanase by *Escherichia coli*, in response to the presence of a  $\beta$ -galactoside or tryptophan in the growth medium.

Except the first chapter dealing exactly with phenomena of this type, the rest of the book deals mainly with the effects of drugs and steroids on the appearance of several enzymes at the cellular or developmental level. This appearance is not necessarily a reflection of a *de novo* synthesis, but may be the result of a decreased degradation attributable or not to a stabilisation of the enzyme studied.

The various contributions of the book will prove very useful to those interested in the mechanisms of biological regulation and their possible roles in health, ageing and disease. The chapter on induction of drug-metabolising enzymes present in liver endoplasmic reticulum is of special interest.

**Georges N. Cohen**

# obituary

**James Gray** was born in London on October 14, 1891. His parents were both Scottish and he always felt himself to be an expatriate Scot. After early education at the Merchant Taylor's School he became first a Scholar and later a Fellow of King's College, Cambridge. Shortly after his election, his academic career was interrupted by the First World War, in which he served, with great distinction, as a Captain in the Queen's Royal West Surrey Regiment. He was awarded the Military Cross and had conferred upon him, by Marshall Foch in person on the field of battle, the Croix de Guerre with palms. After the war he returned to Cambridge to resume his Fellowship and soon to be married, in 1920, to Norah Christine King, who survives him. Not long after this he was appointed Lecturer, later Reader, and in 1937 he was elected to the Chair of Zoology which he occupied until he reached the retiring age, in 1959. During retirement he continued to reside in Cambridge, where he died peacefully in his own home on December 14, 1975.

Gray's first research was concerned with the fertilisation and early development of echinoderm eggs, but already he was a cell biologist rather than an embryologist. It was primarily his interest in cells that led him on to the study of ciliary movement on which he quickly became the world authority, as was recognised by his election to Fellowship of the Royal Society in 1929. After writing a notable book, *Experimental Cytology*, he made up his mind to leave this field; he felt that, using living cells, means were not then available to formulate meaningful questions and to obtain clear-cut answers—and he was not interested in dead cells. In deciding to move into the field of locomotion he was no doubt influenced by the circumstance that he had developed the techniques of cinematography for use on cilia, and these techniques could be applied to other types of movement. Animal locomotion occupied him over the next 25 years, bringing him the award of the Royal Medal of the Royal Society in 1948, and it is for his work in this field that he will be long remembered. His calculation that the power required to drag a dolphin's dead body through water is greater than the power available from its muscles has become

widely known as Gray's Paradox. From the swimming of dolphins to the swimming of spermatozoa, from the movement of snakes to the movement of minute nematode worms he explored the undulatory mode of propulsion, and also investigated, in collaboration with H. W. Lissmann, the modes of terrestrial locomotion seen in amphibia. During the early part of his retirement he was able to bring all this work together in his second great book, *Animal Locomotion*.

Later in life Gray became increasingly involved in advisory work for national organisations. He was a trustee of the British Museum (1948–60), a member of the Agricultural Research Council (1942–47), President of the Marine Biological Association (1945–55) and President of the British Association in 1959. From 1951–59 he was a member of the Development Commission and at one time Chairman of its Fishery Advisory Committee. For his public work he was made CBE in 1946, and in 1954 he received a Knighthood. He was honoured by many universities, by Aberdeen and Edinburgh with the L1 D., by Durham, Manchester and Wales with the D.Sc.

Gray's influence upon the development of zoology was greater even than his direct contribution to it. He was foremost among a band of rising young biologists who in the years immediately after the First World War led the subject into new paths and established Experimental Zoology in the face of traditionalist opposition. He continued to foster this movement through the Society for Experimental Biology, at whose meetings he was regularly to be seen, and through the Journal of Experimental Biology which he edited from 1925 to 1954. His influence was, naturally, nowhere stronger than in his own university. During his tenure of the Chair the teaching of Zoology was transformed—but gradually, for he was emphatically opposed to unnecessary disturbance and dislocation. This was a time when the director of research and his team of research students were beginning to make their appearance on the university scene. Gray would have none of this. He looked upon research students as independent research workers in their own right; as long as they were swimming he left them alone, if ever they got into serious

difficulty they were dramatically rescued. Gray believed passionately that the mainspring of a successful university department was the activity of the staff in research. What line of research they chose mattered nothing provided that it was scientifically sound and pursued with enthusiasm; for, he argued, this enthusiasm would rub off on the undergraduates and, far more than mere knowledge imparted to them, would bring out their best qualities. One has but to look at the list of zoologists who were at one time research students in Gray's department and then went off to become Heads of Departments themselves to see how well the system worked.

As Head of Department himself he was always approachable, always ready to listen to someone in trouble, always ready to step in where he could be of help. There was also a rough side to his character. He was slow to wrath, but it was always a grave matter when he was aroused. Yet he was scrupulous to keep his personal feelings to himself, and they were never allowed to influence his official policy or decisions. In private life, though he had many very close friends, his happiest hours were spent on summer holidays in Scotland with his family.

**J. A. Ramsay**

**Joseph F. Foster**, Professor of Chemistry in Purdue University and former Chairman of the Department, died suddenly on October 7, 1975 at the age of 57. He was distinguished for his research on the physical chemistry of macromolecules, especially on starch and proteins. He was probably the foremost contributor to our knowledge of the serum albumin molecule during the last twenty years. He demonstrated its reversible expansion in acid solutions, and discovered two Conformational transitions in albumin, one in acid solution (the N $\rightleftharpoons$ F transition) and another in neutral slightly alkaline solution. From this he inferred and demonstrated the microheterogeneity of albumin preparations. He was extending and deepening these important studies up to his untimely death. He will be greatly missed by his colleagues in protein chemistry.

**John T. Edsall**

# announcements

## Awards

In addition to the winners already mentioned of the prizes in Cancer Immunology awarded by the Cancer Institute of New York, were also **Dr Garri Abelev**, N. F. Gamaleya Institute of Epidemiology and Microbiology, Moscow, and **Dr Eva Klein**, Karolinska Institute, Stockholm, Sweden.

## Appointments

**Dr Michael Gibbons** has been appointed Professor of Liberal Studies in Science at the University of Manchester.

**Dr W. H. Cockcroft**, at present the G. F. Grant Professor of Pure Mathematics at the University of Hull, is to become Vice-Chancellor of the New University of Ulster in October.

## International meetings

March 1-3, **First World Hydrogen Energy Conference**, Miami Beach, Florida (1st World Hydrogen Energy Conference, Conference Services, University of Miami, PO Box 248005, Coral Gables, Florida 33124).

March 15-19, **Development of Nuclear-based Techniques for the Measurement, Detection and Control of Environmental Pollutants**, Vienna (The IAEA Kärntner Ring 11, PO Box 590, A-1011 Vienna).

March 22-26, **The Management of Radioactive Wastes**, Vienna (The IAEA Kärntner Ring 11, PO Box 590, A-1011 Vienna).

March 29-April 2, **The Exploration of Uranium Ore Deposits**, Mexico City (The IAEA, Kärntner Ring 11, PO Box 590, A-1011 Vienna).

## Miscellaneous

The **Lady Tata Memorial Trust** offers fellowships and scholarships for research on leukemia and allied conditions. The fellowships are tenable for 3 years and the scholarships for 1 year, renewable for 2 more. For further particulars apply to The Secretary of the (European) Scientific Advisory Committee, Lady Tata Memorial Trust, Chester Beatty Institute, Fulham Road, London SW3. Applications must be submitted by March 31.

## Reports and publications

Smithsonian Contributions to Zoology No. 204. Taxonomic Indexes to Ostracoda (Suborder Myodocopa) in Skogsborg (1920) and Poulsen (1962, 1965).

## Person to Person

The change in the tensile strength of cellulose on burial in soil is a technique of general application in ecology, but for repeatable results, a high-quality standard test cloth must be available. The Shirley Institute, Manchester has agreed to manufacture, and sell at cost price, such a material if initial demand is sufficient. Anyone who might be interested should contact Dr D. W. H. Walton, British Antarctic Survey, Monks Wood Experimental Station, Abbots Ripton, Huntingdon, Cambs. PE17 2LS

There will be no charge for this service. Send items (not more than 60 words) to Martin Goldman at the London office. The section will include exchanges of accommodation, personal announcements and scientific queries. We reserve the right to decline material submitted. No commercial transactions.

## The Shackleton incident could profit international law

THE incident at sea last week, in which the British research ship Shackleton had to make rapidly for port in the Falkland Islands after a warning shot had been fired across its bows by the Argentine destroyer *Almirante Storni*, must not be seen simply as an isolated event connected with a territorial dispute and a trigger-happy captain. In recent years the freedom of marine scientists to do pretty well what they wanted even within sight of foreign territory has been rapidly eroded, and there is no sign that when the Law of the Sea conferences have run their course life will be much easier for those who need to come fairly close to foreign coastlines. The point which should be abundantly clear is that Argentina is prepared (not for the first time) to take strong action against infringements of what she regards as her own economic zone by research vessels. She, along with many other countries, has sought to have the power to regulate scientific research within that zone.

The research conducted from Shackleton used conventional geophysical techniques: magnetometry, gravimetry and refraction and reflection seismology. Most of it was being carried out in deep water in the Scotia Sea, and the programme, under the supervision of Birmingham University, has been running for many years. The purpose of the work is to attempt to put the unique area off South America into a plate tectonic context.

Those countries, Britain included, which have attempted

to produce guidelines for international discussion on what is pure and what is applied research would almost certainly rate Shackleton's operations as 'pure'. But it is not as simple as that. Theories of the regional evolution of the Earth's crust have a lot in them for the economic geologist and thus for the prospecting industry; a clear picture of past geological history will not point a finger at exactly where hydrocarbons will be found, but it will provide some helpful signposts. Reasonably, scientists may protest that their work is the pursuit of knowledge for its own sake, that it is not supported by commercial interests, and that their results will be available internationally. But equally reasonably, countries with inadequately developed technology and expertise to capitalise on this information may feel themselves consistently outmanoeuvred when it comes to negotiating exploration rights. Their only defence then may be to demand some sort of technical assistance in exchange for access.

In a month's time the Law of the Sea Conference will resume in New York, and among other things will attempt to come to terms with a 'single negotiating text' including draft articles on marine scientific research. It is likely that the coastal state in whose economic zone another nation wishes to perform research will be called upon to decide whether the research is 'pure' or 'applied' and, in the former case, presumably to grant permission without too many strings attached. An appeal procedure to international experts is proposed if agreement cannot be reached. This seems a much better approach than any attempt by the United Nations to produce a universally acceptable list of topics to be regarded as pure.

It will be a pity if the Shackleton affair cannot be viewed at the conference as more than a territorial dispute. For, squabbles apart, it provides a rather good concrete example of the sort of research operation that is going to give rise to international disagreement; yet there is no reason why intelligent give and take on technology transfer and technical advice should not resolve such disputes. If this incident could be freed from its accretions of diplomatic conflict and considered simply as an ideal case for the Law of the Sea Conference to consider when legislating, some good could come of it. But it will need a certain detachment from the British delegation. □

## Looking at the job first

*In Nature last November, Cyril Cooper of the Institution of Professional Civil Servants highlighted the discontent among UK Civil Service scientists, and argued that it stemmed largely from differences they experience in salary and career progression compared with graduate administrators. David Budworth of the Confederation of British Industry replies.*

THE NEWS that the Expenditure Committee is to examine the progress made in implementing the 1968 Fulton Report on the Civil Service is indeed welcome. Although the stimulus has no doubt been the rising public indignation at the advantages in terms of pay, security, and perhaps most conspicuously pensions that civil servants enjoy, the terms of reference of the investigation seem likely to be sufficiently wide to permit the Committee to tackle the problem of civil service scientists, which has been consistently ducked in recent years.

While it may well be good trade union tactics to argue, as Cyril Cooper does (November 20, 1975, page 186) that the scientific civil service is really just an ordinary part of the higher reaches of the service and should be treated as such, this approach flies in the face of economic reality and common sense. It is certainly also in flat contradiction of the Fulton principle of "look at the job first". Regrettably perhaps, but undeniably, the number of jobs available for administrators in the civil service has increased, and with it the security and career prospects of the incumbents, in our developing welfare state in which authority is looked upon to solve all the problems.

Science having conspicuously failed in its overblown claims to solve these problems, the opportunities for scientists have not expanded in a similar way. As David Davies has reminded us (May 22, 1975, pages 293-296), the scientific civil service has been static in numbers for the best part of twenty-five years, and it suffers from considerable internal embarrassments caused by its over-concentration of older scientists. Yet these under-used and probably unhappy people are a considerable national resource of talent and experience. Diverting them to supposedly useful tasks in their present locations is unlikely to do much of value. They must be moved out to

contribute to solving our national problems in the places where it is increasingly being recognised that something effective can be done. industry and the schools.

A Select Committee such as the Expenditure Committee is perhaps the only type of body which can look at these problems relatively free from civil service establishment influence. The Fulton Committee itself brushed aside the suggestions made to it, significantly including some from inside the service itself, that the scientific civil service would benefit from not being a career service; and Lord Rothschild's forthright comments on the immobility of scientific civil servants were safely defused by the terms of reference given to the Bondi task force which was set up to tackle the problem.

It is greatly to the credit of that body and of its chairman, whose personal commitment to mobility has been amply proved by deeds as well as words, that it did manage to rise slightly above its terms of reference and record its view that permanent moves were, in the end, more important than the immensely difficult and therefore marginally effective secondments to which it was nominally confined. Ironically perhaps, the work so far of the interchange unit set up in the Civil Service Department to keep the flame of scientific mobility alive, seems to have proved the critics of civil service privileges right, for the movement into the service has greatly exceeded the movement out.

Of course, as is apparent from Cyril Cooper's article, all pretence that the "fair comparison with outside employment" system for determining pay applies to civil service scientists has been abandoned, following the report of the late Pay Board's Advisory Report No 3 of April 1974. This body again tamely accepted that something closely approximating to parity should exist between specific grades in the

administration and scientific groups of the service.

The reforms in the scientific civil service which are needed to effect a long-term cure are fairly clear in outline, and have been put forward so often that there is no need to repeat them here; but what of the short and medium term? We cannot afford to wait another 30 years or so, even assuming that the necessary changes are made, for the situation to right itself. Something must be done before that, and preferably soon. The former Department of Trade and Industry admitted in a burst of frankness in 1972 that it wanted to reduce the burden that its laboratories placed on public expenditure, but its attempts to do so by selling contract research cannot have made much impact. The unproductive PSOs mentioned by David Davies can hardly be declared redundant, particularly with unemployment at its present levels; but could not some way be found of getting them out to somewhere where their undoubted abilities might be put to use? From all accounts, good quality scientists and mathematicians are still not coming forward for teaching posts, and even when they do it seems that local authorities cannot afford to pay them. Is it totally beyond the wit of what is supposed to be the best administrative civil service in the world to devise some methods of utilising those on the public payroll to do the jobs which need to be done?

Again, if the Government is serious in its commitment to putting the needs of manufacturing industry above almost all other calls on its resources, there will be a need to move more brain power, and to move it pretty quickly, to where it can be commercially effective. Some scientists in government laboratories have proved themselves to be effective in marketing their services. Perhaps they could be equally useful in marketing the mechanical engineering and other products by which we live. Or will the real gap in our country, that between those who live on taxpayers' money by the skilled deployment of political argument, and those who live by exploiting their entrepreneurial abilities in some kind of market, be allowed to get even worse, so that we all eventually starve?

# "Genetics" and how we made it

Steven Rose, Professor of Biology at the Open University, looks at the origins and purpose of the OU's new genetics course

SINCE the beginning of this month some 900 Open University students have been settling down for their standard 12 hours study a fortnight to follow a new second level Genetics Course—a set of 16 sequential study Units ranging in context from classical genetics by way of molecular and cytological genetics to population and human genetics, each with an accompanying TV and radio programme and a series of "home experiments". What makes the Genetics Course different from all the rest of the OU science teaching, however, is that it is the result of almost 3 years of collaboration between the Biology Department of the OU and the Department of Genetics at Birmingham, the Unit of Genetics at Hull, the School of Biology at Sussex and a member of the biology staff at the University of York. Teaching staff from the four collaborating universities were released from most of their other teaching duties in order to work on the production of this Course—a participation made possible by a grant from the Nuffield Foundation, which has an interest both in promoting inter-university teaching projects and in the development of the type of structured teaching that the OU has pioneered at University level. But the involvement was not just that of individuals, for each participant had the support of his department and access to its own particular area of genetic and teaching expertise. The result has been a novel Course that can be used both by the OU and in many other teaching institutions.

There were several reasons for choosing genetics for this experiment. The modern synthesis of genetics underlies most areas of biology. It is a subject that, throughout its history, and to the present day, has been interwoven with social and philosophical controversy concerning its interpretation and implications. It is very well suited for a problem-oriented, student-active teaching approach. And finally, a prosaic but important point is that not even all universities, and certainly rather few polytechnics and colleges, have biology schools large enough to be able to teach Genetics across the full range, from the molecular to the population and human levels. Hence the brief of the Joint Universities Genetics Course Team has been to prepare a Course that will eventually be able to be used in whole or in part by a very wide range of institutions even when they do not have a full range of genetic

skills represented amongst their teaching staff.

Working as an inter-university team has had both its pleasures and its perils. We came into the venture with differing views, based on our differing experiences, not merely on *what* should be taught but on *how* it should be taught. University teachers tend to be individualists, but, meeting practically monthly since 1973, together with the BBC staff, educational technologists, technicians and researchers who comprise the full Course Team, has welded us into a collective teaching group. In such a team, every assertion about what should be included and how it should be approached has to meet the challenge and critical assessment of our colleagues. We have been able to seek the advice of expert assessors outside the team to comment on various sections of the Course during its development and to call on a panel of students to assess the drafts of the Units for their success as teaching documents, so as to point to areas of potential obscurity or theoretical or factual overload. It has been particularly instructive and we believe useful to have had, for instance, biometricians confronted with developmental geneticists and being forced to convince each other—and the rest of us—of the case for including their respective approaches in a Course in which every minute of the students' time is precious and academic pretentiousness or hobbyhorses cannot intrude. One result, incidentally, has been a considerable rethinking of the amount of mathematics that is essential to an understanding of biometry at this level and a series of experiments in ways of presenting it which we have been able to test with a number of volunteer students.

## The Course itself

The Course itself, seen as a linear sequence (although each of its Units may be used separately) begins by asking: What is genetics? What sorts of questions do geneticists ask and how do they obtain the answers? Not surprisingly it goes back to Mendel, and includes a reprint of a translation of his original (1865) paper at this point. There follow four Units on chromosomes and genes; recombination; linkage and maps; and chromosome organization and changes. The next three Units cover molecular genetics, cytoplasmic inheritance and developmental genetics and there are five Units on the analysis of populations, biometry, plant

and animal breeding and evolutionary and ecological genetics. The final two Units focus on human genetics, and confront some of the major currently controversial issues in human genetics (for instance the question of whether the biometrical approach has anything to contribute to the analysis of group differences in IQ score, the XYY programme and the prospect of genetic engineering). The main teaching sequence is accompanied by a parallel Unit which sets present-day genetic theories into the context of their history and social relations (not forgetting past controversies like that around eugenics and social Darwinism). There is also a specially prepared statistics Unit. All the texts are designed to be self-instructional, with opportunities for the students to assess their own progress by tackling problems *en route* through the Units (OU students will also have a series of programmed tutorials through the year).

Integral to the teaching material are the video and audio tapes, which will be transmitted fortnightly by the BBC over the year, beginning this month. The TV includes both studio animations and experimental demonstrations and also film material involving many leading geneticists, both in this country and abroad, in their own labs or in the field. The radio has a varied role, from radio-vision (for example of fine-structure genetic mapping and the derivation of biometric equations) through to historical programmes on the development of phage genetics and the Lysenko episode. Among those taking part in radio or TV programmes (apart from members of the Course Team itself) are Bradshaw, Cain, Crick, Delbrück, Edgar, Lewontin, Levins, Luria, Sager, Sonneborn, Stent, Stern, Suzuki and Watson.

Finally, for OU students there is a "package" of experiments to be done at home which include genetic studies on tomato seedlings, on micro-organisms and *Drosophila*, as well as a set of observations to be made on humans which will be sent back to be analysed centrally for their genetical implications.

For OU students taking the Course this year, it will be just one component of their degree programme. But at the

same time they will be participating in the final stages of a substantial experiment. Throughout the year we will be monitoring their progress, and that of

students at some conventional universities and colleges who are also using the Course or parts of it. For only this will tell us how close we are to our

ultimate objective—a first rate and comprehensive second level genetics teaching Course which can be widely used in Britain and abroad. □

## USSR

# Environmental protection under state socialism

*In the Soviet Union environmental issues have surfaced in recent years as just one consequence of the country's rapid development. The problems seem as intractable there as anywhere else. Vera Rich reports.*

ECOLOGICAL problems seem to be as much a concern of the Soviet Union as they are of other industrialised countries. The prospectus for the Five-Year Plan lays considerable stress upon conservation and environmental protection, and the science and technology section includes among its major aims: "to study the scientific principles of the use and conservation of soils, mineral resources, the plant and animal worlds, the air, and water basins. To expand complex investigations of the world's oceans. To effect the further development of methods of forecasting the weather and natural disasters".

Commenting on this programme in the English-language *Moscow News* (No. 1, 1976), Academician Inokentii Gerasimov implies that the problem of conservation, although a real one, arising from rapid urbanisation and industrialisation, is nevertheless qualitatively different from that in capitalist countries: in the Soviet Union, he argues, "there are no social reasons for the irrational utilisation of natural wealth. Environmental protection under socialism, with its planned economy and no privately owned natural resources, becomes an important task of the state. Hence, environmental protection in our country is part of the current and long-term economic plans".

Taken at its face value, Gerasimov's comment would imply that, in the Soviet Union, any ecological hazard would be of a short-term nature only: the result of a temporary imbalance between one part of the Plan and another. Such short-term imbalances do occur, and at a fairly low level of the administrative hierarchy may become the subject of criticism in the media. Last November, for example, Minsk Radio noted that reafforestation (to replace planned felling) in Byelorussia was falling behind schedule,

while in the Brest, Minsk and Grodno Oblasts, excessive felling had taken place and the authorities concerned had failed to take the required "essential measures" against fire and timber-poaching. "Anti-social elements"—fish-stealers, litter-droppers, and others who have not yet learned the norms of behaviour proper to a socialist society—present another possible environmental threat. They too are the subject of exhortation in the media, particularly at the local level; on occasion, the state-sponsored Society of the Friends of Nature has been called upon to organise vigilantes to deal with a particular outbreak of "hooliganism".

These, one might conclude from Gerasimov, are the main dangers to the Soviet environment—fairly local and minor disturbances, far down the administrative and social ladder. In fact, the problem is somewhat more complex. The Soviet authorities have in recent years become increasingly aware that their natural resources, though vast, do not constitute the infinity promised to Peter the Great by his geographers. At the Twenty-Fourth Party Congress in 1971, Mr Brezhnev stressed this new approach: "As we take steps to accelerate scientific and technological progress," he said, "we must ensure that this is combined with the rational use of natural resources and should not cause dangerous pollution of air or water, nor exhaust the soil".

This marks a fairly new approach. The early years of the Soviet Union were marked by rapid industrialisation. On posters and cartoons, the smoking factory chimney became the standard symbol for progress. In accordance with Lenin's equation (Communism = Socialism + Electrification), rivers were dammed and spillways built with little, if any concern for the ecological consequences. The writings of Marx dwell mainly on the urban proletariat and barely touch on conservation; and from Lenin's work isolated quotations can be extricated to serve as slogans. Concern was directed more towards utilising than conserving natural resources, of the major theoreticians, only Engels showed concern with the long-term outcome of remodelling the environment. For many reasons, per-

haps ideological as well as practical, the relevant passages seemed to make little impression on the planners. To turn rivers aside from their courses, to plant orchards where there once were deserts, to carpet the barren steppe with horizon-to-horizon grain-fields—such achievements, as well as bringing immediate economic benefits, would demonstrate at home and abroad the intrinsic superiority of the Soviet system of planning.

In the 1920s, of course, in spite of industrial expansion during the last decades of Tsarism, the vast majority of the Soviet Union was still in the state of a country emerging from feudalism, and a system of tied serfdom remained within living memory. Thus, after some elementary laws were passed—the nationalisation of land, the prohibition of fish poaching, the establishment of certain national parks and health resorts—little attention was given to ecological problems: the drive to take the country into the twentieth century outweighed all other considerations. Only two major pieces of conservation legislation were passed under Stalin. These dealt with the establishment of "shelter belts" of trees to prevent erosion (1948) and the control of air pollution (1949), and the first remained something of a dead letter.

Only during the late 1950s, under Khrushchev's policy of opening up undeveloped areas, were a large number of laws passed on conservation and the environment, reflecting a growing awareness of the need for a coherent policy in this field. In many cases, the laws passed at that time set extremely high standards, as though they were intended as "socialist ideals" rather than practical policies: in certain cases virtually the same law was promulgated several times, suggesting considerable difficulties in implementation. Nevertheless, the laws were published in the press and became common knowledge. In the atmosphere of "the thaw", concerned individuals began to voice protests against the most flagrant infringements either officially, or, later, through the *samizdat* literature. Furthermore, the growing international concern with conservation impelled the Soviet authorities, if only for prestige reasons, to show that the homeland of socialism was not lagging behind in its concern about a universally pressing problem. It is now clear that many of the "developers" were, by present standards, carried too far by their zeal. Many recent Soviet "achievements" in

conservation are, in fact, motivated by the need to clean up the mess of a former generation.

### The case of Lake Baikal

A classic example of this is the case of Lake Baikal. This lake, the deepest in the world, has long been famous for its pure water and its extensive flora and fauna, with 708 unique types of living organisms, including freshwater seals. In *Moscow News* Gerasimov announced proudly, "It can be definitely said now that Lake Baikal will not die of pollution, as have many other lakes in the world". Under the Tsars, virtually the sole contact between Lake Baikal and the world of industry was the Trans-Siberian railway which skirted part of its southern shore. Inevitably, perhaps, the forests of the Baikal region came to be utilised, and the tributaries of the lake used for rafting timber prior to its further shipment down the Angara, Baikal's sole outlet. But the construction of cellulose and pulp mills in the unique habitat of Lake Baikal seemed odd in a system claiming to use natural resources "rationally" for the good of present and future generations.

The plans for the mills were approved in 1957, but it was not until 1962 that the first authoritative protests began with an article in *Komsomolskaya Pravda* by the Director of the Limnological Institute of the Siberian Branch of the Soviet Academy of Sciences. Over the following decade, numerous similar articles were published, notably in *Literaturnaya Gazeta* and *Priroda*; Gerasimov himself was prominent in the campaign. Since campaigns of this nature in the State press (as opposed to the *samizdat* network) can only take place with tacit approval from Government bodies involved, there was either a high-level interdepartmental dispute over Lake Baikal or at least an effort to show official concern.

The indications are that there was opposition from the Academy of Sciences, the Geographical Society of the USSR, and the Expert Commission for the Coordination of Scientific Research. Nevertheless, under the auspices of the Ministry for Timber Production, the mills were built and began operation, discharging effluent into the lake. Even when effluent treatment installations were fully operational, the water discharged was yellowish and barely potable, and by no means comparable in quality with the original lake water. The only sound "economic" reason ever offered for the siting of the mills was the exceptional purity of the Baikal water—a purity needed for the production of certain high-quality products. As early as 1965, however, it was observed that water from the

effluent outfall was being carried back by the current to the "pure" water inlet of the mills (*Priroda*, No. 11, 1965). Consequently it was necessary to process the intake water before use. This demanded the installation of expensive pre-treatment equipment the authorities had hoped to avoid by using Baikal water in the first place.

During the last five-year plan, considerable attention was devoted to the problem of the Baikal habitat. New legislation with Party backing was introduced in September 1971, and a special "emergency charter" was approved by the Ministry of Land Reclamation and Water Economy in November 1974. Timber-felling was forbidden within a radius of 50 km of the lake, and the tributaries of Baikal have been cleared of the sunken timber which might have absorbed much of the oxygen from the water and covered fish-breeding grounds; "very costly" outfall treatment plant has been installed at the cellulose mills, and white-fish hatcheries have been introduced to replenish depleted stocks.

Lake Baikal has always been of keen interest to ecologists throughout the world, but more recently it has attracted increased attention because of the construction of the Baikal-Amur Railway. Ecological restrictions relating to this at times verge on the absurd (workers must not spray mosquitoes with insecticide) or over-zealous (devastated areas from natural forest fires on the route are to be planted with seedlings, rather than left to regenerate naturally). But if all the recommendations are carried out, the future of Baikal is certainly assured, and the lake and its environs could well become an ecological show-place. The decision to admit American scientists to observe and participate in research on the lake suggests that already the worst hazards have been dealt with, which is gratifying. But the general question remains whether state ownership of resources entails their best use and protection.

Freshwater seal from Lake Baikal

## CANADA

SINCE the beginning of the year the outlook for Canadian science and technology for 1976 has not seemed a particularly optimistic one. The Ministry of State for Science and Technology, contrary to some predictions, did manage to survive the federal government's anti-inflation programme which killed off a number of other federal initiatives such as Information Canada, the Company of Young Canadians and Opportunities for Youth, and reduced others, such as the Local Initiatives Program. But the programme still means less money for science and technology generally.

Specifically, the Industrial Research and Development Incentives Act, which has provided between \$20 million and \$30 million a year for industrial research, will be repealed; reductions will be made in the Programme for Advancement of Industrial Technology and the Defence Industry Productivity Programme; and medical and other scientific research grants will be frozen.

The cuts were made in an attempt to prove to Canadians that the federal government was serious about fighting inflation, and that it intended to set an example. But since then the Prime Minister has gone further, telling the Canadian people that the anti-inflation measures are in fact attempts to control an economy that proved itself unable to work as a free market system—a remark that produced angry responses, including a call for an election by a former Progressive Conservative Cabinet minister.

Altogether, the government said it would cut \$1,500 million from its future spending plans. The loss to scientific research funds was estimated at \$14.8 million and to industrial incentives at \$8 million. These are losses that the scientific community mostly regards as insupportable, in the light of the federal government's recent policies and the impact of inflation.

In a letter to the editor of the *Toronto Globe and Mail*, John Polanyi, Professor of Chemistry at the University of Toronto, pointed out that the total funds available to the National Research Council (NRC), the chief funding body for fundamental research in Canada, will have increased at an average rate of only 2.5% a year from 1969 to 1977, while the cost of doing research during the same period had increased by 100%.

The NRC grants committees, on which he has served, "are quite unable to keep existing research projects of high promise moving ahead, while at the same time giving a genuine opportunity to the scientists of tomorrow to prove their mettle". And, he went on,

"our neglect of science is something that sets us clearly apart from countries with which we might reasonably compare ourselves. In the United States, in France, in Germany, even in beleaguered Britain, the support of basic science has roughly kept pace with inflation. Only in Canada has inflation been used, year after year, as a device for diminishing the nation's investment in this fundamental activity."

In a letter to the same newspaper, Dr Gordon Forstner said that in medical research "somewhere between 150 and 300 technicians will lose their jobs, and a programme which has been deflated steadily during the last five years will be shattered."

● In such a climate, it was with mixed feelings that some Canadians heard that the heavy water plant at Glace Bay, Nova Scotia, was starting up and would shortly produce heavy water not only for nuclear reactors in Ontario and Quebec but also for those in Britain, Argentina and South Korea. Although heavy water is vital to Canada's CANDU reactors (in which it acts as coolant and moderator), the Glace Bay plant has been one of the most disastrous undertakings of an otherwise successful nuclear programme.

In 1964, the province of Nova Scotia brought in a US nuclear scientist, Jerome Spevack, to design the Glace Bay plant. There were difficulties from the outset. Completion was delayed from 1966 to 1967, then again to 1969. Technical difficulties occurred as a result of using salt water from the nearby Atlantic Ocean in the process, instead of fresh water. Finally, in 1970, inspectors discovered that the salt water had corroded the pipes, and a \$30 million repair was needed.

By that time, Spevack's company, Deuterium of Canada Ltd, had spent \$100 million on the plant, all of it public money, because Nova Scotia was the major shareholder and provided the finance. The province had bought out Spevack's interest for \$3 million in 1966, and taken full control in 1969. In 1971, the federal government provided the funds for the plant's purchase by Atomic Energy of Canada Ltd (AECL), and spent another \$130 million on what has been almost a complete reconstruction.

Eventually, the plant is expected to become self-sustaining and make enough money to pay back AECL's investment. The Nova Scotia government is to get the plant back after AECL has recouped its investment, but the province plans them to sell it back once more to AECL—finally washing its hands, as it were, of the whole affair.

## Alternative technologies urged in pesticide report

*Carried to excess, the best things may do more harm than good. Colin Norman reports from Washington on a study of pesticides.*

A COMMITTEE of the National Academy of Sciences has warned, in a mammoth study published last week, that unless alternatives to conventional chemical pesticides are swiftly developed and adopted, agricultural production in the United States could soon begin to suffer. The committee bases that conclusion on the fact that several potent products have been either severely restricted or banned entirely because of environmental and health hazards, and also the fact that several pests are developing resistance to the poisons which are sprayed on them in copious quantities each year.

The study, which took more than three years to complete and which runs to five massive volumes, is an attempt to assess the current state of the art in pest control and to pinpoint some of the problems which lie ahead. In the course of its analysis, the committee has questioned the costs of some government regulations, criticised current pest control practices, cast doubt on the value of some of the Department of Agriculture's most ambitious and costly efforts to eliminate particular insect species and, by implication, criticised the federal government's agricultural research efforts.

The basic theme running through the huge tome is that although chemical pesticides have served agriculture—and, for that matter public health pro-

grammes—very well, the problems of declining effectiveness "warrant substantial expansion of present efforts to promote alternative technologies, including integrated pest management". The chairman of the committee, Dr Donald Kennedy, professor of physiology and zoology at Stanford, said last week, for example, that genetic resistance to toxic pesticides is growing at an "alarming rate", and he suggested that unless effective alternatives are developed, some agricultural land could conceivably be taken out of production.

As for specific alternatives, the committee notes that so-called 'third generation' compounds, which affect hormonal development or reproductive processes in insects, have some desirable qualities, but it suggests that "there is reason to be pessimistic about the prospects for controlling major crop pests with these compounds." One potential problem with third generation agents is that resistance is likely to develop to them, the committee states.

Insect control by pathogens, such as baculoviruses, is especially promising, but the committee cautions that large-scale use of such agents will require improved methods for culturing insect host tissues. Moreover, the development of new agents will require some advances in basic research. The use of genetic techniques, such as breeding resistance to pests into crop plants, and introducing genetically modified pests into the environment, are also promising, but again the committee

Crop-dusting: must an alternative be found? (Photo: Popperfoto)

cautions that there are potential problems facing widespread application of some of the techniques. The use of sterile male insects to reduce reproduction in a target population, for example, is effective only when the population has been reduced by other means. Moreover, since potential markets for sterile male insects are likely to remain small, there is little commercial incentive for private firms to get into the business of producing them.

Thus, the general message is that although various alternatives are promising, there is no magic 'insect zapper', as Kennedy put it, to replace chemical poisons in the near future. "The task of pest control over the next 10 years will almost certainly become larger rather than smaller", the committee concludes. It therefore recommends that research efforts be stepped up, and in particular that basic research on organisms and ecosystems be given more attention by various government agencies.

As for efforts designed to eradicate individual pest species entirely, the committee warns that such schemes have limited chances of success and frequently turn out to be inordinately expensive. In particular, the committee recommends against a programme,

strongly urged by some scientists in the US Department of Agriculture, which is designed to eradicate the boll weevil from the cotton fields of the southern United States. The scheme, which would employ a variety of pest control techniques, would cost about \$1,000 million. Although extensive trials conducted in 1972 indicate that the programme would have a good chance of success, the committee suggests that there is considerable doubt that the boll weevil could be eradicated entirely. The committee cautions that if the programme fails, it may endanger public confidence in the alternative methods of pest control which would be used.

One of the problems which the committee encountered in its research was an appalling scarcity of data on pesticide use in the United States. "The pest control enterprise places a billion pounds of toxic materials into the environment each year", the committee states, "but it is considered 'normal' for us to have only the vaguest idea of how much each compound was used where, and then only after a decade lag". It therefore urges that much more effort be put into monitoring pesticide use and that chemical companies be required to report their production and sales figures to the federal government. □

### OSETP progress

A longstanding desire of the scientific community in the United States came a step closer to reality last week when the Senate unanimously approved a bill to re-establish a science policy office in the White House. The bill is similar in many respects to a version passed by the House last November, but there are a few important differences which must be ironed out before the measure is sent to President Ford for his signature. The Senate bill would establish an Office of Science, Engineering, and Technology Policy in the White House, headed by a Director who would also be the President's Science Adviser. Unlike the House bill, the Senate version specifies that the director of OSETP would sit on the powerful Domestic Council and be a statutory adviser to the National Security Council. The Senate version would also set up a programme designed to strengthen science policy arrangements at the state level, and to provide grants to states for the application of technology to various pressing domestic problems. It is now expected that the bill will be ready for Mr Ford's signature by the end of March.

## Triple resignation

THE embattled nuclear power industry in the United States suffered a potentially severe political setback last week when three senior engineers in the reactor division of the General Electric Company (GE) quit their jobs and announced that they will campaign for anti-nuclear groups. They said in their letters of resignation that they have become so concerned about questions of reactor safety, proliferation of nuclear weapons, and radioactive waste disposal that they can no longer work for the industry and keep their doubts to themselves.

Each had spent his entire professional career working for GE and, until they quit on February 2, all three were employed at the company's facility in San Jose, California. Although they have raised no new issues, their espousal of the anti-nuclear cause will clearly have substantial impact on public concern about the hazards associated with nuclear power.

That impact is likely to be most keenly felt in California where, on June 6, voters will determine the future for nuclear power in that state. All three have announced that they will campaign heavily in support of a

proposition, to be put to a state-wide vote during the California Presidential primary election, which would almost certainly halt construction of nuclear power plants in California and eventually lead to shut down of existing plants there.

News of the resignations prompted swift reactions in Washington. Congressmen and Senators who have previously expressed concern about nuclear power issued statements publicising the development; Senator John O. Pastore, the chairman of the powerful Joint Committee on Atomic Energy, has tentatively scheduled a committee hearing on February 18 at which the three engineers will testify; and the head of the Nuclear Regulatory Commission, William A. Anders, met with them last week to hear their concerns.

At a press conference called by the Union of Concerned Scientists, an outspoken anti-nuclear organisation, the three engineers said last week that no single event prompted their departure from the world's largest manufacturer of nuclear equipment. All three said that their concerns have been growing for some time, and they felt that the nuclear industry has been seriously downplaying the risks

associated with nuclear technology.

The three engineers are Dale G. Bridenbaugh, formerly Manager of Performance Evaluation and Improvement, who has headed a special project to assess the adequacy of the primary containment vessels of GE's nuclear reactors; Gregory C. Minor, former Manager of Advanced Control and Instrumentation, who has been responsible for design of safety systems and control room instruments, and Richard B. Hubbard, former Manager of Quality Assurance, who has been responsible for ensuring that GE's reactor equipment meets federal quality standards.

Though all three said they reached their decisions to leave the nuclear industry independently, Minor's letter of resignation probably sums up their feelings with the statement that he is "convinced that the reactors, the nuclear fuel cycle, and waste storage systems are not safe. We cannot prevent major accidents or acts of sabotage. I fear that continued nuclear proliferation will quickly consume the limited uranium supply and force us into a plutonium-based fuel economy with even greater dangers of genetic damage and terrorist or weapons activity".

## ISRAEL

# Harnessing science and industry

*As the need to coordinate the work of science and industry even more closely becomes increasingly apparent to the recession-bound developed countries, Nechemia Meyers reports from Israel on the debate taking place there.*

"PLANS for increasing the scientific potential of Israeli industry were ready four or five years ago, but no one seemed to be in a hurry to implement them. Now, under the pressure of our worsening economic situation, people in science, government and industry are beginning to think and act much more realistically". So says Dr Eliezer Tal, Director of Israel's National Council for Research and Development.

This new realism comes none too soon, for it will be required if solutions are to be found to the problems Israel now faces. First, Israeli industry must turn out more goods that can compete on the world market and, as Dr Tal points out, these will not come from the labour-intensive enterprises that were opened with such fanfare in the 1950s and 1960s. "In view of Israel's European-level wage structure," Tal argues, "she must concentrate on the development of high-technology products equivalent in price and—more important—in quality with those coming from the USA, western Europe and Japan".

Another problem intimately linked with this is the one of finding jobs for science graduates. The country's seven institutions of higher learning are fully staffed, and with budgets for higher education on the decline—they went down 30% in real terms during the past two years and will drop still further this year—some lecturers may even be dismissed. Only a more scientifically oriented industrial sector could, at least theoretically, absorb thousands of 'surplus' science graduates, products of local universities and immigration alike.

A controversial approach to achieving both these goals was recently offered by Richard S. Rosenbloom, Professor of Business Administration at Harvard and, of late, Visiting Professor at the Hebrew University of Jerusalem. The primary problem, as he sees it, is not that Israel spends too little on research and development. On the contrary, the country devotes a larger share of its economic resources to those ends, about 2.4% of its GNP, than any Western nation except the

USA. Even when military research and development is discounted, Israel's expenditure, 1.8% of its GNP, remains greater than the total effort of Belgium and Denmark, and about the same, per capita, as spending on civilian research in Sweden and France, although less than in the USA, the UK and the Netherlands. What disturbs Rosenbloom is that only 14.6% of Israel's civilian research and development is carried out in the business sector, as compared to 50% in Denmark and 80% in Switzerland. And the universities, where most of the other research and development is carried out, are not geared to matching technological opportunity with market needs.

What is the answer? Professor Rosenbloom has a revolutionary suggestion: the creation of an entity he calls "Israel Inc.", which would provide a countrywide framework for the innovative exploitation of technology. Israel Inc., although prepared to consider any area of research and development, would probably concentrate its attention on those where existing achievements indicate that meaningful results are most likely to be achieved, including chemicals, drugs, aircraft, industrial machinery, electronics and instrumentation.

Realising that the idea may sound "strange and impractical", Rosenbloom cites as a possible parallel the experience of General Electric (GE). GE, a highly diversified company which employs 307,000 people (as compared to the 250,000 employed by all industrial companies in Israel), has sales roughly four times as large as those of Israeli industry as a whole, and, with 700 identifiable product lines, covers almost as wide a spectrum as all manufacturing companies here put together. GE might serve as a model, Rosenbloom says, because it is not a single monolithic body, but rather a collection of quasi-independent operating units which are, at the same time, subject to certain strong influences from a central organisation.

The first step towards "Israel Inc." would be the creation, under government auspices, of a National Council for Industrial Technology, which would include the heads of all large science-oriented companies, representatives of some of the smaller companies, academics from pertinent university branches and senior government officials. Sub-groups of the council would deal with such topics as market projections, technological

evaluations, manpower, funding and so on.

Next on the Rosenbloom agenda would be the establishment of an Authority for Industrial Technology, managed by the council and owned jointly by industry and government. The authority would operate its own national research and development laboratory and, at the same time, stimulate contact between research and development establishments in various sectors of the economy. Engineers and scientists employed by the authority would not only work in its laboratory, but also be sent out to other research and development centres and to universities. This system of rotation, Rosenbloom believes, would serve to break down the barriers that now hamper the flow of knowledge into industrial innovation and cut off contact between researchers and the markets in which their knowledge could be exploited.

Dr Tal agrees with Professor Rosenbloom on many points, including the advisability of merging the welter of small companies which now exist into large industrial units where serious research and development becomes possible, and the need to link industrial research with industrial policy. The Israel Government, Dr Tal declares, must decide on specific industries to promote, rather than encouraging investment in a wide range of enterprises. He would, however, shy away from the establishment of something like "Israel Inc.", which "might stifle initiative rather than promote it."

Attitudes inside industry also had to change. All large American firms, Tal points out, have a Vice President for research and development who plays a key role in policy decisions. This is far from being the case in Israel where, for example, it was only a few weeks ago that one of the country's largest companies even appointed a top level adviser on technology. Vice Presidents are still undreamed of.

A Swiss-born chemist, Rene Bloch, who heads a small but rapidly developing company engaged in work on synthetic membranes, has his own suggestion for the promotion of industrially oriented research. "To attract our most brilliant scientific minds to industry, we must give them more money and, particularly, more prestige than their university colleagues." As a symbolic first step, Dr Bloch suggests that the country's major national scientific awards—the Israel Prize and the Rothschild Prize—should henceforth go not to "ivory-tower types whose research pays off in papers", but to applied scientists whose research pays off in dollars. □

## IN BRIEF

**Concorde verdict**

The US Secretary for Transportation's 16-month probationary clearance for Concorde, which immediately inspired the Environmental Defense Fund to apply to the District Court of Appeals for a review of the verdict, is still expected to receive Presidential support, despite hostile Congressional opposition. A decision on access from the airport authorities involved is now awaited: the Port Authority of New York and New Jersey, responsible for Kennedy airport, is reportedly anti-Concorde, but Washington's Dulles Airport is Federal controlled.

**JET set?**

Strong demands for a final decision on the siting of the Joint European Torus (JET) are likely when the EEC council of research ministers meets at the end of the month, and Britain looks like losing not only the battle to have the £70 millions fusion project sited at

Culham but possibly the 40 scientists engaged on preliminary work there as well—with Britain apparently isolated in its opposition to the EEC Commission's recommendation that the project should go to Ispra in Italy, the United States is rumoured to have started moves to collect Culham talent for its own fusion research programme.

**AGRs start**

Years behind schedule, two of Britain's highly expensive 1,250 MW advanced gas-cooled reactors (AGRs), Hinkley Point B in Somerset and Hunterston B in Ayrshire, last week made their first contributions to the national energy supply. Hinkley, now with an estimated capital cost of about £159 millions, generated only a little electricity before being stopped, pending further tests, but both are expected to build up to full power over the next few months.

**Mediterranean clean-up**

Experts from Mediterranean states,

meeting for two weeks in Barcelona under the auspices of the United Nations Environment Programme to discuss measures to clean up and prevent pollution of the Mediterranean, have received the text of a draft treaty embracing pollution from rivers and coastal establishments and exploitation of the sea bed, as well as dumping by ships and aircraft.

**Indian oil**

The Indian Government is to increase investment in oil exploration by a third to £200 millions as part of a bid to boost crude oil production. The target is self-sufficiency by the early 1980s, by which time the annual requirement is expected to be around 30 million tonnes. Though land-based wells at present produce less than a quarter of that figure, seismic surveys indicate potentially rich reserves in the offshore continental shelf. Optimistic interpretations even suggest that India could be an oil exporter within a decade.

THE toxicity, stability and pervasiveness of polychlorinated biphenyls (PCBs) as uncontrolled contaminants are known from a series of investigations that started in 1966, but very little has been done about it. Poisoning occurred in Japan in 1968 from eating rice oil containing PCBs. Clinical effects reported included stillbirths, undersized infants, bone and joint deformities and neurological disorders. Wholesale poisoning of chickens took place when PCBs leaked into fishmeal during processing. The contaminated feed produced low hatchability, and many newly-hatched chicks died. PCBs are distributed widely in major waterways in the USA; their presence led the Food and Drug Administration to warn against eating Lake Michigan fish, and the US Fish and Wildlife Service to call recently for eliminating all sources of PCBs in the environment within three years.

Apparently PCBs have escaped bans because they do not kill insects. They are frequently compared with DDT, which they resemble somewhat in chemical structure, and they can be mistaken for DDT in chromatography, but the resemblance ends there. PCBs are far more stable and more toxic to vertebrate organisms than DDT, which is broken down by enzyme systems that do not change PCBs. PCBs were in North Atlantic surface water at about 20 parts per  $10^{12}$  as compared with less than one part for DDT, even though the fall-out of DDT was estimated as twice that of PCBs. The Environmental

Protection Agency (EPA) is conducting a vendetta against DDT and other chlorinated hydrocarbon insecticides, but has soft-pedalled PCBs—perhaps because of pressure and influence on the EPA by the Environ-

**DDT: bystander or participant?**

THOMAS H. JUKES

mental Defense Fund (EDF), whose head scientist engagingly revealed EDF's motivation as follows: "If the environmentalists win on DDT, they will achieve, and probably retain in other environmental issues, a level of authority they have never had before. In a sense, then, much more is at stake than DDT".

The toxic effects of PCBs and mercury on wild birds may have provided a convenient weapon for clobbering

DDT. However, Scott and his collaborators at Cornell University simultaneously compared the effects of PCBs, DDT and methyl mercury on laying hens. Hatchability was reduced at 8 weeks from 92% in the controls to 50% with 10 p.p.m. of PCBs and to 2.4% with 20 p.p.m. DDT had no effect on egg production or hatchability at the highest level fed (100 p.p.m.), and increased the breaking strength of eggshells on a low-calcium diet. Methyl mercury, 10 p.p.m., adversely affected egg production, eggshell strength, fertility, and hatchability, and it increased morbidity and mortality. Adverse effects attributed to DDT, especially on eagles, have been reported in regions contaminated with mercury. The Cornell workers noted that many reports relating reproductive declines in wild birds to DDT and DDE were based on analyses that did not distinguish DDT from PCBs, and that some investigators had tried to reinterpret results in terms of PCBs.

DDT has never been recorded as having poisoned human beings through the food supply or by industrial exposure. Scott *et al.* say that "condemnation by correlation", in the case of DDT, "may have been downright dangerous to public health". In contrast to pesticides, whose transport and use are publicised, monitored and regulated, PCBs are unrestricted. They have been dumped out of discarded electrical capacitors and transformers, and put on roads to settle dust. The dust is now being stirred up again.

## Closure in Belgium?

SIR,—Due to a political decision, a research institute I head is about to be closed (*Institut de Recherche Interdisciplinaire en Biologie Humaine et Nucléaire*) and another to be severely handicapped (*Département de Biologie Moléculaire*, under Professor J. Brachet) at the University of Brussels. In a European country where the stability of employment is high and the turnover rate of personnel very low, this situation is highly unusual.

The Institute was created in 1963 to develop, in connection with clinical research units and with a sister group in Pisa (Italy), the use of radioisotopes in medical research and medicine. Since then, it has slowly evolved into what is now the *Institut de Recherche Interdisciplinaire* of the *Université Libre de Bruxelles*, a lab where physicists, chemists, biologists and MDs collaborate in biomedical research on many subjects (thyroid metabolism, cancer, cyclic nucleotides, lung physiology, theoretical biology, etc.).

Since its creation, the group has been subsidised by Euratom and the Universities of Brussels and Pisa. In 1969, Belgium did not participate any more in the Euratom programme of Nuclear Medicine. At that time, the government decided to support and create new research groups, "Actions Concertées", in the universities which would, like the Medical Research Council research units in Great Britain and the National Institutes of Health clinical research centres in the US, be catalysts for university research. This has worked well since then. The groups of Brussels were the first to be created and thus the first to arrive at the end of their five year contract.

This year, the government developed a new framework for research in which the whole structure of Belgian research is changed. This project has been criticised. One of its features is the concept of subsidising university research in proportion to the number of students. The government has agreed that the groups would fit in well in this new programme, but it has tied the granting of finance to the "Actions Concertées" to the approval of its programme. As the new project is now delayed, and as the contract is coming to its end, no financial support is planned for 1976. Thus the group is now, because of a political squabble, left "in the air".

Most of the permanent staff was not paid at the end of December. Thus in a few weeks the group might be disbanded. This situation has been much discussed in the Belgian press. The Minister insists that the Universities should take over temporarily, but the hard pressed university is financially and legally unable to do it. It is already badly burnt by a new "loi-programme" on finances, which includes a new subsidisation scheme for universities and which caused much turmoil and student demonstrations in the country in 1975.

Yours faithfully,  
(Professor) J. E. DUMONT

## Crisis in Italian universities

SIR,—I was impressed by the objectivity and completeness of Gillian Boucher's article (November 20, page 190). The causes of the Italian university crisis do not require further elucidation, still less comments like those of Giacomo Morpurgo (December 11, page 475). Morpurgo's letter, if published in an Italian magazine and not in an authoritative and widely circulated scientific journal such as *Nature*, would not deserve mention. His statements are ridiculous and untrue.

It is absurd to assert that the "intended aim" of the recent laws was to assure a permanent position for a large number of leftists "disposed to aggressive political activity". Morpurgo knows that these laws were promulgated by a Christian Democrat government which has ruled the country for thirty years.

After the results of the June 15 elections nobody should be surprised that the majority of university teachers are left wing. The intellectual class in Italy (with the exception of a few people like Morpurgo) was leftist long before June 15.

It is true that departments are invaded less frequently now than a few years ago. But this phenomenon is not confined to Italy. In every country student dissent is weaker than it was in 1968, for reasons much more serious than those invented by Morpurgo.

The recent laws have given tenure to a large number of university teachers and researchers whose positions had been precarious for a long time pre-

viously. The laws have repaired old injustices. If many teachers do not deserve their present positions, that is the fault of the University "baroni" who, by keeping their staff in menial positions for their own convenience, have given them the right to exploit the new laws. One of the privileges of the full professors was to create whatever positions they wanted and to assign them to whoever they liked for as long as they liked. If today the Department of Physics in the University of Genoa has more teachers than students, that, too, is the fault of Professor Morpurgo and his colleagues.

Yours faithfully,  
FRANCESCO GHIRETTI

## Water to the Dead Sea

SIR,—While it would be possible to generate electric power (November 6, page 9) from the flow of seawater into any depression lying below sea level—the Dead Sea (surface at  $-390$  m), the Qattara Depression ( $-138$  m), or possibly even the Caspian Sea ( $-28$  m)—there is one thermodynamic possibility that applies to the Dead Sea alone. It is possible to deliver fresh water to the valley of the Dead Sea by a spontaneous process using a system with no moving parts.

The osmotic pressure of seawater is about 25 bar, and this pressure is reached with a head of 250 m of water. Any greater pressure would cause fresh water to flow through an osmotic membrane such as those used for desalination by reverse osmosis. Fresh water could be delivered to the valley of the Dead Sea not much below  $-250$  m. This water could then be used to irrigate a substantial area, particularly around the mouth of the Jordan River.

To use the flow of seawater into the Dead Sea exclusively for the generation of electric power is to neglect that what the desert most needs is fresh water. There is no reason, however, why the two projects cannot be combined, with fresh water being obtained at negligible added capital cost over that for electric power alone.

Yours faithfully,

## Superfluid $^3\text{He}$ : magnetic pendula

from P. V. E. McClintock

OBSERVATIONS at La Jolla of nonlinear magnetic ringing seem to have demonstrated the existence of significant deviations from the predictions of "simple pendulum" models of dynamic magnetism in superfluid  $^3\text{He}$ . The experiments, by Webb, Sager and Wheatley (*Phys. Rev. Lett.*, **35**, 1010; 1975) can, however, be regarded as confirming the general correctness of the by now well-accepted pairing theory of the superfluidity.

In the picture of superfluid  $^3\text{He}$  which has emerged as a result of the last three years' intensive experimental and theoretical activity, liquid  $^3\text{He}$ -A, which is the stable phase for temperatures near 2.4 mK and pressures above 22 bar, can be considered as a mixture of three separate but interpenetrating components: two magnetically active superfluids capable of exhibiting non-dissipative flow, and a normal fluid component. One superfluid consists of pairs of atoms whose nuclei both tend to point parallel to a magnetic field (the up-spin superfluid) while the other is made up of pairs whose nuclei both tend to be antiparallel to the field (the down-spin superfluid). There are no pairs with opposed nuclear spins in the A-phase. The two superfluids behave almost independently of each other, being only weakly coupled by way of the nuclear dipole interaction. The coupling is, however, sufficient to allow pairs of atoms to pass from one superfluid to the other so that an equilibrium between their respective populations can be maintained.

Very interesting phenomena follow a small disturbance of this equilibrium by, for example, suddenly changing the magnitude of the applied magnetic field by a small increment: this slightly alters the chemical potential of the up-spin relative to the down-spin superfluid, and thus requires a transfer of pairs between them in order to establish a new equilibrium between their populations.

A striking consequence of Leggett's equations (*Am. Phys.*, **85**, 11; 1974) is that such a flow should be oscillatory in character. In fact, as both Leggett

and also Maki and Tsuneto (*Prog. theor. Phys.*, **52**, 773; 1974) have pointed out, there is a remarkably close analogy with the a.c. Josephson effect, which involves an oscillatory transfer of pairs of electrons between two weakly coupled pieces of superconductor. In  $^3\text{He}$ , unlike the superconducting case, the two weakly coupled superfluids are not, of course, physically separated, being on the contrary completely interpenetrating. Nonetheless, the physics of the two situations, and the equations that govern them, are extremely similar: as in the case of the Josephson effect, it turns out that the equation which describes the flow of pairs between the up-spin and down-spin superfluids is formally identical with the equation describing the motion under gravity of a simple pendulum. As the result of small disturbances from equilibrium, one therefore expects that the system will oscillate with a characteristic frequency which is independent of amplitude: this internal Josephson effect or (as Richardson very reasonably suggested in his invited address to the LT14 conference) "Leggett effect" has been observed experimentally in a number of laboratories.

Larger disturbances from equilibrium should show non-linearities of precisely the same form as are exhibited by a simple pendulum. For example, one would expect a decrease in frequency at large amplitudes; and, for very large amplitudes, a frequency which is almost independent of potential energy, no matter whether this corresponds to the nuclear dipolar coupling in  $^3\text{He}$  or to the gravitational potential energy of the simple pendulum. The latter situation corresponds to the pendulum receiving such a substantial initial push that it goes "over the top" and rotates freely in the vertical plane. It is nonlinear effects of this nature which have been studied in some detail at La Jolla.

One of their experiments involved cooling some liquid  $^3\text{He}$  to just below the transition temperature  $T_0$  of 2.4 mK, under a pressure of 22 bar. The cell was a long rectangular cavity

with a cross section of 1 mm  $\times$  10 mm, and a static magnetic field was applied parallel to the longest walls: this approximated to an ideal geometry in which the highly anisotropic superfluid  $^3\text{He}$ -A should have taken up a well-defined texture. A small incremental change  $\Delta H$  in the magnetic field was made and a suitably positioned sensing coil was then used to detect the resultant oscillations (ringing) in the magnetisation of the liquid.

As expected on the basis of preliminary experiments and in the light of the theory, the frequency of the ringing was found to depend on the size of  $\Delta H$  which, in the pendulum analogy, represented the initial impulse given to the pendulum. Their result is shown in

Nonlinear ringing of the magnetisation of superfluid  $^3\text{He}$ -A, following a change  $\Delta H$  in the magnitude of the applied magnetic field (after Webb, Sager and Wheatley, *Phys. Rev. Lett.*, **35**, 1010; 1975). The initial ringing frequency  $f_R$  is divided by the characteristic A-phase frequency  $f_A$ , and plotted against  $\Delta H$  which has been normalised such that the anticipated zero in  $f_R$  should occur at unity on the abscissa. The dashed line represents a theoretical prediction, and is analogous to the behaviour of a simple pendulum.

Fig. 1. It can be seen that for small  $\Delta H$  the ringing frequency  $f_R$  remains close to the characteristic A-phase frequency  $f_A$ . For larger  $\Delta H$ ,  $f_R$  decreases, although not so fast as predicted by theory (the dashed line) and passes through a minimum. The latter situation is believed analogous to the pendulum having been given an initial impulse of exactly the right magnitude just to take it to the top of its orbit, where it therefore remains, which is why the theoretical curve indicates zero frequency. The facts that a minimum in  $f_R$  is observed rather than a zero, and that the minimum apparently occurs at slightly too large a value of  $\Delta H$ , may perhaps represent a genuine deficiency of the simple theory. The rapid rise in frequency just beyond the minimum seems, however, to be in reasonable agreement with expectation; and the so-called ringing-up and ringing-down phenomena which were observed close to the minimum constitute a striking verification of the general correctness of the pendulum model: experimentally, it was found that when the initial  $f_R$  was just to the left of the minimum in Fig. 1, the frequency increased (rang up) with time, corresponding to the increase in frequency of oscillation of a pendulum when frictional damping processes reduce the amplitude of its swing; and, for an initial  $f_R$  just to the right of the minimum, the frequency decreased (rang down) with time, corresponding to the frictional slowing down of a freely rotating pendulum.

Perhaps the physically most significant result of these experiments arises from measurements very close to  $T_c$  of the driven mode, corresponding to free rotation of the pendulum, which occurs

for very large  $\Delta H$ . Under these conditions  $f_R$  varies almost linearly with  $\Delta H$ ; with a constant of proportionality which is independent of the nuclear dipole forces, and is related only to the inertia of the rotating vector which is the analogue of the pendulum. The experimental results have turned out to be in excellent agreement with what would be expected on the basis of the already widely accepted pairing model of superfluidity in  $^3\text{He}$ .

The La Jolla group has also performed equivalent experiments for the other, low temperature, superfluid phase,  $^3\text{He-B}$ . Here, things are much more complicated because a third superfluid component, consisting of pairs of atoms with opposed nuclear spins, is also present. An equivalent pendulum analogy involves consideration of two coupled pendula. Maki and Hu have calculated (*J. Low Temp. Phys.*, **18**, 377; 1975) that there should be two zeros in  $f_R$ . The experiments have indeed demonstrated two rather shallow minima, but not occurring at the predicted values of  $\Delta H$ . However, the ringing up and ringing down phenomena could again be seen; and the frequencies of the driven mode were again in excellent agreement with the pairing model.

The quantitative discrepancies between the La Jolla data and predictions based on the conceptually very attractive pendulum models look real enough, but they will be treated with a certain amount of caution until the experiments have been repeated elsewhere: these measurements are being performed very close to the limits of present technology and the systems under study—magnetically active, anisotropic superfluids—are unique □

resource partitioning in communities of plants or animals have increased at four times this average rate, with a doubling time of less than 3 years. Our rough estimates indicate that work in theoretical ecology is generating papers at a rate similar to, if not greater than, this empirical work

In theoretical biology in general, and theoretical ecology in particular, this increase in papers is reflected in an increase in the number of journals—*Biometrika* (born in 1901), *Bulletin of Mathematical Biophysics* (1939), *Biometrics* (1945), *Journal of Theoretical Biology* (1945), *Mathematical Biosciences* (1967), *Theoretical Population Biology* (1970), *Journal of Mathematical Biology* (1974), *SIAM Journal on Applied Mathematics, Part C* (1976). This trend is faster than exponential, and indeed here a naive extrapolation will suggest an infinite number of journals within a few decades. This explosion in number of papers, and perhaps even in information, creates both human and financial problems.

Of these expanding numbers of theoretical papers in ecology, some contain insights of enduring use to theorist and empiricist, while others represent incremental advances in specialised areas. But essentially all those published are worthy of publication in some form. An established hierarchy in the importance of the various journals would be one rational response (and it exists to a certain extent), except that no publisher is keen to accept low place on the totem pole, and many reviewers seem to apply the same standards (sometimes too harsh, sometimes too lenient) to all work, regardless of the journal. This swelling flood of papers in theoretical ecology is exacerbated by traditions that allow mathematicians to present proofs and analysis in exquisite detail. Empiricists, on the other hand, are not allowed the analogous luxury of publishing their field notes. There is much to be said for innovative publishing practices whereby the major mathematical assumptions and conclusions are published, with the full proofs supplied in manuscript form to the referees and available as *samizdat* to those who care to write to the author. This practice could at least halve the bulk and cost of the journals listed above.

A variation of this idea, which has the advantage of conferring greater permanence on the material, is to publish the full paper in microform, and publish a lengthy abstract in conventional journal form. This is a logical outgrowth of the practice of putting journals into microform; for a review of contemporary trends, see Lynden (*Microform Review*, **4**, 15–24; 1975). In a recent survey (News and Com-

## The ecology of the ecological literature

from Judith May and Robert M. May

EVERYONE is familiar with the arrant nonsense produced by assuming that the current rate of population growth will continue indefinitely at its present value of about 2% per annum. If such a rate were sustained for around 5,000 years, the globe would be a ball of human protoplasm, expanding into space at the speed of light. This sort of naive extrapolation can be performed for various other quantities, many of which exhibit exponential growth rates faster than that of the human population as a whole. Thus if the rate at which the population of scientists grew in the 1960s were projected, in a mere two to three centuries there would be more scientists than people. Obviously such calculations are

not to be taken literally, but they do dramatise trends: in particular, the estimate above suggests that for the scientific community the growth rates of the 1960s were pathological, and that the slower growth rates of the 1970s are nearer the norm.

One of the basic products of scientists, namely published papers, has also grown exponentially in volume. Derek de Solla Price (in *Little Science, Big Science*, Columbia University Press, 1963) has documented a long term pattern of exponential growth in the number of scientific publications, with a doubling time of 10 to 14 years. Ecologists may rejoice or despair at Schoener's (*Science*, **185**, 27–39; 1974) observation that published studies of

ment in *Microform Review*, 4, 179–182; 1975) of 53 major publishing organisations representing 1,427 journals, roughly one third “expressed themselves in regard to how they would publish in microfiche.” Of these about one half were considering publishing the entire journal in microfiche but with a hard-copy version of contents and abstracts. Many of these publishers were also thinking of publishing the experimental details, appendices and other source and supplementary material only in microfiche and the abstracts or shorter versions of the articles in a paper edition. There are clearly many advantages to a two-tier system, with a conventional journal containing full summaries of the results, and with details published in microform (which could be produced directly from manuscript, saving time and expense). With contemporary techniques paper copies can be supplied on demand from a central microform holding.

Quite apart from the increasing number of journals, the rising production costs for individual journals create problems. One response for many journals has been to levy page charges, and sometimes to discriminate (often by slower publication) against those who cannot pay the charges. Van Valen (*Evolutionary Theory*, 1, 119–130; 1975) has recently made a tentative survey of various kinds of financial discrimination by journals catering to the broad area of ecology and evolution: of the various kinds of subtle and not-so-subtle discrimination he catalogues, the commonest is a mandatory charge for pages in excess of  $x$  (where  $x$  is typically around 10). Van Valen's figures suggest that of journals published in this general field in the USA, 69 of 112 manifest one or more discriminatory practices. The corresponding figures for Britain are 5 of 41; for the remainder of Europe 23 of 48, for Japan 6 of 8; for Canada 2 of

8. The average cost per 100 pages of the journal to the subscriber is roughly constant for the various countries (with commercial publishers based in Germany tending to be significantly higher), and for the various publishers.

Socially responsible readers of *Nature* will be relieved to know that Van Valen classes it as not discriminatory.

## Myelin structure

from N. P. Franks

New freeze-fracture studies by Pinto da Silva and Miller (*Proc. natn. Acad. Sci. U.S.A.*, 72, 4046, 1975) have questioned current concepts of myelin structure. Myelin is usually thought to be unlike any other plasma membrane. It has an unusually low protein content (about 20% by weight), very little enzymatic activity (Adams *et al.*, *J. Neurochem.*, 10, 383; 1963) and a lipid composition likely to result in a particularly stable bilayer (O'Brien, *Science*, 147, 1099; 1965). This is all consistent with the principal function of myelin being that of an electrical insulator of nerve axons.

The most widely accepted model of myelin structure is that of a basic lipid bilayer, with most of the protein distributed outside the hydrocarbon region. Support for this picture came from the freeze-fracture results of Branton (*Expl Cell Res.*, 45, 703, 1967), which showed that the fracture faces of frozen myelin were relatively smooth (similar to those seen with lamellar phases of lipids alone) in contrast to the particulate appearance of the fracture faces of other membranes. Since most membranes are thought to fracture within the hydrocarbon region, and since in some cases the particles have been shown to be protein-containing structures, Branton's results were consistent with a bilayer of lipids relatively uninterrupted by protein. More detailed information about the protein distribution has come from the X-ray diffraction work of Caspar and Kirshner (*Nature new Biol.*, 231, 46; 1971). Using an absolute electron density scale, previously established by Blaurock (*J. molec. Biol.*, 56, 35; 1971), they interpreted their electron density profiles as showing that the concentration of protein in the aqueous spaces between bilayers was 15–20% by volume (possibly higher near the lipid headgroups) with less than 10% by volume at the centre of the hydrocarbon region. The electron density profiles of Caspar and Kirshner impose important constraints upon models of myelin structure and were taken to support the notion that there was little

protein in the hydrocarbon region.

Surprisingly, Pinto da Silva and Miller now report a widespread distribution of particles on the freeze-fracture faces of myelin. They suggest that the previous observations of Branton were restricted to regions of high shadowing angle, where the particles were obscured. In untreated myelin, frozen shortly after dissection, the particle distribution was found to be uniform. If, however, the membranes were either fixed or glycerol impermeated then the particles aggregated and formed clusters in the plane of the membrane. Similar particle clustering has been observed in several other membranes, but what is remarkable about the photographs of Pinto da Silva and Miller is that the particle-rich regions in one membrane seem to line up with particle-rich regions in the adjacent membrane of the myelin sheath (this correspondence sometimes continuing across as many as 50 membranes). Furthermore, neighbouring membranes in the particle-rich regions seem more closely apposed than those in particle-free regions.

Although Pinto da Silva and Miller admit that the particle clustering itself is likely to be an artefact, they conclude that the correspondence between particle-rich regions from one membrane to the next does reveal an intermembrane interaction which exists *in vivo*. They argue, by analogy with other freeze-fracture studies on membranes, that the particles represent protein-containing structures which traverse the lipid bilayer. They suggest that these structures stabilise the myelin sheath by interactions across the cytoplasmic and extracellular spaces. Because the fracture faces are thought to represent an essentially hydrophobic environment, Pinto da Silva and Miller argue that the protein is likely to be apolar in nature and suggest the Folch-Lees proteolipid as a possible candidate. Indeed, the fact that about 80% of the myelin protein (Folch-Lees and Wolfgram proteolipids) can be solubilised in organic solvents argues for an apolar site for these proteins. It remains to be shown, however, that the particles observed by Pinto da Silva and Miller do represent protein-containing structures which are present *in vivo*. If this is the case then current models of myelin structure may have to be revised.

## Chemical antagonism in plant communities

from Peter D. Moore

ALMOST a hundred and fifty years ago De Candolle observed that the growth

### A hundred years ago

M. Berthelot, the celebrated chemist, is a candidate in the moderate Republican interest for the representation in the French Chamber of Deputies, of the district in which the Institute is situated.

from *Nature*, 13, February 10, 297; 1876.

of certain weeds was injurious to crops and postulated that the immediate cause of injury could have resulted from the excretion of toxins, possibly from their roots. Back in 1925, Massey (*Phytopathology*, **15**, 773; 1925) conducted experiments which involved planting such species as potato and tomato beneath the canopy of walnut trees and observed that wilting and death of the test plants occurred wherever they were in contact with the roots of the walnut, even when they were well clear of its canopy. He also showed that portions of bark from walnut roots could cause root death in water cultured tomatoes, thus indicating the involvement of some chemical factor rather than a competitive interplay for a mineral or water resource.

The importance of such chemical interactions between higher plants, sometimes termed allelopathy, is still probably underrated in ecological circles despite some valuable recent reviews, such as those of Whittaker and Feeney (*Science*, **171**, 757; 1971) and Rice (*Allelopathy*, Academic Press, New York; 1974). This has undoubtedly resulted from the general scarcity of information relating to chemical interactions in natural communities of plants. Many potential researchers must have been discouraged by the practical difficulties involved in designing experiments to test for allelopathic interactions, especially when one considers the physicochemical complexity of the soil in which such interactions occur and also the likely involvement of soil microbial communities. It may well be that some reported allelopathic agents are in fact the products of microbial degradation of the original plant tissues rather than the direct results of a plant's metabolism. Such a possibility, however, although of academic interest, does not preclude the evolutionary development of allelopathic competitive mechanisms which involve microbial symbionts. The fact that such mechanisms favour the host plants (and thereby favour the decomposer microbe) is of prime importance to the student of plant community dynamics. This being so, it should be possible to design simple experiments which do not attempt to disentangle the peripheral question of microbial involvement, but which are concerned with the overall outcome of plant-plant interactions involving allelopathy.

Just such an experiment has recently been reported by Newman and Rovira (*J. Ecol.*, **63**, 727; 1975) who have looked for chemical interactions between a number of common British grassland species. Four grass species and four herbaceous dicotyledons were chosen, none of which had given any field indication of allelopathic mechanisms at work. Plants were grown in

buckets of sand, together with an inoculum of soil from their original habitat; it is to be expected, therefore, that the normal rhizosphere microflora was present. Leachate of these pots (and of a control pot lacking plants) was applied to all other species examined and its influence upon the growth rates and mineral content of their shoots was examined.

The leachate from certain 'donor' species had a consistent and statistically significant effect in depressing the yield of receiver species. Yorkshire fog grass (*Holcus lanatus*), catsear (*Hypochaeris radicata*) and white clover (*Trifolium repens*) were most effective in this respect. Sweet vernal grass (*Anthoxanthum odoratum*) appeared to be the most sensitive species as a receiver of leachate, while *Trifolium repens* grew faster when supplied with almost any plant leachate than under the equivalent control conditions. *Anthoxanthum* was of additional interest in that its growth when supplied with its own leachate was faster than under any other conditions. Both *Holcus*, and the crested dog's tail grass (*Cynosurus cristatus*) also showed some growth stimulation when treated with their own leachate.

Although lack of rigorous replication in this experiment precludes detailed conclusions concerning the precise interaction of individual species, it is evident from these results that allelopathic mechanisms could be of considerable importance in determining composition and pattern in neutral grassland swards. Of particular importance is the demonstration that species differ in their toxic potential and also in their sensitivity as receivers of toxins. Self stimulation amongst grassland species could be of considerable importance in the attainment of dominance within a sward, whereas self sensitivity could lead to a wider spacing of individuals and an avoidance of intraspecific competition for resources within the population. Newman and Rovira's results, in this respect, agree well with the behaviour of their species in the field, but the observations of other workers are not so simply explained. For example, McNaughton has demonstrated auto-inhibition of seed germination in the reed mace, *Typha latifolia* (*Ecology*, **49**, 367; 1968), yet this is a species which can dominate extensive areas. The selective advantage of autotoxicity may operate in different ways in different species.

By far the most important point to emerge from Newman and Rovira's data, however, is that allelopathy is a potentially important mechanism for species interactions even in situations where such chemical devices have not previously been suspected. They effectively by-pass the ecologically

irrelevant question of microbial involvement; indeed, in using only young roots in their leachate production, they could be underestimating the overall influence of allelopathy in these species if there is a microbial intermediary involved. □

## Volcanic processes in ore genesis

from I. G. Gass

A packed lecture hall and an international range of contributors testified to the interest engendered by the recent joint meeting of the Institute of Mining and Metallurgy and the Volcanic Group of the Geological Society held in London on January 21-22 on the subject of Volcanic Processes in Ore Genesis. Seemingly, the timing and the topic were right and sufficient progress has been made in the area in recent years to attempt a synthesis.

Two major themes pervaded the meeting. On the one hand were the academics who, using trace element and isotope geochemistry and even naked thermodynamics, erected hypotheses and models for the tectonic setting, origin and circulation of ore-forming fluids. At the other extreme were those who provided the critical evidence as to whether these data applied to a particular ore deposit. Fortunately, speakers such as J. P. Hunt (Scripps Institution: ex-Anaconda), T. Sato (Japan Geological Survey) and G. Constantinou (Cyprus Geological Survey) with experience in both areas more than adequately bridged the all too common gulf between the two.

Stable isotope studies strongly suggest that the origin of the ore-carrying solutions was either seawater, in the case of massif sulphides formed at or near constructive margins, or meteoric waters for ore bodies such as porphyry coppers, emplaced above subduction zones. The role of magmatic waters is minimal in the former and minor in the latter; magmatic processes seem to provide the thermal energy and very little else. Both thermodynamic models of geothermal systems, as presented by J. W. Elder (University of Manchester), or modification of stable isotope ratios (E. T. C. Spooner, University of Oxford and T. H. E. Heaton, Kilbride) indicate that the circulation of the solutions that cause mineralisation follows immediately after the magmatic thermal event and that they are short-

lived in terms of thousands rather than millions of years and vigorous. There are therefore signs of a semi-quantitative breakthrough in the understanding of geothermal processes. This has been brought about by the use of a wide spectrum of analytical techniques on, for instance, the ophiolite massive sulphides of Cyprus and the porphyry copper of El Salvador. Their use elsewhere will markedly enhance our understanding of the processes involved in ore genesis.

Happily, the days when it was considered almost indecent for 'pure' academic scientists to concern themselves with 'ores' are over. A period of fruitful collaboration between hard-headed practicality and high quality academic research is, it is hoped, here to stay. □

## Phyto-insanitary Britain

from a Correspondent

A LARGE proportion of the money devoted to agricultural research in the UK is spent on phytopathology and crop protection and has enabled the production of virus-free and disease-resistant crops that can be fully protected by insecticides, fungicides and herbicides, to give near maximum possible yields.

Phytopathology research within the UK has been mostly confined to known indigenous pathogens but there is an additional threat from the vast amounts of plant material imported in many different forms every day. This comes from all over the world and frequently carries pathogenic organisms or strains of pathogens alien to this country. Fortunately most of these pathogens cannot survive in the unfavourable climate but the few that can may cause economically serious diseases.

Many such diseases have already entered the UK through the importation of infected plant material. Fire-blight of apples and pears, for example, was unheard of in Britain 20 years ago, though it was widespread in North America. It is now an established disease in southern England affecting hawthorns, many ornamental species of Rosaceae and posing a potential threat to apple and pear species, though disease outbreaks have been mostly confined to South-East England (*Ann. appl. Biol.*, **69**, 137; 1971). This disease has put severe restrictions on nurserymen who wish to export apple and pear varieties. Tobacco ringspot virus has also been introduced recently on pelargoniums imported from the USA.

The fruit industry suffered another setback recently when the Ministry of Agriculture reported that at least 150 acres of plums have some levels of infection with plum pox (sharka) virus, an aphid-borne virus. This potentially devastating disease originated in south-eastern Europe but has now spread throughout most of the continent. The Germans unknowingly introduced plum pox into their own plums from propagating material brought back from Yugoslavia after the last war, which resulted in serious losses in crop production in some regions. The virus is now endemic in many parts of Eastern Europe infecting a wide range of *Prunus* species (*Acta. Horticulturae*, **44**, 155, 1975).

Britain, through the Nuclear Stock Association (Tree Fruits), has been producing virus-free plums for nurserymen and fruit farmers for several years. Ironically a wide range of *Prunus* species from all over Europe is also imported even though the dangers of plum pox have been apparent for many years (*Pl. Pathol.*, **17**, 66, 1968). Much of this material is accompanied by phytosanitary certificates of the exporting countries which are not necessarily the countries of origin. These certificates state that the material has been inspected and is certified free of certain diseases.

Most virus diseases cannot be detected by visual inspection, however, particularly in dormant plants in transit. When the material arrives in the UK it is again inspected by the Ministry of Agriculture Plant Health Inspectorate who are not equipped to detect most virus infections at this stage. The plants are then distributed to nurseries for propagation, and are often grown close to virus-free rootstocks and mother-trees in the nuclear stock scheme. In the retesting of nuclear stocks carried out last year some plum pox infection was found.

As plum pox severely affects Victoria plum, the most widely grown cultivar in the UK, the survival of the plum industry is threatened unless steps are taken to eradicate this disease.

Because of the present loopholes in the system, which have been apparent for many years, particularly for virus diseases, it may only be a matter of time before diseases such as apple proliferation, oak wilt and pear moria are introduced.

Unlike countries such as New Zealand and the USA, the UK is failing to implement effective phytosanitary measures. Farmers and growers in Britain are not getting the protection they require and production is being restricted or made more costly by the introduction of new diseases. For too long exporting countries have been able to sell sub-

standard and infected plant material, undercutting local industries and threatening the health of home-produced material. It is time that the Ministry of Agriculture and Plant Health Branch heeded the warnings of research workers and implemented effective phytosanitary procedures. □

## Observing satellites

from a Correspondent

On January 17, 1976, there was an all-day meeting, at the Royal Society, in London, of optical observers of satellites and the university researchers who are, or soon will be, using their observations. The meeting was organised by the Optical Tracking Subcommittee of the British National Committee on Space Research, and the stimulus was the recent award by the Science Research Council to the Universities of Aston and Leicester of grants for research projects based on optical observations of artificial satellites. The current observing effort is to be augmented by recruiting a second team for the Hewitt Camera at Malvern and an increase in staff in the Satellite Orbits Group at the Appleton Laboratory, Slough, which provides the prediction service.

THE morning session began with an outline of the university proposals from their initiators, C. J. Brookes (University of Aston) and A. J. Meadows (University of Leicester). Brookes's programme includes a varied group of geophysical studies based on orbital analysis. The aims are to obtain better values of zonal harmonics in the geopotential, to study the variation of atmospheric rotation rate and air density during a solar cycle, and to study in detail the radiation pressure effects on orbits, using balloon satellites. Meadows proposed to concentrate on two topics: first, analysis of resonant lunisolar perturbations, by intensive observation of satellites at particular inclinations (56.06° being a promising starter); and second, studies of spin rates of similar satellites in orbits at different heights, to distinguish the effects of atmospheric and magnetic damping in the hope of measuring the variations in both.

After these plans for the future, some recent results from orbital analysis were presented. D. M. Brierly (Royal Radar Establishment, Malvern) described his determination of air density at a height of 128 km from a

THERE have been many studies of nucleon transfer reactions at low energies (5 to 50 MeV) and these have given much information on the single particle states of nuclei (see for example, *Nature*, **254**, 18; 1975; **256**, 615; 1975). Very few analyses have been made at higher energies, partly because it is then difficult to resolve the final states and partly because it is thought unlikely that such studies could give any information that could not be obtained from the technically much easier studies at lower energies.

In 1974 a group working at the Saturne synchrotron (*Phys. Lett.*, **52B**, 57) published the results of their measurements of the  $^{12}\text{C}(\text{p},\text{d})^{11}\text{C}$  neutron pickup reaction at 700 MeV. These data were remarkable because the energy resolution was sufficient to resolve several states of  $^{11}\text{C}$ , and thus provided the only stripping or pickup data available above 200 MeV.

The group made a preliminary analysis of their data using the distorted wave formalism, with the zero-range approximation for the neutron-proton force. At high energies, however, the momentum transfers are large, and this invalidates the approximation. They also ignored the D-state component of the deuteron wave function, although this is expected to contribute strongly at high energies. In spite of this, they found that the overall shape of the differential cross section is given quite well by their calculation, as shown in the figure, but the absolute magnitude is wrong by a factor of two.

In the past few years computer programs using a finite range neutron-proton force have been developed,

mainly to analyse heavy ion reactions. Rost and Shepard (*Phys. Lett.*, **59B**, 413; 1975) have now used one of these programs to analyse the  $^{12}\text{C}(\text{p},\text{d})^{11}\text{C}$  data, and have also included the effect of the D-state of the deuteron.

As shown in the figure, they found that the theory then gives a cross-section in good agreement with the experimental data, both in absolute magnitude and in overall shape. As expected the contribution of the D-state is dominant, so the previous agreement in shape must be largely fortuitous. It is thus very important

## Neutron pickup at high energies

from P. E. Hodgson

for reactions of deuterons at high energies to use an accurate deuteron wavefunction, and the results can themselves provide information about that wavefunction.

This conclusion is reinforced by studies of the contribution of the S-state component of the deuteron wavefunction Rost and Shepard used an S-state waveform calculated from the Reid soft-core potential, that has been obtained by fitting a large body of nucleon-nucleon and deuteron data. Calculations with the Hulthén wavefunction, a simple analytical function widely used at low energies, gave cross sections completely in disagreement with the experimental data.

This work shows the value of repeating familiar analyses at sub-

stantially higher energies, whenever it is practicable to do so.

Differential cross section for the  $^{12}\text{C}(\text{p},\text{d})^{11}\text{C}$  reaction at 700 MeV compared in the top section with zero-range and exact finite-range distorted wave calculations. The zero-range curve has been arbitrarily divided by two to fit the data. The lower section shows the individual cross sections for the S-state  $L=1$  and the D-state  $L=1,2,3$  contributions.

decaying Molniya satellite, entirely on the basis of visual observations from Britain. Brookes presented the results of his first orbit determination, of Cosmos 373 (1970-87A) at 25 epochs between 1971 and 1975: this orbit, at inclination  $62.9^\circ$ , is closer to the critical inclination of  $63.4^\circ$  than any other orbit that has been accurately analysed, and he has determined the oscillation in perigee height caused by odd zonal harmonics in the geopotential as 59 km—the largest value yet established. D. G. King-Hele (Royal Aircraft Establishment, Farnborough) described new results obtained by himself and D. M. C. Walker in determining the atmospheric rotation rate from orbital analysis; the variations with height and local time have now been separated, and three curves of the variation of rotation rate with height were shown, for average local time, for evening (18-24 h) and morning (4-12 h).

The afternoon session began with an

excellent presentation by J. Eady (Ordnance Survey) of the work of the Hewitt Camera at Malvern, owned and operated by the Ordnance Survey. He commended the beautiful design of this accurate camera, a great tribute to the skill of the late Mr Hewitt, and looked forward to its increased use with a second observing team. The session continued with a succession of short contributions on topics connected with satellite observing. D. A. Richards (University College of Wales, Aberystwyth), offered some thoughtful comments on the slower time response of the eye in poor light, and demonstrated how the eyes see the linear swing of a pendulum as an ellipse if the light to one eye is reduced by a filter. The other contributions, to flash through them even more rapidly than they were presented, included a kaleidoscope of satellite shapes (J. A. Pilkington); an experimental demonstration of flash behaviour with satellite models (M. D.

Waterman); recent work on radio tracking of satellites at Kettering and associated stations (G. E. Perry); the telemetry of Soviet navigation satellites (C. D. Wood); a possible explanation of the break-up of the Pegasus balloon and several other US satellites (R. D. Eberst); the US Navy satellite tracking network (D. G. King-Hele); an analysis of a lengthy questionnaire on observing previously completed by the participants (M. D. Waterman); and a film of the Apollo-Soyuz Mission.

Apart from the formal presentations the meeting was intended to allow the visual observers to meet the new university researchers; to introduce the latter to some of the problems of observing; and to allow the volunteer visual observers to meet each other, to renew their enthusiasm, and to see how their unpaid work was utilised by the scientists. The subsequent comments of the participants suggested that these aims were fully achieved. □

## Head-tail radio sources in the cluster of galaxies Abell 1314

Jacques P. Vallée & Andrew S. Wilson\*

Sterrewacht, Leiden, The Netherlands

*A high resolution study of the cluster of galaxies Abell 1314 has revealed two 'head-tail' radio sources, associated with the galaxies IC708 and IC711. The tail of IC711 extends fully 820 kpc. The source properties are described and discussed in terms of the 'radio trail' model.*

THE 'head-tail' radio sources are characterised by a highly elongated radio structure, near one end of which lies the associated optical galaxy—usually a giant elliptical. The first examples of these tadpole shaped objects were discovered by Ryle and Windram<sup>1</sup> in the Perseus cluster, and roughly a dozen have now been recognised, mainly through observations with the aperture synthesis instruments at Cambridge and Westerbork. Most, perhaps all, of these sources are associated with clusters of galaxies. A compendium of currently recognised 'head-tail' galaxies is presented in Table 1, along with their more salient properties.

The most satisfactory explanation of these objects is the 'radio trail' hypothesis<sup>2</sup>. As the galaxy ploughs through a dense intracluster gas at supersonic speed, it is envisaged to eject pairs of plasmoids in opposite directions, as commonly assumed for 'normal' double radio galaxies. These blobs then brake by interaction with the intracluster medium, and form a trail behind the galaxy. Jaffe and Perola<sup>3</sup> developed two models based on this idea. In the first (the 'independent blob' model), the dynamic and radiative evolution of a series of ram pressure confined plasmoids was calculated. This model has difficulties with the spectral data and so they considered a second case (the 'magnetospheric' model), in which the galaxy is endowed with a strong magnetic field, drawn out into a magnetotail by the rapid motion through the surrounding gas. The double structure and symmetry of the tails<sup>2,4-7</sup>, and the detection of compact sources at the positions of the galaxies themselves<sup>5,7</sup>, speak strongly in favour of the 'radio trail' hypothesis; and the polarisation data on NGC1265 (ref. 9) indicate the magnetic field to be aligned more or less along the tail, as might be expected in models invoking galaxy motion through an intracluster gas (for example the 'magnetospheric' model).

It is important to discover more of these objects to attack the following problems: first do 'head-tail' galaxies occur preferentially in rich clusters? Much needed information on the elusive intergalactic medium could thus be obtained. Second, can the shape of the tails be completely accounted for in terms of the orbit of the galaxy in the cluster's gravitational field, or are additional processes (for example 'gales', or a buoyancy effect in the intracluster gas) required to explain the pronounced curvature observed in some sources? Third, is there any

tendency for these objects to occur in clusters which also contain other active radio galaxies (see ref. 4)? Fourth, are the energy losses of the relativistic electrons by synchrotron radiation, inverse Compton scattering, and adiabatic expansion so severe that particle acceleration is required a large distance from the parent galaxy?

We report here two new 'head-tail' galaxies (IC708 and IC711), both located in the cluster of galaxies Abell 1314, and discuss their structure and interrelationship. This work forms part of a continuing programme to search for such sources with the Westerbork Synthesis Radio Telescope (WSRT).

### Selection of objects and observations

Owen<sup>10,11</sup> has surveyed over 500 Abell clusters of galaxies with a resolution of 10' at  $\lambda = 21$  cm, and presented contour maps of sources with complex or multiple features. Although his map of the radio emission from Abell 1314 shows extended structure, the resolution is inadequate to delineate the nature of the source and determine unambiguously with which cluster galaxy, if any, it is associated. This field seemed a promising candidate for higher resolution investigation, so we observed it with the WSRT at  $\lambda = 49$  cm (610 MHz) and  $\lambda = 6$  cm (4,995 MHz). The former wavelength, where the resolution is  $\sim 1'$ , is ideal for the detection of faint, extended features, whereas the latter enables a higher resolution ( $\sim 6''$ ) investigation of the more intense, compact regions.

The WSRT and the procedure for data analysis have been fully described elsewhere<sup>12,13</sup>. Briefly, the instrument consists of twelve 25-m parabolic antennae along an east-west line. Ten of these (telescopes 0 to 9) are fixed and the other two (telescopes A and B) are moveable along a rail track. The signal from each of the ten fixed telescopes is correlated with that from each of the two moveable ones, resulting in twenty simultaneous baselines ranging from the separation 9-A to 9-B + (19 × 72 m) at intervals of 72 m. Fourier transformation and linear combination of the correlated signals yield maps of the four Stokes parameters<sup>14</sup>. The reception pattern of the individual paraboloids causes emission away from the field centre to be attenuated. For the extended radio structure associated with IC711 and IC708, the attenuation at  $\lambda = 49$  cm is always < 3%. At  $\lambda = 6$  cm, the maximum attenuation of the extended structure on the maps of IC711 and IC708 is 15% and 6% respectively. Both the contour maps and the quoted flux densities have been corrected for these small effects. The observational parameters, sensitivities and highest resolution obtainable are summarised in Table 2.

### Results at 49 cm and optical identifications

Figure 1a and b is a radio photograph and a contour plot of the brightness (total intensity) distribution in the central region of Abell 1314 at  $\lambda = 49$  cm (the cluster diameter is

\*Present address: Astronomy Centre, University of Sussex, Brighton, UK.

Redshift values in parentheses are estimated from apparent magnitudes. Flux densities and powers at  $\lambda = 21$  cm in parentheses are estimated from scaling down the corresponding values at  $\lambda = 49$  cm using a spectral index of  $-0.7$ . A Hubble constant  $H_0 = 50$  km s $^{-1}$  Mpc $^{-1}$  and a deceleration parameter  $q_0 = 1$  have been used throughout to compute the powers at  $\lambda = 21$  cm and the corresponding linear sizes.

$\sim 2^\circ$ ). A highly elongated radio structure can be traced on a scale of  $15'$ , at the southern end of which, but still within the radio contours, lies the galaxy IC711. We identify the elongated feature as a 'head-tail' source associated with this galaxy, for the relative position of optical and radio features is typical of such objects and our observations at  $\lambda = 6$  cm (see next section and Fig. 2) show IC711 to be active. If the extended structure to the north of declination  $49^\circ 22'$  and elongated in position angle  $\sim 30^\circ$  is, in fact, a part of the tail and if IC711 is a member of the cluster, the overall length of the source is  $> 800$  kpc ( $H_0 = 50$  km s $^{-1}$  Mpc $^{-1}$ ). IC711 is then the longest 'head-tail' galaxy known, with a distance  $\sim 200$  Mpc. The tail of IC711 passes to the east of another well resolved, but more intense and compact, source at declination  $49^\circ 20'$ . This source is identified with the galaxy IC708, although the apparent peak of the emission at  $\lambda = 49$  cm is displaced some  $20''$  from the optical centroid. Observations of IC708 at  $\lambda = 6$  cm (Fig. 3) show, however, that it is both active and possesses a well developed radio trail, fully accounting for the displacement apparent in the lower resolution map at  $\lambda = 49$  cm. Webber<sup>15</sup> observed Abell 1314 at three radio frequencies and detected two sources which he identified with IC709 and IC711. Our observations show the former identification to be incorrect. Although the galaxy IC709 does lie close to the tail of IC711 (between IC711 and IC708), we do not detect it, allowing an upper limit for its flux ( $S_{49\text{ cm}} < 10$  mJy) to be established.

In the central part of the cluster, two other bright galaxies are detected at  $\lambda = 49$  cm. IC712, an elliptical galaxy with  $m_v \simeq 14$  (A. Oemler, personal communication), lies  $\sim 7'$

to the north of IC711, and coincides with an unresolved radio source (RA (1950.0) = 11 h 32 min 06.47 s, dec. (1950.0) =  $+49^\circ 21' 15.6''$ ) with flux density  $S_{49\text{ cm}} = 58$  mJy. The

Fig. 1 The brightness (total intensity) distribution in the central part of the cluster of galaxies Abell 1314 at  $\lambda = 49$  cm and resolution  $52'' \times 69''$ . *a*, Radio photograph (kindly made by W. Jaffe). *b*, Contour map. In *b*, the crosses show the positions of the optical galaxies, measured by Oemler (personal communication), and the half-power beam width is represented by the ellipse in the bottom right hand corner; the contour values are: 5, 10, 15, 25, 50, 100, 150, 200, 350 and 500 mJy (beam area) $^{-1}$ .

Table 2 Observational parameters

Galaxy observed	Whole cluster	IC708	IC711
Field centre RA (1950.0)	11 h 32 min 00 s	11 h 31 min 12 s	11 h 32 min 00 s
dec. (1950.0)	$49^\circ 20' 00''$	$49^\circ 20' 00''$	$49^\circ 14' 00''$
Wavelength (cm)	49	6	6
Observing time (h)	$1 \times 12$	$1 \times 12$	$1 \times 12$
Minimum baseline (m)	72	36	54
Spacing increment (m)	72	72	72

R.m.s. noise (mJy (beam area) $^{-1}$ )	1.6	1.2	1.2

**Fig. 2** The brightness (total intensity) distribution in the galaxy IC711 at  $\lambda = 6$  cm. The half-power beam width ( $12'' \times 16''$ ) is shown by the ellipse in the bottom right hand corner and the cross marks the centroid of the optical galaxy. The contour values are: 2.5, 5, 7.5, 10, 20, 30 and 40 mJy (beam area) $^{-1}$ . The inset in the bottom right hand corner shows the  $\lambda = 6$  cm nuclear source at a resolution of  $6'' \times 8''$ , with contour values: 1.25, 2.5, 3.75, 5, 10, 20 and 30 mJy (beam area) $^{-1}$ .

second galaxy ( $m_v = 15.7$ ) is a spiral with a flux  $S_{49\text{cm}} = 70$  mJy and radio position RA = 11 h 30 min 40.45 s, dec. =  $+49^\circ 18' 49.8''$ . If this last galaxy is a member of Abell 1314, its radio power at  $\lambda = 49$  cm is  $3 \times 10^{23}$  W Hz $^{-1}$ ; it is unresolved at  $\lambda = 49$  cm. Markarian 178, an object possessing a strong ultraviolet excess, lies  $\sim 14'$  north-west of IC712, and is not detected in our survey, implying that its flux  $S_{49\text{cm}} < 5$  mJy; its redshift ( $v_r = 270$  km s $^{-1}$ ) is much lower than that of the cluster, and Sargent<sup>16</sup> has suggested that it is a dwarf emission-line galaxy. A more complete discussion of the optical identifications of other radio sources in the field will be presented elsewhere.

## Results at 6 cm

To explore the structure of the brighter parts of IC711 and IC708 with finer resolution, we have observed them with the WSRT at  $\lambda = 6$  cm. The map of IC711 with resolution  $12'' \times 16''$  (Fig. 2) shows an unresolved source, whose position agrees well with the centroid of the optical galaxy (as measured from the blue Palomar Sky Survey print) and is presumably to be identified with its nucleus. To the north-west of this source lies the tail, the brighter parts of which are detected up to  $\sim 3'$  from the galaxy. Between the brightest part of the tail and the nucleus, little radio emission is found. On the 'radio trail' hypothesis, this would imply that IC711 has not ejected double plasmoids recently. A close examination of the radio contours within  $10''$  of the compact source at a resolution of  $6'' \times 8''$  (see inset in Fig. 2) yields, however, evidence for a double feature apparently emerging from the nucleus. Although the brightness of this feature is only about twice r.m.s. noise, it is interesting that it is 'swept back' in the general direction of the tail itself. Basic data relevant to IC711 (and IC708) are summarised in Table 3.

The structure of IC708 at  $\lambda = 6$  cm is shown in Fig. 3. The intense resolved source on the  $\lambda = 49$  cm map (Fig. 1) superimposed on IC708 may now be seen to consist of four components. The brightest, unresolved at  $\lambda = 6$  cm, lies close

to the centroid of the optical galaxy (Table 3) and is, as in the case of IC711, presumably to be identified with the nucleus. Stretching  $> 1'$  to the west of the nucleus are two well resolved strands, implying that IC708 is also a 'head-tail' galaxy. There is no reason to believe that the fourth component,  $\sim 1'$  of the nucleus, is physically related to IC708. The nuclear source is weakly (three times r.m.s. noise) linearly polarised (see Table 3).

## Discussion

Our observations of IC708 and IC711 are consistent with the 'radio trail' model in its general form<sup>2</sup>. The observations at  $\lambda = 6$  cm show the two galaxies to be active, implying that the nucleus is the supplier of energy in both cases, as is known to occur in 'normal' radio galaxies. The source morphologies strongly suggest a radio trail, particularly for IC708. A more careful scrutiny of the properties of IC711, however, reveals a difficulty with the simple models developed by Jaffe and Perola<sup>3</sup>. This problem centres around the large size of the source, an aspect we now discuss.

**Fig. 3** A contour map of the brightness (total intensity) distribution in IC708 at  $\lambda = 6$  cm and resolution  $6'' \times 8''$ , superimposed on the blue Palomar Sky Survey print. The half-power beam width is shown by the ellipse in the bottom right hand corner, and contour values are: 2.5, 5, 7.5, 10, 25, 50, 75 and 100 mJy (beam area) $^{-1}$ .

In both the 'independent blob' model and the 'magnetospheric' model, the relativistic electrons are envisaged to be accelerated within the optical galaxy rather than in the tail itself. We now show that severe difficulties result from this assumption in the case of IC711. An electron radiating at  $\lambda = 49$  cm in a typical equipartition magnetic field in the tail of  $4 \times 10^{-6}$  gauss has a half life to synchrotron radiation and to inverse Compton losses on the microwave background of  $t_{1/2} = 9 \times 10^7$  yr. Writing  $L$  = length of tail = 820 kpc, the average velocity of propagation  $V$  of such electrons with respect to the galaxy must be  $\geq L/t_{1/2} = 8,600$  km s $^{-1}$ , if they are accelerated within the galaxy. In the 'independent blob' model, the maximum possible  $V$  is simply the velocity of the galaxy with respect to the intracluster gas  $V_g$  (since ram pressure eventually brings the plasmoids to rest), which, if the galaxy is a member of the cluster, is surely much smaller than the above value. The value of  $V$  appropriate for the 'magnetospheric' model is less obvious since, although it is to be expected that the relativistic particles propagate through the thermal gas at about the Alfvén speed  $V_a$  (refs 17 and 18), the velocity of the thermal plasma in the

tail  $V_t$  with respect to the galaxy is unknown. Jaffe and Perola took  $V_t = V_g$ , so the maximum possible is  $V = V_g + V_a$ . The assumption  $V_g \ll 8,600 \text{ km s}^{-1}$  then implies  $V_a \geq 8,600 \text{ km s}^{-1}$ , that is, a thermal particle density  $\rho \leq 2 \times 10^{-30} \text{ g cm}^{-3}$ . Implicit in the 'magnetospheric' model is a rather uniform magnetic field aligned along the tail, and, with such a low gas density, appreciable polarisation could be expected at  $\lambda = 49$

duration of past activity in IC711 itself, presuming the intra-cluster gas to have a distribution similar to that of the galaxies. The much shorter length of the tail of IC708 could be accounted for if it has just entered the western edge of the dense gas. The apparent expansion of the two strands of IC708 near RA = 11 h 31 min 11 s (see Fig. 3) is indeed suggestive of a reduced gas density there.

Table 3 Some data on IC711 and IC708

Source parameter	IC711	IC708
Positions (1950.0): radio nucleus	RA = 11 h 32 m 03.90 $\pm$ 0.05 s dec. = 49° 13' 57.8 $\pm$ 0.6''	RA = 11 h 31 m 16.27 $\pm$ 0.05 s dec. = 49° 20' 19.3 $\pm$ 0.6''
centroid of optical galaxy*	RA = 11 h 32 m 03.95 $\pm$ 0.1 s dec. = 49° 13' 56.5 $\pm$ 1.0''	RA = 11 h 31 m 16.36 $\pm$ 0.1 s dec. = 49° 20' 18.1 $\pm$ 1.0''
Visual magnitude	14.8	14.4
Angular size of galaxy-tail at $\lambda = 49 \text{ cm}$ (arc min)	15	1.5
Corresponding linear size in plane of sky at $\lambda = 49 \text{ cm}$ (kpc)†	820	80
Linear size of nucleus (FWHM) at $\lambda = 6 \text{ cm}$ (kpc)‡	< 3	< 3
Flux densities (mJy): total, $\lambda = 49 \text{ cm}$	1,047 $\pm$ 100	1,432 $\pm$ 70§
nucleus, $\lambda = 6 \text{ cm}$	44 $\pm$ 3	114 $\pm$ 5
Linear polarisation of nucleus: percentage (%) at $\lambda = 6 \text{ cm}$	< 6	3.6 $\pm$ 1.2 (r.m.s.)
position angle (°) at $\lambda = 6 \text{ cm}$	—	134 $\pm$ 10
Power at $\lambda = 49 \text{ cm}$ (W Hz <sup>-1</sup> )†	$5 \times 10^{24}$	$7 \times 10^{24}$
Radio luminosity (W)†	$5 \times 10^{34}$	$8 \times 10^{34}$
Minimum energy in tail (erg)‡	$5 \times 10^{58}$	$1 \times 10^{58}$
Equipartition magnetic field in tail (gauss)‡	(2–6) $\times 10^{-6}$	$7 \times 10^{-6}$

\*Measured from the blue Palomar Sky Survey print with the 'Coradigraph' measuring machine at the Royal Greenwich Observatory.

†Assuming  $H_0 = 50 \text{ km s}^{-1} \text{ Mpc}^{-1}$ , deceleration parameter  $q_0 = 1$ , and a radio window extending from 10 MHz to 100,000 MHz.

‡Minimum energy estimates have been made assuming the total energy in cosmic ray protons to be equal to that of the electrons.

§Preliminary results at  $\lambda = 21 \text{ cm}$ , when combined with those at  $\lambda = 6 \text{ cm}$ , indicate that the background source 1' to the south of the nucleus of IC708 (see Fig. 3) has a spectral index  $\alpha = -0.6 \pm 0.1$ . Extrapolation of this spectrum to  $\lambda = 49 \text{ cm}$  yields  $S_{49\text{cm}} = 55 \text{ mJy}$ . The flux quoted for IC708 represents the flux of the whole source on the  $\lambda = 49 \text{ cm}$  map minus the above flux of the background source.

cm, since the Faraday rotation would be very low. Our data, however, show the tail of IC711 to be < 3% linearly polarised at  $\lambda = 49 \text{ cm}$  in the brighter parts. Of course, a more random magnetic field could account for the lack of polarisation, but in that case relativistic electrons should diffuse down the tail more slowly. These arguments suggest that the relativistic electrons radiating at  $\lambda = 49 \text{ cm}$  can probably not propagate from the nucleus to the end of the tail in the face of the energy losses. This conclusion is true *a fortiori* if the tail does not lie in the plane of the sky, if the magnetic field is stronger or weaker than the assumed equipartition value, or if adiabatic losses are also included. Our discussion implies, therefore, that the relativistic particles may be reaccelerated within the tail of IC711 itself, or somehow replenished from the intracluster medium. The latter possibility has been proposed by W. A. Christiansen (personal communication).

The size of IC711 and IC708 visible on the Palomar Sky Survey red print are at least 25'' and 65'' respectively. Examination of Figs 2 and 3 shows that the radio-emitting plasmoids are already swept back when < 10'' from the nuclei, well within the optical extents. A similar conclusion may be drawn from the  $\lambda = 6 \text{ cm}$  map of NGC1265 (ref. 7), and constitutes rather direct evidence that the intracluster gas blows through the galaxies, probably sweeping out any pre-existing gas, as has been proposed on theoretical grounds<sup>19</sup>. This conclusion depends only on the validity of the 'radio trail' hypothesis in its most general form.

The size (FWHM) of the distribution of optical galaxies in Abell 1314 is, after correction for the background galaxies,  $\sim 20'$  and  $15'$  in RA and dec. respectively. The latter value is close to the length of the tail of IC711, and we speculate that the extent of its radio trail is determined by the scale of the intra-cluster gas necessary to contain the plasmoids, rather than the

It is intriguing to note the change in position angle of elongation in the tail of IC711 at dec. = 49° 22', quite near IC708. There is, however, no definite evidence for any interaction between the two sources, and the peculiar morphology of IC711 could be accounted for in terms of projection effects, an elliptical orbit through the cluster being viewed obliquely.

We thank our colleagues in Leiden for discussions and E. B. Clements for assistance in measuring optical positions. We were supported by postdoctoral research fellowships from the National Research Council of Canada (J.P.V.) and the Royal Society European Programme (A.S.W.). The Westerbork Synthesis Radio Telescope is operated by the Netherlands Foundation for Radio Astronomy with the financial support of the Netherlands Organisation for Pure Research (ZWO).

# T4 gene 32 protein model for control of activity at replication fork

Herbert Moise & Junko Hosoda

Space Sciences Laboratory, University of California, Berkeley, California 94720

*Limited hydrolysis of gene 32 protein by various proteinases results in the production of three stable cleavage products. Two of these products show an affinity for native T4 DNA cellulose that the uncleaved protein does not exhibit. A model for proteolytic cleavage and for the local unwinding of DNA in advance of the replication fork is discussed in terms of this unusual binding affinity.*

GENE 32 protein (P32) of bacteriophage T4, isolated and characterised by Alberts *et al.*<sup>1</sup>, is essential for DNA replication<sup>2</sup> and recombination<sup>3,4</sup>. It has the unique ability to convert duplex DNA to single strands at a temperature that is 40 °C below the melting temperature ( $T_m$ ) of the DNA and is therefore thought to be responsible for local unwinding of duplex DNA in advance of the replicating fork. This ability to denature duplex DNA results from strong cooperative binding of P32 to single strands with little or no binding to double-stranded regions. Preferential binding of P32 to single strands, besides melting the duplex, has the reverse effect of facilitating base-pair alignment between single strands. Presented with single-stranded DNA, P32 induces a chain conformation (in the DNA) which increases the reannealing rate of homologous strands, a reaction which might be important to recombination.

Direction of the reaction denaturation $\longleftrightarrow$ renaturation in the presence of P32 depends on stability of the duplex. At levels of ionic strength and  $Mg^{2+}$  concentration presumed to be present *in vivo*, the  $T_m$  of T4 DNA would be about 85 °C and at physiological temperatures the presence of P32 alone would be inadequate to keep the duplex apart in advance of the moving replication fork.

A protein of molecular weight 27,000, which copurified with P32 (35,000) has been shown to denature T4 DNA and bind cooperatively to the denatured DNA. In the same conditions P32 could do neither<sup>5</sup>. This protein was named P32\* because it was derived from P32. Here, we show that production of P32\* is the result of a protease contaminant introduced during purification and that treatment of P32 with chymotrypsin, trypsin or pepsin, each produces P32\*-like molecules (27,000) and two other partial hydrolysates (34,000 and 26,000). We tested the binding of these limited hydrolysis products to single- and double-stranded DNA and found different combinations of affinities for each. A possible relationship between proteolysis and the binding/denaturing abilities of these products is discussed in terms of a model of reversible denaturation of duplex DNA.

## Origin of proteolytic activity in purified P32 preparations

On storage of purified P32 at 4 °C, a second component of lighter molecular weight (27,000) increased at the expense of P32 (ref. 5). This suggested that a protease

contaminant had copurified with P32 and was slowly producing P32\* from P32 by limited hydrolysis.

Three possible sources of proteolytic contamination were examined: a protease from *Escherichia coli*, a T4-induced protease, or contamination of pancreatic DNase I used during the preparation of cell extracts from which P32 was purified. T4 is known to induce a proteolytic activity related to processing of its head precursor proteins. This activity is present in lysates from some head negative (gene 23) mutant-infected cells and is absent in gene 21 mutant-infected cells<sup>6</sup>.

Purified <sup>35</sup>S-labelled P32 was treated with cell extracts from: *E. coli* cells infected with a gene 23 mutant (*amB17*); *E. coli* cells infected with a gene 21 mutant (*amN90*); uninfected *E. coli* cells; or a solution of pancreatic DNase I. Results are shown in Fig. 1; only the DNase solution produced any appreciable amount of proteolysis as judged by a decrease in molecular weight after 1 h incubation at 37 °C.

Commercially available DNase is known to be contaminated with chymotrypsinogen B (ref. 7). Purification of the DNase to remove chymotrypsinogen B (ref. 7) before preparation of cell extracts resulted in isolation of P32 with a greatly reduced amount of copurifying P32\*. Incubation of purified <sup>35</sup>S-labelled P32 with DNase pretreated with tosyl-phenylalanyl-chloromethyl-ketone (TPCK) caused substantial reduction in the amount of hydrolysis products formed. Therefore it seems likely that hydrolysis of a trace amount of chymotrypsinogen B to chymotrypsin B was mainly responsible for the P32\* found in aged P32 preparations.

## Limited hydrolysis of P32 with known proteinases

Having established that production of P32\* resulted from protease contamination, we decided to try and produce P32\* from P32 by proteolysis with known proteinases. If this could be done then we could design and undertake experiments to determine why P32\* is able to denature T4 DNA and P32 cannot.

Treatment of P32 with three proteinases, bovine- $\alpha$ -chymotrypsin, bovine trypsin, and bovine pepsin in varying conditions (substrate concentration 0.2 or 0.86 mg ml<sup>-1</sup>; enzyme concentration 0.1–100  $\mu$ g ml<sup>-1</sup>; temperature 4 or 37 °C; reaction time 1 h at pH 8.1) produced three products: P32\*-I, -II and -III with molecular weights of 27,000, 34,000 and 26,000 respectively (for mechanism, see discussion under model for proteolysis). Conditions needed to reach a specific stage of hydrolysis differed with enzyme used but there was a definite order of appearance and disappearance of the three products. This order together with the position of each product after electrophoresis in SDS gels (12.5% acrylamide) is presented in Fig. 2.

In general, in the mildest conditions, P32\*-I, a molecule with the same mobility as that of P32\* appeared. With increasing enzyme concentrations two new products,

**Fig. 1** Autoradiogram of  $^{35}\text{S}$ -labelled gene 32 protein analysed on SDS gels. P32 treated with: *a*, T4 *amb17* (gene 23)-infected *E. coli* cell extract; *b*, *ambN90* (gene 21)-infected cell extract; *c*, uninfected cell extract; *d*,  $100\ \mu\text{g ml}^{-1}$  pancreatic DNase I (Worthington); *e*, untreated control. Markings with corresponding numbers along left-hand side denote position and molecular weight ( $\times 10^3$ ) of reference proteins marked with radioactive ink before autoradiograms were taken. 68, bovine serum albumin; 40, ovalbumin; 25, chymotrypsinogen; 17, myoglobin; and 12.5, cytochrome *c*. Treatment of  $^{35}\text{S}$ -labelled P32 with cell extracts:  $^{35}\text{S}$ -P32 was added to the cell extracts to give a final concentration of  $200\ \mu\text{g } 2.5 \times 10^5\ \text{c.p.m. ml}^{-1}$ . After incubation of protein with cell extracts for 1 h at  $37^\circ\text{C}$ , an equal volume of SDS sample buffer ( $0.125\ \text{M}$  Tris-HCl, pH 6.8, 10% 2-mercaptoethanol, 4% SDS $^{12}$ ) added and mixture frozen until SDS gel electrophoresis. SDS gel electrophoresis: Proteins were analysed on 12.5% polyacrylamide slab gels $^{13}$  containing 0.1% SDS using a discontinuous buffer system $^{12}$ . Proteins, in sample buffer, were denatured by heating samples in boiling water for 2 min. Samples were loaded on to gels and electrophoresis carried out at a constant current of 15 mA for 4 h. Gels were fixed in 30% TCA, stained with 0.1% Coomassie blue in 30% TCA, and destained in 7.5% acetic acid. Gels were dried and autoradiograms taken.  $^{35}\text{S}$ -labelled P32 preparations: *E. coli* B $^{\text{F}}$  grown to  $4 \times 10^8\ \text{cells ml}^{-1}$  in 200 ml low sulphate M9 medium (sulphate concentration  $5 \times 10^{-5}\ \text{M}$ ) was infected; after 8 min superinfected for a total multiplicity of ten, with T4 *amb17*292 (gene 55) a mutant which overproduces P32 (ref. 15). At 10 min  $^{35}\text{S}$ -sulphate (final concentration  $30\ \mu\text{Ci ml}^{-1}$ ) was added. After 90 min cells were collected and frozen. Purification of  $^{35}\text{S}$ -P32 was same as for non-radioactive P32, except DEAE-cellulose chromatography omitted. Non-radioactive P32 added to final concentration  $200\ \mu\text{g ml}^{-1}$  to act as carrier. Non-radioactive P32 preparations: *E. coli* B $^{\text{F}}$  grown to  $4 \times 10^8\ \text{cells ml}^{-1}$  in M9A medium was infected as described above. After 90 min cells collected and frozen until needed. Purification of P32 as described previously $^1$ ; 50 g cells yielded about 35 mg purified P32. Undigested P32 (both radioactive and non-radioactive) used in this experiment and those in Fig. 3 contained a small amount of P32\* and three additional bands between the position of P32\*-II and P32\*-I (see text). These three minor components were absent when P32 was prepared using DNase pretreated with diisopropylfluorophosphate (DFP) followed by hydroxylapatite column chromatography to remove contaminating chymotrypsin B (ref. 7); therefore, they probably are intermediates of P32 digestion by chymotrypsin B to produce P32\*. Cell extracts: Cultures (100 ml) *E. coli* B $^{\text{F}}$  in M9A medium grown at  $37^\circ\text{C}$  to  $5 \times 10^8\ \text{cells ml}^{-1}$  infected with T4 *amb17* (gene 23) or *ambN90* (gene 21) and superinfected 5 min later for a total multiplicity of eight. Cells collected by low speed centrifugation 30 min after infection. Cell pellets suspended in 5 ml sonication buffer $^1$  and sonicated. After high speed centrifugation to remove cell debris, supernatants used to treat  $^{35}\text{S}$ -P32. Uninfected cell extract prepared in same way.

P32\*-II and -III appeared. (The position of P32\*-II after electrophoresis in SDS gels was too close to that of P32 to detect a small amount of P32\*-II in the presence of a large excess of P32. Therefore, the fact that P32\*-I was seen first does not mean that P32\*-II was produced after P32\*-I, but rather P32\*-II was not seen until the amount of P32 was reduced.) With further increases in enzyme concentration and/or reaction temperature, P32 then P32\*-II and then P32\*-I disappeared. Several examples showing each stage of hydrolysis are presented in Fig. 3.

Pepsin was least efficient of the three proteinases probably because it was used at a suboptimal pH;  $1\ \mu\text{g ml}^{-1}$  was

required to produce a small amount of P32\*-I (column 2, Fig. 3). With higher concentrations of pepsin, stage *c* (Fig. 2) hydrolysis was reached but hydrolysis did not proceed beyond this point. Chymotrypsin with an activity midway between that of pepsin and trypsin produced any stage of hydrolysis indicated in Fig. 2 with  $1\ \mu\text{g ml}^{-1}$  producing stage *c* as shown in column 4 of Fig. 3. Trypsin, with the strongest proteolytic activity of the three proteinases, produced stage *c* and stage *d* hydrolysis at concentrations of  $0.1$  and  $1\ \mu\text{g ml}^{-1}$ , respectively. Chymotrypsin and trypsin at concentrations higher than  $10\ \mu\text{g ml}^{-1}$  and at  $37^\circ\text{C}$  were able to digest P32\*-III to even shorter peptide fragments.

### Affinity of proteolysis products of P32 for single-stranded DNA-cellulose

Affinity of the limited hydrolysis products for single-stranded DNA was examined by chromatography on single-stranded (calf thymus) DNA-cellulose columns. Limited digests containing all four components (P32, P32\*-I, -II and -III) in  $50\ \text{mM}$  NaCl were loaded on columns of single-stranded DNA-cellulose and eluted off with increasing concentrations of NaCl (Table 1). Regardless of which proteinase was used for digestion, products with the same molecular weights behaved the same way. All four species adsorbed at  $50\ \text{mM}$  NaCl. Both P32 and P32\*-I showed strong binding to the single-stranded DNA with elution of either requiring a concentration of NaCl higher than  $0.6\ \text{M}$ . On the other hand both P32\*-II and P32\*-III showed a drastic loss of affinity as both eluted off the column with  $0.4\ \text{M}$  NaCl.

### Affinity of chymotrypsin-digested products for native T4 DNA-cellulose

It has been shown that P32\* can denature T4 DNA $^5$ . P32\* bound strongly to duplex T4 DNA-cellulose, whereas P32 did not (J. H. and C. Brack, unpublished). Presumably P32\* is also able to denature duplex T4 DNA bound to cellulose and then bind to single-stranded regions. Binding of P32 and the limited hydrolysis products of chymotrypsin digestion to native T4 DNA-cellulose was examined to see if the products showed affinity to T4 DNA-cellulose as P32\* did. Chymotrypsin was used because its activity is midway between that of trypsin and pepsin (Fig. 3). Digests containing all four components were loaded on to columns of T4 DNA-cellulose in  $5$  or  $25\ \text{mM}$  NaCl at  $4$  or  $20^\circ\text{C}$ . Results are summarised in Table 1b. In these conditions neither P32 nor P32\*-II showed any binding to T4 DNA-cellulose. P32\*-I and P32\*-III both bound in the four sets

**Fig. 2** Diagrammatic representation of position of limited hydrolysates produced by chymotrypsin, trypsin or pepsin, after electrophoresis on SDS gels. *a*, Untreated P32; *b-e*, limited proteolysis products with increasing enzyme substrate ratio or with increase of reaction temperature.

of conditions listed above. P32\*-III eluted at NaCl concentrations of 0.1–0.2 M. P32\*-I had stronger binding, as a NaCl concentration of 0.4 M was necessary for elution. This strong binding of P32\*-I is similar to the binding reported earlier for P32\* (ref. 5). The implication is that P32\*-I is capable of denaturing T4 DNA and binding cooperatively to it. The weaker binding of P32\*-III suggests that it is binding in a different manner from P32\* or P32\*-I.

### Model for limited proteolysis (Fig. 4)

Regardless of proteinases used the products were indistinguishable by SDS gel electrophoresis and chromatography of DNA-cellulose, yet these proteinases each have a different specificity for the bond they hydrolyse: trypsin is specific for the carboxyl group of lysyl and arginyl residues; chymotrypsin for the carboxyl group of tryptophanyl, phenylalanyl and tyrosyl residues; pepsin for the carboxyl group of tryptophanyl, phenylalanyl, tyrosyl, methionyl, and leucyl residues. Therefore, we propose that because of the three-dimensional structure of the native P32 molecule there are only two regions exposed to proteinase attack. Both of these regions contain one or more of the bonds specific to their respective proteinase and these bonds are proximal to one another.

Proteolysis within one of the two regions removes a peptide (or peptides) of molecular weight 8,000 to produce P32\*-I. We call it A peptide for simplicity, until further investigation can establish whether one or more than one peptides are removed. P32\*-I produced by chymotrypsin cannot be exactly the same as P32\*-I produced by trypsin. Their molecular weights and their DNA-cellulose-binding properties, however, are close enough so that they are indistinguishable on SDS gel electrophoresis or DNA-cellulose column chromatography. Similarly, proteolysis within the other region removes a peptide (or peptides) of molecular weight approximately 1,000 (B peptide) to create P32\*-II. Hydrolysis at both regions, to remove A and B peptides, produces P32\*-III. Loss of A peptide did not decrease affinity to single-stranded DNA. It did, however, increase affinity to duplex (T4) DNA in both P32\*-I and P32\*-III. Removal of B peptide resulted in decreased affinity for single-stranded DNA-cellulose. Removal of both A and B peptides, as in P32\*-III, resulted in decreased

Fig. 3 Autoradiogram showing position of  $^{35}\text{S}$ -labelled P32 limited hydrolysates after electrophoresis. *a*, Column 1, untreated P32; column 2, P32 treated with  $1\text{ }\mu\text{g ml}^{-1}$  pepsin; *b*, column 3, untreated P32; column 4, P32 treated with  $1\text{ }\mu\text{g ml}^{-1}$  chymotrypsin; *c*, column 5, untreated P32; column 6, P32 treated with  $0.1\text{ }\mu\text{g ml}^{-1}$  trypsin (TPCK-treated); column 7, P32 treated with  $1\text{ }\mu\text{g ml}^{-1}$  trypsin. Digestion was in sonication buffer<sup>1</sup> at  $4^\circ\text{C}$  for 1 h. Equal volume SDS sample buffer added and samples heated in boiling water for 2 min before electrophoresis. For preparation of  $^{35}\text{S}$ -labelled P32 and electrophoresis, see Fig. 1.

affinity for single-stranded DNA but increased affinity for duplex DNA.

### Model for control of P32 activity at replication fork

Both DNA replication and recombination, in which gene 32 participates, are extremely complex reactions involving a multitude of different proteins. In such systems, it is probable that proteins function as complexes and that protein-protein interactions are the major factor in control of each component's activity.

Efforts to reconstruct the T4 DNA replication apparatus from purified components have been successful<sup>8</sup>. This system requires six T4 gene products (32, 41, 43, 44, 45, and 62) all of which are necessary for *in vivo* replication. Isolation and purification of these six has been accomplished. Because components interact synergistically with one another they probably form a complex of unique structure. This complex has a propagation reaction *in vitro* which closely mimics that found *in vivo*. All six must be present *in vitro* for extensive synthesis by strand displacement on duplex DNA templates (leading strand synthesis) and for *de novo* DNA chain initiation on single-stranded DNA templates (lagging strand synthesis), even though the individual components may not have the same activity (or any activity at all) outside the complex<sup>8</sup>.

Table 1 Column chromatography of P32 and its limited proteolysis products on DNA-cellulose

Protein	Molecular weight ( $\times 10^{-3}$ )	Expt <i>a</i> —Chromatography on denatured DNA-cellulose				Expt <i>b</i> <sup>†</sup> —Chromatography on native DNA-cellulose				
		NaCl* (M)	Adsorption		Elution		Adsorption	Elution		
			0.05	0.4	0.60	2.0		0.005 or 0.025	0.1	0.2
P32	35		+	—	—(†)	+	—	—	—	—
P32*-I	27		+	—	—(†)	+	+	—	—(†)	+
P32*-II	34		+	+	—	—	—	—	—	—
P32*-III	26		+	+	—	—	+	+	—	—

\* In buffer *b*: 20 mM Tris-HCl, pH 8.1, 1 mM  $\text{Na}_3\text{EDTA}$ , 1 mM  $\beta$ -mercaptoethanol and 10% glycerol.

† A small fraction occasionally eluted at this concentration.

‡ T4 DNA-cellulose was irradiated with ultraviolet light<sup>17</sup>. Unirradiated T4 DNA-cellulose gave similar results (J.H. and C. Brack, unpublished).

$^{35}\text{S}$ -labelled P32 ( $0.84\text{ mg}$ ,  $2.4 \times 10^5\text{ c.p.m. ml}^{-1}$ ) in buffer *b* was treated with  $1\text{ }\mu\text{g ml}^{-1}$  (freshly dissolved) enzyme at  $4^\circ\text{C}$  for 1 h. Either TPCK ( $10^{-3}\text{ M}$ ), for chymotrypsin-treated samples, or tosyl-lysyl-chloromethyl-ketone (TLCK,  $10^{-3}\text{ M}$ ), for trypsin-treated samples, was added. After 15 min more incubation to allow time for complete proteinase inhibition, solution was loaded on DNA-cellulose column. Experiment *a* combined results of four separate single-stranded calf thymus DNA-cellulose columns<sup>16</sup>, all run at the same time. Products for each column were produced by different proteases—trypsin, chymotrypsin or pepsin. Digests containing 0.05 M NaCl were applied, columns were washed with 2 ml 0.05 M NaCl and proteins eluted off with 1 ml each of following concentrations NaCl: 0.4, 0.60 and 2.0 M. Each fraction (0.5 ml) was monitored for radioactivity, and analysed on SDS gel electrophoresis. Experiment *b* combined results of chromatography of limited hydrolysis products of chymotrypsin on four separate native T4 DNA-cellulose columns (ultraviolet-irradiated<sup>17</sup>). Columns were loaded at  $5^\circ\text{C}$  or  $20^\circ\text{C}$  with digests containing either 0.005 or 0.025 M NaCl. Proteins were eluted with following concentrations NaCl: 0.1, 0.15, 0.2, 0.4 and 0.60 M. (In all four cases products with the same molecular weight behaved the same way, regardless of loading temperature or NaCl concentration.)

Fig. 4 Model for limited proteolysis of P32.

Two types of protein-protein interaction have been reported for P32; intra-action, that is, self-association; interaction, that is, an affinity for T4 DNA polymerase<sup>5</sup>. Self-association, as first described, was regarded as related to the cooperative binding of P32 to DNA<sup>1</sup>. Affinity for T4 DNA polymerase is related to P32 stimulation of polymerase activity<sup>6</sup>. When P32 molecules are within the replication machinery, there would undoubtedly be greater probability of increasingly complex intra- and interactions.

High susceptibility of A and B peptides to hydrolysis by various proteinases implies that these peptides are easily accessible to other proteins. Removal of either or both resulted in modification of the binding characteristics. Based on the data presented in this report, we suggest that A and B peptides are involved in protein-protein interactions and through such interactions the activity of P32, *in vivo*, is controlled.

With the removal of A peptide, affinity of P32\*-I and P32\*-III for duplex T4 DNA is greatly increased. This suggests that A peptide might be involved with the DNA-binding site in that its presence or absence greatly influences denaturing ability of the protein.

This involvement could be a direct spatial relationship to the DNA-binding site. It could also be that the interaction of A peptide with another protein leads to a conformational change in P32 resulting in a change in binding ability. It may be that, *in vivo*, A peptide limits the mode of action of P32 to that of a renaturing protein. This could have profound biological significance because the presence of too strong a denaturing protein could cause disastrous uncontrolled melting of the chromosome.

Based on this consideration we developed the following model: The role of A peptide is to localise unwinding of duplex DNA in advance of the replication fork (or within the replication complex) as shown in Fig. 5. P32, *in vivo*, acts in a renaturing or denaturing mode as regulated by A peptide and the environment in which A peptide is

placed. When P32 is outside the replication complex, A peptide exerts an inhibitory influence on denaturing, and P32 reacts in a renaturing mode. Proteolytic removal of A peptide *in vitro* produces P32\*-I with more potent denaturing activity than the original P32. In theory, the same, or even stronger, activity could be reversibly produced *in vivo* by the interaction of A peptide with the replication complex, which generates an environment in which denaturation of the duplex DNA should take place.

We have adopted part of a published model of self-association of P32 as follows: P32 dimer is the basic DNA binding unit in physiological conditions; the dimers insert themselves between two strands and bind to the phosphodeoxyribose backbone holding the bases in an outward position<sup>18</sup>. The advantage of this model is that with the bases held partially separated from each other, they are free to hydrogen bond with the incoming nucleotide precursors. After the replication complex (engaged in leading strand synthesis) has passed over the P32 molecules, which have been holding the duplex DNA apart, A peptide no longer interacts with the replication complex and again asserts its inhibitory influence. Thus P32 no longer prevents hydrogen bonding between the newly made leading strand and its template. P32 remains bound to the opposite strand (Fig. 5) which then acts as the template for lagging strand synthesis. P32 is required for lagging strand synthesis, and it does not fall off the single strands until lagging strand synthesis takes place.

Our data have shown that B peptide is involved in the tight binding of P32 to single-stranded DNA. There could be at least three different reasons for this: P32 has more than one DNA-binding site and B peptide contains some of them; loss of B peptide induces a conformational change unfavourable to tight binding; or B peptide is related to the cooperativity of self-association of P32.

Extensive studies of self-association by sedimentation equilibrium has led to the proposal that there are at least two types of self-association: association to dimers, which are resistant to high salt concentration and the presence of  $Mg^{2+}$  and association of these dimers to higher molecular weight aggregates in conditions of low ionic strength and high protein concentration<sup>10,11</sup>. An earlier model suggested that in physiological conditions P32 exists as dimers and association of these dimers is related to cooperative binding<sup>19</sup>. In a later model this idea was modified to suggest that binding to DNA occurs after P32 has aggregated to a higher molecular weight species<sup>11</sup>. In our more dynamic model (Fig. 5) the change of P32 to a stronger denaturing protein could include increased affinity between dimers. This would result in a contiguous binding site at the front of the replication complex, attractive to dimer-unit binding.

# Body weight, diet and home range area in primates

Katharine Milton

Michael L. May\*

Department of Zoology, University of Florida, Gainesville, Florida 32601

*Primates show a strong positive relationship between body weight and home range area. Dietary habits also influence home range area. Folivorous primates occupy smaller home range areas for their body weight than do frugivores and omnivores. Primates generally require smaller home range area per individual than solitary terrestrial mammals, but primates living in social groups have much larger total home range than individual solitary mammals. This trend may necessitate higher expenditures of energy in food-gathering or modifications in movement patterns.*

NUMEROUS studies during the past decade have shed light on relationships between various aspects of primate ecology<sup>1-5</sup>, but as yet there has been no quantitative summary of data on home range area of primates that takes into account the effects on spatial needs of both body size and diet. A strong positive relationship exists between body weight and home range area in lizards<sup>6</sup>, birds<sup>7,8</sup> and solitary mammals<sup>9</sup>, while McNab<sup>9</sup> showed for mammals and Schoener<sup>8</sup> for birds that feeding habits also have a predictable effect on the home range area of many species. Clutton-Brock<sup>10</sup> pointed out that rather small differences in feeding ecology may affect markedly the ranging patterns of primates. Here we analyse data on the body weight, diet and home range area of 36 primate species, and demonstrate a relationship among these variables.

The home range data in this paper are taken from diverse sources and are undoubtedly not perfectly comparable (Table 1). Most body weights were obtained by averaging adult male and adult female body weights, and thus do not take into account interspecies differences in sociometric sex ratio or the fact that many group members may be subadult. Average weights in general are probably overestimated, particularly in the case of large terrestrial omnivores like the baboon (*Papio*), in which sexual dimorphism is marked. For most species, however, sufficient data are not available, either on group composition or weight variation with age and sex, to permit calculation of more accurate average weights. In addition, rather large (for example, twofold) errors in estimating body weight will cause a shift in log weight of < 10% of the entire range of data. We believe that errors introduced by differences in techniques of home-range estimation and those resulting from inaccuracies in calculating weight are not sufficient to be critical to our general conclusions.

Diet was determined from the sources of home-range information whenever possible, supplemented by material summarised by Jolly<sup>3</sup> and Kay<sup>11</sup>. We classify as folivores those species that seem to depend on foliage, mature or immature, as their staple diet. Frugivores are primarily fruit eaters, taking only a small amount of foliage and little or no animal protein. Species eating roughly equal proportions of both foliage and fruit and little or no animal protein are classified as generalist primary consumers, and those which seem to actively seek out and probably to depend on animal protein in the diet are

classified as omnivores. Obviously there are degrees of folivory\* frugivory and omnivory and no category should be regarded as definitive; they are our best estimate of the dietary preferences of individual species. Terrestriality and arboreality, too, are points on a continuum, and assignments should not be regarded as absolute. Generally, unless a species is known to consistently travel or forage on the ground each day, we considered it arboreal.

Regressions of  $\log_{10}(\text{home range})$  on  $\log_{10}(\text{body weight})$  were fitted by the method of least squares. Significance of the regressions was determined by calculating Student's *t*-statistic for the deviation from zero of the slopes. Our criterion for significance is the 0.05 level of probability. Spearman rank correlation coefficients *r* for the untransformed data served as an additional confirmation of correlation between variables. The tests were in agreement in all cases.

## Individual home range allocation

Figure 1 shows home range area divided by the number of individuals per group ( $HR_i$ ) as a function of body weight. The species are listed in Table 1. There is a strong positive relationship between body weight and home range area in primates ( $r^2 = 0.44$ ;  $t = 5.14$ ,  $P < 0.005$ ). The slope of the regression line is 0.79, compared with 0.63 found by McNab<sup>9</sup> for temperate-zone solitary terrestrial mammals. The figure also shows each species placed in one of the four dietary categories. The more folivorous primates show a strong tendency toward a smaller  $HR_i$  than the frugivorous and omnivorous species. Eight of twelve terrestrial primates have a larger  $HR_i$  than might be expected for their weight, whereas arboreal primates show a wider scatter both above and below the regression line.

McNab divided mammals on the basis of food habits into 'hunters' (discrete particle feeders, for example, granivores, frugivores, insectivores, carnivores) and 'croppers' (browsers and grazers). Frugivorous and omnivorous primates resemble McNab's hunters in feeding habits, whereas the folivores are more like his croppers. Figure 2 shows primates grouped as hunters (frugivores and omnivores) or croppers (folivores), compared with relationships predicted by McNab for hunters and croppers. Generalist primary consumers are not considered in this comparison because they are not readily assigned to either category, and because the small sample size and weight range involved severely limits the value of any statistical treatment. The trend in this group seems, however, to resemble that among croppers more than hunters.

Both of the subgroups considered show stronger relationships between body weight and  $HR_i$  than do primates in general (for primate hunters,  $r^2 = 0.66$ , for croppers  $r^2 = 0.49$ ). The slope of the primate hunter line, 0.83, is close to that calculated for hunters by McNab, although the expected values are only about half those predicted by McNab. The slope of the line for primate croppers is 1.06, steeper than that of McNab's cropper line or the primate hunter line but not significantly different from either. Analysis of covariance of  $\log HR_i$  with feeding category and body weight for primate hunters and croppers using a randomised groups design<sup>12</sup>, shows that adjusted group means are significantly different ( $F = 69.1$ ,  $P < 0.01$ ), with croppers having substantially smaller home ranges. Primate

\* Present address: Department of Physiology and Biophysics, University of Illinois, Urbana, Illinois 61801.

croppers also tend to occupy smaller  $HR_i$  than do solitary, non-primate croppers up to  $\sim 2 \times 10^4$  g.

Values of  $HR_i$  should give some idea of the relative amount of space required to provide adequate resources for individuals of a species. What factors determine  $HR_i$ ? Clearly body size is very important; once this has been accounted for other influences become more apparent. Folivory is associated with allocation of relatively small areas per individual in arboreal primates. Most of these animals are at least partially croppers in the sense of McNab<sup>9</sup>, and are likely to have concentrated resources available. Also, the height of the tree canopy may have an especially marked effect on the size of the home range of leaf eaters. This third dimension adds to the density of resources per unit area and to the actual distance travelled in space per unit area<sup>13-15</sup>. In addition, McNab has recently suggested (personal communication) that rates of metabolism of arboreal folivorous mammals may be below those expected for mammals in general, so conceivably the energy requirements

of many folivorous primates are relatively low. All of these explanations; however, entail difficulties, some of which are discussed below.

Frugivores tend to have larger  $HR_i$  than folivores. Typical tropical forests are highly heterogeneous in species composition<sup>16-18</sup>. Fruiting trees are often widely dispersed in time and space. Thus most frugivores depend on clumped, unstable food sources, a resource pattern which has been associated with a relatively large home range area<sup>10</sup>. Also, there is some reason to suspect that frugivory is correlated with high rates of metabolism<sup>19</sup>.

Among generalist primary consumers  $HR_i$  may vary with the proportion of fruit and leaves eaten. For example, in Guanacaste, Costa Rica, where it feeds  $\sim 85\%$  of the time on foliage, *Alouatta palliata* has a small  $HR_i$  (K. Glander, personal communication) when compared with the same species on Barro Colorado Island where it spends approximately equal amounts of time feeding on foliage and fruit (K. M., personal

\* Body weights taken from Kay<sup>11</sup>, Napier and Napier<sup>40</sup>, or from same source as home range data.

† Indicates habitat and feeding class: A, arboreal; T, terrestrial; L, folivore; F, frugivore; P, generalist primary consumer; O, omnivore.

Fig. 1 Home range per individual as a function of body weight. Vertical lines connecting similar symbols indicate data from different studies of the same species. Values for the log of the mean home range for the species were substituted for these points in all calculations here and in Figs 2 and 3. Heavy solid line is least squares regression of  $\log_{10} HR_i$  on  $\log_{10}(\text{body weight})$  for primates ( $\log HR_i = 0.79 \log BW - 2.32$ ). Dashed line is regression calculated by McNab<sup>8</sup> for solitary, temperate zone mammals. Open symbols designate arboreal species; solid symbols terrestrial species.  $\diamond$ ,  $\circ$ , folivores;  $\triangle$ ,  $\bullet$ , frugivores;  $\triangle$ ,  $\bullet$ , generalist primary consumers;  $\square$ ,  $\blacksquare$ , omnivores.

observation). The siamang (*Symphalangus*), which spends ~ 50 per cent of its annual feeding time eating foliage, has a smaller home range than the gibbon (*Hylobates*), a smaller primate that seems to be more frugivorous<sup>18,20</sup>. *Lemur catta*, a generalist primary consumer that was studied at two sites, had a smaller home range where it was more frugivorous. In the study site where it ate less fruit and had a larger home range, however, it was sympatric with another lemur species, *L. fulvus rufus*, that also ate some fruit. Further, *L. catta* was much more frugivorous than *L. fulvus rufus* and had a much larger  $HR_i$  in the habitat where the two species were sympatric, even though they have about the same body weight<sup>21</sup>.

Arboreal omnivores generally occupy a large  $HR_i$  for their body weight, as large, in fact, as terrestrial omnivores. This suggests that arboreality *per se* does not reduce the area required to provide adequate nutritional resources for omnivores. Arboreal omnivores probably depend more heavily on insects in the diet than the larger, terrestrial omnivores, and may, therefore, occupy a slightly higher trophic level than their terrestrial counterparts. Nevertheless, solitary arboreal squirrels, which are also discrete particle feeders (but are certainly primarily herbivorous), have  $HR_i$  comparable to the primate  $HR_i$  of this group<sup>22,23</sup>.

Terrestrial primates as a group tend to have an  $HR_i$  somewhat larger than expected for their body weight. Some of these species live in arid regions that probably have lower densities of resources per given area<sup>2</sup>. The patas monkey (*Erythrocebus patas*) is an extreme case and it has a very large  $HR_i$ . Home range data are not available for two other arid country species, the hamadryas baboon (*Papio hamadryas*) and the gelada (*Theropithecus gelada*), but information on daily range indicates that they also cover very large home range areas<sup>2</sup>. Except for these arid land forms, it is not clear that terrestriality in itself is correlated with large  $HR_i$ . Terrestrial folivores do have larger  $HR_i$  values than arboreal folivores, but the differences may arise simply from their larger size.

Primate hunters and croppers generally have lower values of  $HR_i$  than predicted for temperate zone solitary mammals of corresponding feeding habits. The small individual home ranges may reflect: (1), the fact that some hunters may some-

times graze or browse; (2), the high productivity of many tropical areas compared to mesic temperate zone habitats; (3), the additional resource space provided by the depth of the forest canopy; or (4), the greater efficiency of utilisation of area as a result of being social. All of these factors may contribute in particular cases. Certainly some frugivores, and very probably some terrestrial omnivores, eat enough leaves or grass to make a substantial impact on their resource area requirements. The year-round high productivity of many tropical regions may be important, but much of this productivity may be unavailable as animal food<sup>18,24-26</sup>. The idea that the greater vertical extent of the resource space for arboreal species should reduce the  $HR_i$  required is attractive *a priori*, but it is not clear why this should apply to folivores only. Some of the possible effects of sociality are discussed below.

We have not tried to take into account the effect on home range area of overlap between conspecific groups, although one might expect that  $HR_i$  as well as total home range would be larger in species with greater overlap. The little data available suggest this may be true, since most species with non-overlapping ranges (for example, *Callicebus moloch*, *Symphalangus syndactylus*, *Colobus guereza*, *Propithecus verreauxi*), occupy home range areas smaller than or equal to the predicted values.

### Total home range

Figure 3 shows total group home range ( $HR_t$ ) as a function of body weight. The slope of the regression is significant ( $r^2 = 0.56$ ;  $t = 6.54$ ,  $P < 0.005$ ). Much of the deviation from the regression in Fig. 3 may be due to variation in group size, since there is a strong correlation between group size and  $HR_t$  ( $\rho = 0.67$ ;  $P < 0.0001$ ) irrespective of body weight.

Broad patterns of variation in total group home range are generally similar to those noted for  $HR_i$ . Both folivores and generalist primary consumers tend to have smaller  $HR_t$  than frugivores and omnivores. To a greater extent than  $HR_i$ ,  $HR_t$  of terrestrial species tends to be higher than expected.

Perhaps the most interesting aspect of Fig. 3 is that  $HR_t$  for many group-living primates is far larger than the home range of solitary animals of similar body weight, although solitary

Fig. 2 Influence of diet on  $HR_i$ . Heavy solid lines are regressions of  $\log_{10} HR_i$  on  $\log_{10}(\text{body weight})$  for frugivores and omnivores (primate hunters, PH;  $\log HR_i = 0.83 \log BW - 2.17$ ) and folivores (primate croppers, PC;  $\log HR_i = 1.06 \log BW - 3.66$ ) separately. Generalist primary consumers are excluded from the calculations. Dashed lines are regressions calculated by McNab<sup>8</sup> for solitary, temperate zone hunters and croppers (MH, hunters; MC, croppers). Species symbols as in Fig. 1.

Fig. 3 Total home range per group as a function of body weight. Symbols as in Fig. 1. S indicates solitary foragers. Regression equation for primates is  $\log HR = 1.23 \log BW - 2.86$ .

primates occupy home ranges similar to those of other mammals. If, within a given time interval, the primate group covers the same proportion of its home range using the same movement patterns as a solitary mammal, the individual primate may have to expend much more energy in travel than solitary mammals of similar size. How can social primates afford or avoid the higher cost of obtaining their resources? We can suggest three possibilities which are not mutually exclusive and the second and third may be related. First, it is possible that locomotion is a negligible portion of the energy budget. This seems unlikely in view of what is known of the metabolic cost of locomotion<sup>27</sup>. Second, it may be that foraging as a group increases food-finding efficiency enough to compensate for increased travel costs. Undoubtedly energy required for foraging is reduced by a shared pool of traditional knowledge about resource timing and location and travel routes<sup>28-30</sup>. Third, and probably most important, the pattern of movement within the home range may differ consistently between social and solitary animals. For example, a group may traverse a large area over a broad front while each individual moves over a fairly straight course<sup>31,32</sup>. A solitary animal would have to zig-zag back and forth many times to cover the same area. A social animal can feed on smaller food patches in its path and cue other group members to the location of rich patches if the latter are encountered. Some species of iguanid lizards use conspecific cuing for locating rich food resources, and this is probably a time-saving method of food location<sup>33</sup>. A similar model might apply within a group of primates, on a short time scale. As long as there is intraspecific tolerance of feeding at the same patch, straight line movement with cuing on other group members would be an efficient strategy, particularly if food is often clumped in fairly rich patches.

Many social animals seem to move directly between known resource patches rather than depending on chance encounters. Solitary foragers also do this (G. G. Montgomery, personal communication), but perhaps, as suggested above, group knowledge encourages such behaviour by increasing the probability that resource patches will be accurately recognised and remembered. In addition, social animals may utilise only a small portion of their home range within a given time span, covering

the entire area only in the course of weeks or even months. Certainly many group-living primates show such behaviour (for example, *Alouatta palliata* (K. M., personal observation); *Presbytis entellus*<sup>34</sup>; *Pan troglodytes*<sup>35</sup>; *Papio cynocephalus*<sup>31</sup>). Data on daily movements within their home range are scanty for solitary mammals. Red foxes generally cover most of their range each night<sup>36</sup>, while raccoons<sup>37</sup>, rabbits<sup>38</sup>, and anteaters (*Tamandua* (G. G. Montgomery, personal communication)) do so in a few days to a week. Certain social primates traverse much of their home range in a single day, at least occasionally, but except for species which defend relatively small territories, this behaviour is usually interspersed with relatively long periods in a small area (for example, *Cebus capucinus*<sup>39</sup>).

We thank Drs K. Glander, B. K. McNab, G. G. Montgomery, R. Rudran, and H. Schlichte for discussion and unpublished data and Mr Tom Milton for able assistance in all aspects of this study. M.L.M. was supported by a grant from NASA. The Smithsonian Tropical Research Institute provided facilities.

## New map of the optical polarisation of galaxy M82

M82 is the nearest galaxy evidently containing a strong central source of energy, which is possibly similar to the nucleus of a Seyfert galaxy, and this seems to have given rise to an unusual explosive event<sup>1</sup>. The appearance of M82 is that of a flattened irregular system seen nearly edge-on, and if a distinct nucleus exists, it is highly obscured<sup>2</sup> at optical wavelengths. Compact radio features are, however, present, and complex resolved radio and infrared sources and bright visible H II regions occupy an area  $\sim 12'' \times 35''$  in the centre of the galaxy. The outer parts of the galaxy show linear optical polarisation, discovered by Elvius<sup>3</sup>. This is thought to arise from reflection in an extensive halo of dust particles of the light of the bright nucleus (or nuclear region) and of the galactic disk (for a recent discussion, see ref. 4). Consequently, observation of the polarisation can give information about the position and luminosity of the energetic nuclear region, and about the scattering medium. Outstanding questions about M82 involve the existence and nature of a compact nucleus and the morphological and evolutionary state of the whole galaxy.

The observations reported here were obtained with the 1-m telescope of the Wise Observatory, Israel, during the period February 27–March 15, 1975. The polarimetric technique is derived from that of Ohman<sup>5</sup>, but uses a rotating achromatic half-wave plate, and a Wollaston prism to separate orthogonally polarised beams, which are recorded simultaneously and remain in a fixed relationship to the detector. The technique and the computer programmes used in the analysis will be discussed elsewhere. The detector was an electronographic camera<sup>6</sup> on loan from the Royal Greenwich Observatory to the Wise Observatory. The waveband used was B of the UBV system.

The results of the observations are shown in Fig. 1. Each measurement is indicated by a line parallel to the plane of the electric vector and proportional in length to the degree of polarisation, centred on the point observed. Each determination is made over an area  $\sim 8'' \times 8''$ . The map has a superimposed photograph of M82 to illustrate the relationship of the polarisation structure to the bright part of the galaxy. The photograph is from a blue plate taken on the Isaac Newton telescope by Dr S. V. M. Clube. The eight stars indicated were used for astrometric purposes.

These observations show the polarisation at more than ten times the total number of points previously observed, with a spatial resolution three to five times finer. The

**Table 1** Comparison between our measurements and published values for polarised stars

Star	Tabulated value		This work	
	$P(\%)$	$\theta(\text{deg})$	$P(\%)$	$\theta(\text{deg})$
HD 43384	$2.75 \pm 0.05$	$170 \pm 1$	$2.3 \pm 0.4$	$172 \pm 5$
HD 122945	$0.1 \pm 0.07$	$56 \pm 18$	$0.3 \pm 0.4$	$69 \pm 20$
HD 155528	$4.6 \pm 0.09$	$93 \pm 1$	$4.3 \pm 0.4$	$90 \pm 3$
HD 80083	$0.13 \pm 0.09$	$140 \pm 17$	$1.4 \pm 0.4$	$128 \pm 10$

results are complete over a large area of the galaxy, but as we are carrying out further work which may eventually serve to extend and improve the data, we refrain from tabulating the extensive numerical results at this stage.

The accuracy of the observations has been checked by comparison with the previous work<sup>3,7,8</sup> on M82, and by observations of individual stars of known polarisation<sup>6</sup>. The comparison between our measurements and published values for the stars is given in Table 1. From these results, it was not considered necessary to make any corrections for instrumental effects. Also from these results and from the comparison with previous work on M82 and from our internal consistency, the standard error over most of the map, for a typical point with 15% polarisation was estimated as 2% in degree of polarisation, and 3° in position angle. These errors are comparable with previous work. The weaker alignment of the polarisation vectors seen near the edge of the map probably arises from the reduced contrast of the galaxy against the sky background, introducing a noise component. A further interpretation of these results will be given elsewhere, but a preliminary note of the more outstanding features is made here.

The completion of the two-dimensional polarisation study provides data for the construction of improved models of M82. For example, the fairly clear division of the area into regions of high and low polarisation represents a separation in depth, at least near the centre of the map. The edge-on view of the galaxy shows the near side of the disk along the central band, whereas on each side of the disk an unobscured line of sight passes through highly polarised regions directly illuminated by the bright central source, and with large scattering angles. We hope to characterise the central source and the reflecting medium by fitting models to the observational data. Some smaller contribution to the polarisation by other mechanisms is also to be expected and may be apparent in one or two features of the galactic disk in Fig. 1; these most probably arise from the properties of the disk rather than the halo material, and may show that there is some magnetic field

alignment in this irregular object. The centrally symmetric pattern enables a position to be found for the central source of radiation, following Solinger and Markert<sup>4</sup>. The position obtained is indicated in Fig. 1 and on a larger scale in Fig. 2, superimposed on optical and infrared contour maps, and with other interesting positions marked. The centre of symmetry may be influenced by emission from the disk as well as the nucleus of the galaxy (Solinger and Markert assume the disk is symmetrical), and it is not at present clear what difference this will make. The position obtained was, however, found to be consistent, within the indicated error, when different areas of the map were used in its derivation, and it is quite independent of previous polarisation studies.

Some previous writers have been at pains to emphasise that various central features in M82 were almost coincident, but we would point out that there is no detailed correspondence between them, such as would be expected if a true nucleus were present. The most intense radio component (cross-hatched in Fig. 2) has no special position in the infrared source, which itself is only near to the centre of symmetry. The optically brightest spot, which is sometimes assumed to be the centre in dynamical studies, is close to the centre of the infrared source but not to the other features.

The lack of an identified singular nucleus does not, however, preclude the possibility that M82 has some resemblance to a Seyfert galaxy. A compact nucleus may be present, but still unidentified, and even if no such nucleus exists, an interesting possibility arises from McCrea's theory of the Seyfert phenomenon<sup>10</sup>, which he ascribes to supernova events at the rate of perhaps one every 10 yr, in a limited volume. (No direct triggering of the events is called for, but star formation may be stimulated by previous outbursts.) In the case of M82, referring to Fig. 2, the active region of the galaxy may be ~300 pc in diameter, about ten times the size of a Seyfert nucleus, and the process would be much modified; however, it seems particularly appropriate for a galaxy such as M82, containing as it does a large amount of interstellar matter and regions of star formation (H II regions) within the 300 pc central active domain. A galaxy of this type, if we had a face-on view, might not qualify as a Seyfert from its spectral characteristics, but could represent the connecting link between Seyferts and normal galaxies.

We thank the Wise Observatory of Tel Aviv University and the Smithsonian Research Foundation for the use of their facilities at Mitzpeh Ramon, Israel, the SRC for support, and Dr J. Pilkington and D. J. Bonnick, P. Armstrong and A. Coulson for help.

## Variations of the infrared polarisation of VY Canis Majoris

A REMARKABLE change in the infrared polarisation of VY Canis Majoris has been observed in 1974 and 1975. This star was found, in 1970, to have a large and peculiar polarisation<sup>1</sup>. Further observations carried out in 1971 and 1972 confirm the existence of a polarisation peak at  $1.6 \mu\text{m}$  and a rapid rotation of the position angle of polarisation from visible to infrared wavelengths<sup>2-3</sup> (see Fig. 1). The polarisation declines rapidly with wavelength from ultra-violet to infrared, having a dip near  $1 \mu\text{m}$ , and rising further in the infrared, with peak at  $\lambda = 1.6 \mu\text{m}$ . Corresponding to the rapid decrease in the polarisation, the position angle rotates by about  $90^\circ$ . Our latest observations show that the hump at  $1.6 \mu\text{m}$  has disappeared.

Our original results suggested that the polarisation could be resolved into two components, visible and infrared polarisations, and the visible polarisation has since been

Fig. 1 The wavelength dependence of the degree of polarisation and the position angle for the observations in 1969 and 1972. +, Serkowski 1969; ●, Shawl 1969; ○, our results 1970; ○, our results 1971; △, Forbes 1971; × Dyck et al. 1971; □, Serkowski, 1972.

Fig. 2 The same as in Fig. 1 but for 1974 and 1975 (+, January, 1974; ×, ●, △, V, Λ, ○ February–April, 1975).

shown to originate mostly from a reflection nebula<sup>4</sup>. High resolution photographic observations have shown that the nebula is highly polarised ( $\leq 70\%$ )<sup>5</sup>. Such a high polarisation can be explained only in terms of Rayleigh-like scattering by very small grains of radii  $< 0.1 \mu\text{m}$ . These small particles, however, would not be capable of producing the infrared polarisation.

The infrared polarisation would have to be attributed to scattering by much larger grains, of radii  $\sim 1 \mu\text{m}$ , concentrated in a fairly dense cloud around the central star. The existence of the polarisation indicates that the distribution of this dust cloud (infrared nebula) is not spherically symmetric, but very asymmetric—probably disk shaped<sup>6,7</sup>.

We repeated the observation in 1974 and 1975, and found some remarkable changes in the infrared region. The observations were done with the same procedure as before<sup>1</sup>, but using a 1-m infrared telescope equipped with a secondary mirror wobbling chopper. The new results are summarised in Table 1 and shown in Fig. 2, in which the average values of the old results are also shown as a dashed line.

Surprisingly, the peak at  $1.6 \mu\text{m}$  has disappeared, the infrared polarisation is smoothly connected with the visible polarisation. Since the observation was regrettably interrupted by the construction of the telescope, when and how the change occurred is not known precisely.

The photometric observations, however, have not shown any significant change in this same period, as shown in

Fig. 3 Photometric observations between 1969 and 1975. (+, Hyland *et al.*, 1969;  $\Delta$ , Low *et al.* 1970; O, our results, 1971;  $\times$ , our results, 1974;  $\odot$ , our results, 1975).

Fig. 3. This implies that neither a drastic change in the stellar emission, nor a global change in the configuration of the dust clouds could have occurred.

The change could have been limited to a very localised region with extremely high polarisation. It might have been caused by a dust cloud ejected from the star. An alternative possibility is that the infrared nebula consists of many fragments, and an outer cloud which lets light out through a gap. The motion of the fragments inside the cloud would then bring different fragments to view, through the gap, and the observed polarisation would change. In this case any gross change in appearance would not necessarily be associated with high speed motion of matter. This is more suitable for explaining a change of the polarisation in visible regions<sup>5,7</sup>, which arises from an extremely large scale reflection nebula.

It has been reported that IRC+10216 showed a periodic variation in infrared polarisation, which correlated with an anti-phase intensity variation<sup>8</sup>. It is interesting in the case of VY Canis Majoris to see whether the change is periodic or not, and what change occurs in optical polarisation as well as in the circular polarisation which had been detected by Serkowski<sup>9</sup> and Gehrels<sup>10</sup>.

## Fe XIII line in R Aquarii

GREGORY and Seaquist<sup>1</sup> have detected radio emission from the interesting object R Aquarii<sup>2</sup>. In the course of reducing plates of this star made in 1970 and 1971 in the course of my He I,  $\lambda = 10,830 \text{ \AA}$  spectral survey, I found the emission line of the forbidden coronal transition of Fe XIII at  $\lambda = 10,747 \text{ \AA}$ . This line ( $^3P_1 - ^3P_0$ ) is often accompanied by the  $^3P_2 - ^3P_1$  line at  $\lambda = 10,798 \text{ \AA}$  at high densities ( $N_e > 10^9$ ). The emission line  $\lambda = 10,747 \text{ \AA}$  is weak, but clearly seen on two spectra (Fig. 1), with intensity of  $\sim 100 \text{ m\AA}$ . The spectrum also shows strong emission lines of He I at  $10,830 \text{ \AA}$  and  $\text{P}\gamma$  as well as a line at  $11,013 \text{ \AA}$  which may be He I  $3^1S - 6^1P$ . I have examined an old plate made by Merrill in 1948 for traces of the coronal lines at  $5,303 \text{ \AA}$  and  $6,374 \text{ \AA}$  (Fe XIV and Fe X) and found them absent. G. Wallerstein (personal communication) has kindly examined his plates from 1970–71 and finds the  $6,374\text{-\AA}$  line definitely absent. If the lines are excited by the  $2,400\text{-K}$  radiation field of the star, the  $6,374\text{-\AA}$  and  $5,303\text{-\AA}$  lines should be much fainter than the  $10,747\text{-\AA}$ , because of their higher excitation energy.

Some idea of the physical conditions in the corona of R Aquarii may be found from the intensity of the line ( $100 \text{ m\AA}$ ) and the absence of other coronal lines. We assume a corona (or part of the nebula) at  $10^6 \text{ K}$  (coronal ionisation—ionisation at  $10^6 \text{ K}$  and  $N_e < 10^{10}$ —is density independent). If collisional excitation were responsible, we would require  $N_e^2 V \sim 3 \times 10^{45} \text{ cm}^{-3}$ . In that case the line at  $10,798 \text{ \AA}$  would

Fig. 1 Two image tube spectrograms of R Aquarii. *a*, September 1968, phase 0.01 (maximum light); *b*, July 1970, phase 0.79, with identified lines and wavelengths ( $\text{\AA}$ ) marked. The Fe XIII line is at extreme left, near the  $10,749\text{-\AA}$  Si I absorption line. Strong He I and  $\text{P}\gamma$  emission is also seen. There are a number of other possible emission lines in the spectrum, but none is identified and they may just be windows in the continuum.

be at least as strong as that at 10,747 Å, however, and the coronal lines in the visible would be excited by the thermal electrons and be much stronger relative to the continuum there. If the coronal density is low, we will still have the ionisation corresponding to the kinetic temperature, but the ions will be excited by photospheric radiation at a rate

$$F_{12} = \frac{1}{w} \frac{g_2}{g} \frac{A_{21}}{\exp(h\nu/kT) - 1} = \frac{0.05}{w} \text{ s}^{-1}$$

for  $T_e = 2,000$  K with  $w$  the dilution factor. Integrating this over a uniform nebula, we find

$$R_{\text{cor}} N_{\text{Fe}} = 2.1 \times 10^{14} \text{ cm}^{-2}$$

or

$$R_{\text{cor}} N_e = 2 \times 10^{18} \text{ for } N_e/N_{\text{Fe}} = 10^4$$

The scale height of such a corona, if distributed barometrically, would be 100 AU, but of course the gravity could not keep it from escaping and other factors must play a role. For  $\lambda = 5,303$  Å,  $A_{21}$  is six times greater, but the exponential term is  $10^{5.6}$  greater, so the emission is  $6 \times 10^4$  less and the line cannot be seen, even though the continuum is lower by 6 mag than the 1.1 μm value.

The thermal radio flux from this corona is, at  $\lambda = 3.5$  cm,  $1.44 \times 10^{-15} R_{\text{cor}} \text{ mJy}$ . If the source size is  $< 1''$ ,  $R_{\text{cor}} < 4 \times 10^{15}$ , and a flux of 5.5 mJy is obtained; for  $T = 2 \times 10^6$  K (also possible for Fe XIII), we have 8 mJy, in rough agreement with the flux measured by Gregory and Seaquist.

We conclude that R Aquarii is surrounded, *inter alia*, by a corona at  $T \approx 10^6$  K and  $R \sim 100$  AU, which produces the observed iron line and may be the source of the radio emission observed.

This research was supported by NASA and the NSF.

*Note added in proof:* A spectrogram obtained on November 23, 1975, on the rise ( $M \sim 9$ ) after an exceptionally deep minimum, showed no Fe XIII emission, but extremely intense P Cygni-type He emission, as well as Pγ emission.

## Pulsars and magnetic monopoles

THE report<sup>1</sup> of the possible existence of magnetic monopoles makes some speculations about their astronomical role worthwhile. Pulsars possess magnetic fields, possibly the highest in the Universe<sup>2</sup>, and it thus seems natural to speculate how these magnetic fields might affect monopoles and how the latter, in turn, could influence the behaviour of the pulsars.

For concreteness, we adopt Schwinger's dyon picture of magnetic monopoles<sup>3</sup>. The magnetic charge  $g$  is then  $6 \times 137 \times e$  and the monopole mass  $M$  gives  $Mc^2 = 400$  GeV. One very important fact is that such a monopole acquires  $\sim 0.25$  MeV by travelling 1 cm in a magnetic field of  $\sim 1$  gauss.

Let us estimate the absorption cross section of a pulsar for a monopole of energy  $\epsilon$ . Assuming that the pulsar field is that of a static dipole, we find that the perpendicular momentum acquired,  $\Delta p$ , by a monopole passing at a distance  $r$  is given approximately by the relationship ( $c$ : velocity of light)

$$\Delta p = g^2 M^2 / \epsilon r^2 c \quad (1)$$

where  $M \approx B_0 R^3$ , is the magnetic moment of the pulsar with maximum surface field  $B_0$  and radius  $R$ . Consider a monopole moving along a path which intersects field lines that do not

curve too much along their approach towards the stellar surface (that is, the collision takes place within not too wide a cone around the magnetic axis). This monopole will be appreciably deflected and thus may be channelled into the pulsar polar region, provided  $\Delta p \gtrsim p$ , or, equivalently, if  $r \lesssim \sqrt{(gM/\epsilon)}$ . This leads to a capture cross section  $\sigma$  (up to a numerical factor of less than unity arising from the geometry)

$$\frac{\sigma}{\sigma_{\text{geom}}} \approx \frac{gM}{\epsilon R^2} \approx 3 \times 10^{16} \frac{RB_0}{\epsilon} \quad (2)$$

where  $R$  is the radius in km,  $\epsilon$  the energy in MeV, and  $B_0$  is in units of  $10^{12}$  gauss.

It remains to estimate  $\epsilon$ . Passage through random magnetic fields in interstellar space probably leads to a substantial acceleration of the monopoles. A further energy gain could be acquired near the pulsar by means of its non-dipolar magnetic field. Such a process would be rather efficient in the vicinity of normal stars where spiralling magnetic field lines carried by the stellar wind extend over large distances: for example, one can estimate that the interplanetary space around the Sun with  $B = 10^{-5}$ – $10^{-6}$  gauss,  $l = 10^8$  km, would provide  $Bl \approx 10^3$ – $10^6$  gauss cm and a pre-acceleration to  $10^{14}$  eV before the actual impact on the dipole field takes place. In contrast, the corresponding mechanism for pulsars is probably much less important, because of the lack of a 'pulsar wind', and because the region where static non-potential magnetic field configurations can occur is limited to within the light cylinder, where  $Bl$  is appreciably smaller than in the interplanetary space.

It is probably safe to take an upper limit of  $\sim 10^{11}$  eV for  $\epsilon$ . For the pulsar case, this would make  $\sigma/\sigma_{\text{geom}} \sim 10^6$ – $10^7$ , making the capture cross section equal to the cross section of the light cylinder, beyond which, anyhow, one would not extrapolate the static formula, or the simple picture of the capture given here. On the other hand for normal stars  $B_0 R$  is substantially lower, and  $\sigma/\sigma_{\text{geom}} \sim 1$ , indicating that in contrast to pulsars, monopoles would arrive at the stellar surface more or less uniformly.

One can thus conclude that pulsars might have a capture cross section for monopoles  $\sim 10^{18}$ – $10^{20}$  cm<sup>2</sup>. Impinging monopoles would be funnelled into the polar regions. Their terminal energy at impact can easily be estimated from

$$\int_{\infty}^R gB(r) dr \approx gB_0 R$$

to be  $\geq 10^{22}$  eV, if we take  $B_0 \sim 10^{12}$  gauss,  $R \sim 10^6$  cm.

Along their way to the pulsar surface the monopoles suffer energy losses due to curvature radiation<sup>4</sup>. If this were the only energy loss, their energy balance would be described by the relationship

$$\epsilon/c = Bg - A\epsilon^4; A = \frac{2}{3}(g^2/\rho^2)(Mc^2)^{-4} \quad (3)$$

where  $\rho$  is the radius of curvature of the trajectory. The resulting saturation energy  $\epsilon_{\text{max}}$  is given by the equation

$$\epsilon_{\text{max}}/Mc^2 \approx (B\rho^2/g)^{1/4} \quad (4)$$

which leads to  $\epsilon_{\text{max}} \approx 10^{21}$ – $10^{22}$  eV (probably an underestimate) if we take for  $\rho$  the radius of curvature of the last open field line, or  $\rho \approx$  radius of the light cylinder  $\approx 10^8$ – $10^{10}$  cm. The value of  $\epsilon_{\text{max}}$  found here is sufficiently large that the value of the terminal energy we found earlier is not appreciably affected. We note, by the way, that the ratio of the radiation reaction force,  $2g^4 B^2 / 3M^2 c^4$ , to the accelerating force  $Bg$  is  $10^{-61} B$  (gauss), which is so small that the ordinary radiation damping can be neglected.

Although a monopole crossing the pulsar magnetosphere will also be affected by the electric field in it<sup>4</sup>, its gyroradius  $r$  in

an electric field  $E$ , which is given by the equation

$$r = \varepsilon/gE \quad (5)$$

will be sufficiently large not to affect appreciably the monopole trajectory.

Let us now investigate whether the pulsar magnetic field could be substantially extinguished by the accretion of monopoles. For this to happen, each pulsar hemisphere has to collect  $N$  monopoles such that  $NgR \simeq B_0 R^2$ . The number of required monopoles is then

$$N \simeq B_0 R^2 / g \simeq 2 \times 10^{30} \quad (6)$$

If we take the pulsar lifetime to be  $\sim 10^{15}$  s, the cosmic flux of monopoles must be  $\lesssim 10^{-4} \text{ s}^{-1} \text{ cm}^{-2}$ , as the extinction of the pulsar magnetic fields seems not to have taken place. This upper limit is 6 orders of magnitude higher than that set already by similar considerations about the Earth's magnetic field<sup>5,6</sup> and 9 orders of magnitude higher than that set by the lack of more than one event found in cosmic ray work<sup>1</sup>.

It thus seems that no useful conclusions regarding the flux of cosmic magnetic monopoles can be drawn from the persistence of pulsar magnetic fields. The situation is not, however, quite as simple as this, because of the high terminal energy of the monopoles. In fact, near the pulsar surface, the accelerating field imparts to the monopole an energy equal to the monopole rest mass energy over a distance of  $\lesssim 10^{-6}$  cm. In a collision with a nucleus, there will be enough energy in the centre-of-mass system to produce a pair of monopoles, if the  $\gamma$  of the monopole equals or exceeds  $\gamma_0 = 2M/m_p \simeq 1,000$  ( $m_p$ : proton mass), or  $\varepsilon \simeq 10^{15}$  eV. We see that there will thus be ample energy to create monopole pairs. The wrongly charged member of the pair will be hurled back into extra-pulsar space with an energy  $> 10^{20}$  eV (compare the mechanisms for pair production in the Sturrock<sup>7</sup> and Ruderman-Sutherland<sup>4</sup> theories of pulsar emission) while its companion will be further accelerated towards the pulsar. If the conditions

$$\gamma_0 Mc^2 / gB < \lambda_{\text{loss}} \text{ and } \lambda_{\text{pair}} \ll l^* \quad (7)$$

are satisfied, where  $\lambda_{\text{loss}}$  is the mean free path for energy losses not associated with pair creation,  $\lambda_{\text{pair}}$  is the pair creation cross section mean free path and  $l^*$  the width of the region with a density sufficiently high for copious pair creation to occur, an avalanche of new monopoles may be generated. The energy loss of a monopole in ordinary matter has been estimated<sup>8</sup> to be  $10^{12} \text{ eV g}^{-1} \text{ cm}^2$ . A layer of width  $\sim 10^{-1}$  cm in the outer crust with a density  $\sim 10^4 \text{ g cm}^{-3}$  would be a suitable environment for the avalanche production of monopoles. If we estimate the number of monopoles  $N_*$  produced in the avalanche to satisfy the relationship

$$N_* Mc^2 \gamma_0 = \varepsilon \quad (8)$$

and use  $\varepsilon \simeq 10^{21}$  eV, we find  $N_* \simeq 10^6$ , and the persistence of the pulsar magnetic fields would lead, for pulsars such as PSR 1933 or PSR0527 with a relatively short lifetime (and a large  $B_0$  in the case of PSR0527), to quite a low upper limit on the monopole flux, which may even be as stringent as the one given in ref. 1.

It is, of course, impossible to estimate  $N_*$  in any reliable way, as long as data on monopole pair-production cross sections are lacking. Nevertheless, in view of the availability in the pulsar crust of a relatively large region where the monopoles undergo frequent collisions while still, on the average, gaining energy from the magnetic field, a very substantial multiplication can be expected to occur.

To summarise our main conclusions: first, the persistence of pulsar magnetic fields may possibly set a more stringent limit on the cosmic flux of magnetic monopoles than the presently available one. The actual value of the limit can only be given,

once the pair-production cross section is known. Second, pulsars may act as copious sources of very high energy (secondary) monopoles (if monopoles really exist). It would be of interest to look for correlations between monopole events and pulsar positions, if monopole events are observed in any significant number.

The annihilation of a pair of oppositely charged monopoles will surely have an extremely low probability. Even if there were the  $10^{30}$  monopoles needed to extinguish the pulsar magnetic field, their density would only be  $\sim 10^{12} \text{ cm}^{-3}$ , and the annihilation mean free path would be many orders of magnitude larger than the pulsar radius. If the monopoles are also electrically charged, as in the dyon model<sup>3</sup>, their accumulation would induce an additional electric dipole field which would, however, be  $\lesssim 10^7 \text{ V cm}^{-1}$  so that its effect could be negligible compared to the already existing magnetospheric field.

## No anisotropy in angular diameter-redshift relationship

Using data for the brightest cluster galaxies, we here consider whether any anisotropy exists in the angular diameter-redshift relationship. This is in response to the finding of Rubin *et al.*<sup>1</sup>, who described a 'curious' distribution of radial velocities for ScI type galaxies having apparent magnitudes  $m$  in the range  $14 < m < 15$ . For two distinct regions of sky, the mean radial velocity for these galaxies differs by  $\sim 1,400 \text{ km s}^{-1}$ ; the corresponding mean apparent magnitude differs by  $\sim 0$  mag, compared with the difference of 0.5 mag expected on the basis of this velocity difference. They tentatively concluded that the Hubble parameter  $H$  is not isotropic.

Le Denmat and Vigier<sup>2</sup> examined the distribution of  $HM$  (see ref. 1) for type I supernovae<sup>3</sup> that have occurred in a wide variety of galaxies, and found a highly significant anisotropy that agrees with that described by Rubin *et al.* We note, however, that the supernova apparent magnitudes given in ref. 3, and used by Le Denmat and Vigier<sup>2</sup>, seem to be mostly post-maximum values and therefore only set lower limits on  $HM$ : little weight can therefore be placed on this result. Jaakkola *et al.*<sup>4</sup> have also found an anisotropy in  $HM$  for compact galaxies with absorption spectra, but they further found that the degree of anisotropy decreases with increasing distance.

If the effect found by Rubin *et al.*<sup>1</sup> is truly cosmological in origin, and is not the result of selection effects, then it should manifest itself in other 'cosmological' relationships, such as the angular diameter-redshift relationship. Rubin *et al.*<sup>1</sup> did not find, with certainty, any difference in the mean angular diameter of the ScI galaxies in their sample, but they described the values they used as being of low weight.

Data obtained<sup>5</sup> from measurement of 48" Schmidt plates form a reasonably homogeneous sample of isophotal angular

diameters for E galaxies having redshift  $z$  in the range 0.004–0.085. Less extensive and less homogeneous are the data measured from 200'' plates, also tabulated by Sandage<sup>5</sup>. We neglect both the 'K-like' correction, that transforms angular diameters to the rest frame of each galaxy (this correction amounts to  $\sim 6\%$  at most for the 48'' data), and the 'seeing' correction ( $\lesssim 1''$ ), which is small by comparison with the smallest angular diameter in the 48'' sample ( $\sim 10''$ ). For the smallest angular diameters in the 200'' sample, the net effect of these two corrections is zero<sup>5</sup>.

Isophotal angular diameters,  $\theta$ , are proportional to  $z^{-1}$  for  $q_0 = +1$ , which is a sufficiently good approximation for our range of  $z$  values. For each galaxy we compute the quantity  $A = \log \theta + \log cz$ , which is analogous to the  $HM$  of Rubin *et al.*<sup>1</sup>.  $A$ , which for low redshifts is a measure of the linear dimensions of galaxies for uniform  $H$ , is not correlated with  $z$  for either sample. Writing  $\langle A \rangle$  for the mean value of  $A$  in each region, we should expect

$$\langle A \rangle_{II} - \langle A \rangle_I = \langle HM \rangle_{II} - \langle HM \rangle_I = \sim 0.1$$

(see ref. 1) if the anisotropy<sup>1</sup> is indeed 'cosmological'. If the alleged anisotropy is not, however, cosmological then we should expect that the difference in the  $\langle A \rangle$  should merely reflect the sampling error, that is  $\langle A \rangle_{II} - \langle A \rangle_I = 0$ .

For the 48'' sample,  $\langle A \rangle_{II} - \langle A \rangle_I = 0.024 \pm 0.030$ , a difference that is not statistically significant (probability  $P = 0.44$ ). In addition there is no tendency for high or low values of  $A$  to be correlated with the regions I and II of Rubin *et al.*<sup>1</sup> ( $P = 0.52$ ). Even if we suppose that the above difference in  $\langle A \rangle$  arises entirely from a difference in  $H$  (that is, we assume that the brightest cluster galaxies in the 48'' sample are both standard candles and standard rods) then  $H_{II}/H_I = 0.95^{+0.55}_{-0.35}$  from the isophotal angular diameter-redshift relationship. This ratio is not significantly different from unity, and in any case is in the opposite sense to that claimed previously<sup>1,2,4</sup>. We note also that no significant difference between regions I and II is found when metric, rather than isophotal, angular diameters are considered. Furthermore, no anisotropy exists in regions of sky other than those delineated by Rubin *et al.*<sup>1</sup>, nor does anisotropy become apparent when various redshift intervals are considered.

Unfortunately sufficiently accurate and homogeneous apparent magnitude values were not available for the 48'' sample so we could not test whether the  $\langle HM \rangle$  for this sample differs significantly between regions I and II. For the smaller and less homogeneous 200'' sample, however, (for which  $\langle A \rangle_{II} - \langle A \rangle_I = 0.051 \pm 0.037$ ;  $P = 0.20$ ),  $\langle HM \rangle_{II} - \langle HM \rangle_I = 0.034 \pm 0.050$  which does not differ significantly from zero ( $P = 0.50$ ). It should be noted, however, that Jaakkola *et al.*<sup>4</sup> have found that the anisotropy is apparently present in their sample of brightest cluster galaxies.

If the anisotropy apparent in the  $HM$  values of ScI galaxies and compact galaxies with absorption spectra is indeed cosmological, then it could be masked in the angular diameter-redshift relationship by the intrinsic dispersion in the linear dimensions of E galaxies. After removal of dispersion from measuring errors, Sandage<sup>5</sup> estimates that the linear diameters of brightest cluster galaxies have a dispersion of  $\sim \pm 20\%$ ; the corresponding dispersion in  $\log \theta$  is  $\approx 0.1$ . Neglecting errors in redshift values, the dispersion in  $A$  arising from this dispersion is  $\sim 0.1$ , which is precisely the magnitude of the difference  $\langle A \rangle_{II} - \langle A \rangle_I$  expected on the basis of the difference  $\langle HM \rangle_{II} - \langle HM \rangle_I$ .

On the other hand, it has similarly been argued<sup>6</sup> that the dispersion in the absolute magnitudes of the galaxies considered could, in certain circumstances, give rise to an apparent anisotropy in  $HM$ . Although Rubin *et al.*<sup>1</sup> regarded the possibility of large scale inhomogeneities unlikely as a means of accounting for the anisotropy, Sandage and Tammann<sup>6</sup> have suggested that inhomogeneities on a scale  $\sim 100$  Mpc compounded with the narrow range of  $m$  values considered in ref. 1,

could explain the Rubin *et al.* result. The equality of the  $\langle m \rangle$  values for regions I and II would then merely reflect the narrowness of the apparent magnitude range chosen by comparison with the dispersion in the absolute magnitudes of ScI galaxies (0.4 mag, ref. 7). Jaakkola *et al.*<sup>4</sup>, however, found that the anisotropy does seem to exist ( $P = 0.015$ ) for compact absorption galaxies with  $13 < m < 18$ .

A further consideration in discussions of effects of this kind should, however, be the homogeneity of the data used. Sandage<sup>8</sup> has argued that much of the dispersion in the absolute magnitudes of brightest cluster galaxies arises from differing observational errors (that is, different observing sites and observing conditions) and clearly this argument would also apply to the absolute magnitude dispersions of other types of galaxy. Similarly, the effect of personal observing habits, as discussed by Penston and Rowan-Robinson<sup>9</sup> in connection with the alleged anisotropic redshift distribution of quasars, could also give rise to systematic observational errors.

Data used in previous examinations<sup>1,2,4</sup> of the Hubble anisotropy have been taken from catalogues in which apparent magnitude values have been obtained from a number of sources and it would be difficult to argue that these data are sufficiently homogeneous in the sense discussed above. Thus any anisotropy in the apparent magnitude-redshift relationship should be regarded as 'not proven' until analysis of a sufficiently homogeneous sample of galaxies shows otherwise.

## Present trends in the Earth's magnetic field

We outline here some of the implications of the latest in a series of models of the Earth's magnetic field derived in association with the World Magnetic Charts published by the British Hydrographic Office. The model, details of which are published elsewhere<sup>1</sup>, is defined by spherical harmonic coefficients representing the internal part of the magnetic field (to twelfth order and degree; 168 coefficients), its secular variation (to eighth order and degree; 80 coefficients), and its secular acceleration (the 26 most significant coefficients) at epoch 1975.0. Because of the greatly improved distribution, accuracy and quantity of data incorporated in the analysis, we believe that this model, particularly with regard to the secular variation, provides a significantly better representation of the Earth's magnetic field than any previous model. It is of interest to compare some of the parameters derived from this model with the trends shown by its predecessors.

To a first approximation (and an extremely good one) the Earth's magnetic field can be represented by that of a uniformly magnetised sphere—the so-called 'centred dipole' model. The orientation of the dipole axis ( $78.7^\circ\text{N}$ ,  $289.5^\circ\text{E}$ ) and its motion

Fig. 1 Rate of decrease of dipole moment. The point for 1970 is from an unpublished model based on observatory data; that for 1980 is obtained by updating the 1975 model using its time-dependent coefficients, and is included to show the trend they imply.

( $0.00^\circ \text{ yr}^{-1} \text{ N}$ ,  $-0.06^\circ \text{ yr}^{-1} \text{ E}$ ) follow closely the trends found by Malin<sup>2</sup>, although they suggest that the westward motion of the axis is slowing down. It is usual to measure the strength of the dipole by  $MR^{-3}$ , where  $M$  denotes the dipole moment and  $R$  the mean radius of the Earth. For the present model, this quantity is 30,701 nT, and is decreasing by 28.8 nT  $\text{yr}^{-1}$ . This rate of decrease is the largest yet found, but is in good agreement with the rather speculative trend noted earlier (see refs 3 and 4, and Fig. 1). The recent points in Fig. 1 are in excellent agreement with the predictions of Malin and Clark<sup>4</sup> which were based on the assumption of a linear change in the decrease of dipole moment, and there seems little reason to revise their estimate that, if present trends were to continue, the field would reverse in about 2230 AD.

A better approximation to the main field is obtained by displacing the dipole from the Earth's centre, without changing its magnitude and direction, to the magnetic centre—the 'eccentric dipole' model. The displacement vector is (474 km,  $19.8^\circ \text{ N}$ ,  $148.0^\circ \text{ E}$ ) and its rate of change ( $2.2 \text{ km yr}^{-1}$ ,  $0.26^\circ \text{ yr}^{-1} \text{ N}$ ,  $-0.05^\circ \text{ yr}^{-1} \text{ E}$ ). The distance of the magnetic centre from the centre of the Earth continues to increase at a remarkably constant rate; there is no support to the suggestion<sup>5</sup> that

the magnetic centre is moving in an ellipse. The rate of northward drift continues to increase slowly, but, more interestingly, the westward drift, previously seen to be slowing down<sup>4</sup>, has now virtually stopped.

The magnetic dip poles are those points on the Earth's surface at which the lines of force are vertical. The model indicates that the north magnetic dip pole is located on Bathurst Island at ( $76.1^\circ \text{ N}$ ,  $259.5^\circ \text{ E}$ ) moving eastwards at  $5 \text{ km yr}^{-1}$ . The south pole is at ( $65.6^\circ \text{ S}$ ,  $139.6^\circ \text{ E}$ ), about 120 km off the coast of Adelie Land, and is moving approximately north-eastwards, towards New Zealand, at  $5.5 \text{ km yr}^{-1}$ . The exact positions and movements of such features as the dip poles may be significantly affected by nearby anomalies, and are better determined by local surveys than by a global model. The positions and movements are, however, entirely consistent with the survey data obtained near the north magnetic pole<sup>6</sup>. Recent survey data are not available for the vicinity of the south magnetic pole, but the declination measures from the nearby observatory of Dumont d'Urville are in good agreement with those expected to be associated with the pole. It is interesting to note that both of the dip poles show an eastward rather than a westward motion.

The evidence seems to indicate that the westward drift of the magnetic field, which has been going on at least since the time of Halley<sup>7</sup>, has recently slowed down and may even have stopped. A numerical estimate of the westward drift is obtained by taking a global mean of longitudinal movements of certain features of the Earth's magnetic field. The best method of taking this mean, and the most appropriate features to consider are still open to discussion. For example, should one consider total intensity,  $B$ , or vertical intensity,  $Z$ ; pattern at the surface of the Earth or at the core-mantle boundary; the whole field or only the non-dipole part of the field? The results obtained from several of these methods are given in Table 1.

Table 1 Westward drift (degrees  $\text{yr}^{-1}$ )

	1975 (ref. 1)	1942.5–1962.5 (ref. 2)
Centred dipole	0.06	0.09
Eccentric dipole	0.05	0.29
Richmond's method (ref. 8):		
Whole field ( $Z$ )	0.09	0.13
Whole field ( $B$ )	0.10	0.15
Non-dipole field ( $Z$ )	0.13	0.21
Non-dipole field ( $B$ )	0.12	0.17
Yukutake's method (ref. 9):		
Whole field	0.07	0.14
Non-dipole field	0.10	0.24

Fig. 2 Westward drift in degrees  $\text{yr}^{-1}$ . *a*, From length-of-day data; *b*, for the eccentric dipole. Point for 1970 *b* as in Fig. 1.

Although the different estimates vary considerably, they all agree that the westward drift is much smaller in 1975 than it was during the interval 1942.5–1962.5, by a factor of two on average. The main reason for this is the diminution in the secular variation of the  $h_2^1$  term, which has for many years been the major contributor to westward drift, and accounted for the large apparent difference between the drift rates of the dipole and non-dipole parts of the field noted in the past. A more reasonable division might have been into  $h_2^1$  and non- $h_2^1$  parts of the field. Traditionally, the westward drift has been interpreted as the difference between the rotation rates of the outer layers of the core (where the field originates) and the mantle. If that were so, the recent reduction in westward drift would imply either a transfer of angular momentum from the mantle to the core—which should be accompanied by an increase in the length of the day—or a redistribution of angular momentum within the core. Following Vestine and Kahle<sup>10</sup> we have adopted the former interpretation, calculated the westward drift that would account for the observed length of day (Fig. 2*a*), and compared this with the observed westward drift of the eccentric dipole (ref. 4 and Fig. 2*b*). The mean ordinate of Fig. 2*a* is arbitrary, and

its scale can be adjusted by altering the thickness of the layer of outer core to which angular momentum is transferred. We have chosen values that bring the recent portions of curves *a* and *b* close together, but to achieve that the thickness of the core layer had to be reduced to the improbably low value of 100 km. Even so, there seems to be little correlation between the two curves, and we conclude that a direct relationship between the westward drift and the length of day has yet to be established.

Regardless of the physical interpretation of westward drift, it provides a simple concept that accounts for much of the secular change of the non-dipole part of the field (though its deficiencies in this respect have been emphasised by James<sup>11</sup>). A better approximation to the secular change is given by a simple rotation of the non-dipole part of the Earth's magnetic field about an axis other than the geographical axis<sup>12</sup>. For the 1975 model, the rotation rate is  $0.145^\circ \text{yr}^{-1}$  in a clockwise direction (when viewed from above) about an axis with its pole at  $(76.1^\circ \text{N}, 273.0^\circ \text{E})$ . The close proximity of this pole of rotation to the dip pole is attributable to chance, as may be seen by examining earlier positions for the pole of rotation<sup>13</sup>. This latest result confirms and extends the trends discussed by Malin and Saunders<sup>13</sup>.

We thank Mr. L. V. Morrison of Her Majesty's Nautical Almanac Office for providing us with length of day data.

## Possible late Precambrian subduction zone in South West Africa

CONTINENTAL margin plate tectonism during the late Precambrian in southern and central South West Africa and western Botswana is strongly suggested by the geographical distribution, stratigraphy, composition and evolutionary characteristics of the pre-Damara, pre-Nama formations (1,350–900 Myr old) occurring north of the Namaqua Tectonic Province<sup>1</sup>. If the distribution of these units is considered it is apparent that a unique pattern exists (Fig. 1). The data for the generalised geological map of Fig. 1 are taken from various sources<sup>2–9</sup> and show: first, the distribution has the form of a prominent and extensive curvilinear feature or 'arc'. Second, the arc separates the undeformed late Precambrian deposits (Nama Group<sup>10</sup>) of the stable platform area—the Kalahari Craton or Plate—from the highly deformed and metamorphosed deposits of the late Precambrian Damara orogenic belt, suggesting that the arc occupies a marginal cratonic position, and third, the trend of the arc and arc structures (such as major faulting) parallels that of the Damaran structural trends, suggesting a possible relationship between the geotectonic development of the arc and the Damaran Orogeny (see Fig. 1).

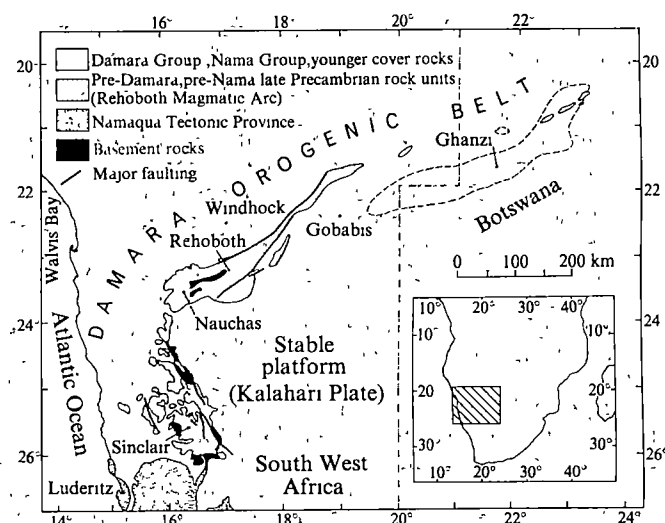

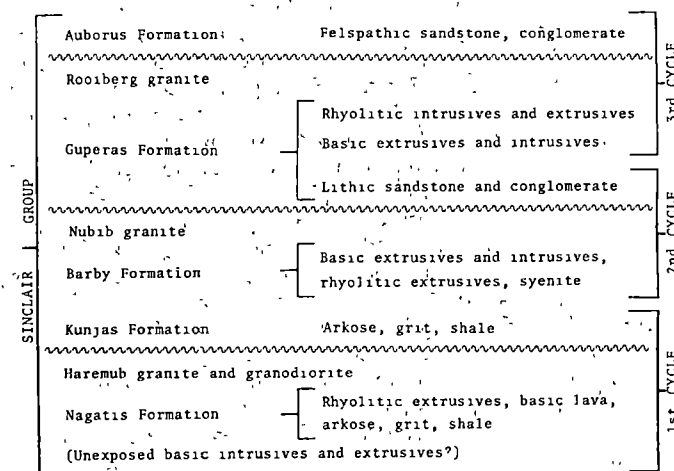

Fig. 1 Distribution of the pre-Damara and pre-Nama late Precambrian formations in southern and central South West Africa and western Botswana.

The various units comprising this late Precambrian arc consist essentially of highly variable sequences of basic, intermediate and felsic lava and volcanoclastics, as well as thick sedimentary deposits which are frequently of obvious local provenance. The sequences were extruded on to and deposited on an older sialic basement of unknown age and were intruded by large amounts of comagmatic high level granitic, rhyolitic and basic to intermediate material. The name Rehoboth Magmatic Arc has been proposed for this volcano-plutonic belt<sup>6</sup>.

The best exposed and most intensively studied part of the belt is the southern portion which is the type area for the Sinclair Group<sup>9</sup>, the geological succession of which is summarised in Fig. 2. The evolution of the Sinclair Group proceeded within three major cycles. The basis for this cyclic subdivision is seen in a repeated pattern of development. The generation and emplacement of basic to intermediate magma into and on to the continental crust, followed by the generation and emplacement of felsic magma into high crustal levels, subsequent vertical tectonics and production of local fault trough basins, followed by erosion of the earlier igneous units and rapid deposition of immature clastic debris into the local basins. The cycle ends with a period of relatively little faulting and tilting.

Basic and intermediate volcanism is shown by extensive piles of calc-alkaline and, to a lesser extent, tholeiitic,

Fig. 2 Geological succession and evolutionary cycles of the late Precambrian Sinclair Group, South West Africa.

flows, building up locally to thicknesses of 8,000 m within individual cycles. The calc-alkaline lavas are characteristically highly porphyritic (plagioclase feldspar and/or pyroxene) and range from 'normal' basalts, basaltic-andesites and andesites to highly potassic varieties having all the compositional and modal characteristics of shoshonites<sup>11,12</sup>. Basic intrusives are comagmatic and represented by tholeiitic gabbros often displaying igneous layering, by basaltic dykes and by bodies of calc-alkaline porphyritic basalt, gabbro, diorite, monzonite and syenite.

Felsic units are high level granite plutons and batholiths, rhyolitic dykes, plugs, domes, flows and volcanoclastics. A distinct compositional break exists between the felsic and basic igneous rocks of the Sinclair Group, and the available evidence indicates that the felsic magmas represented the first products of melting of predominantly lower crustal material<sup>9</sup>. Heat for the fusion process was evidently supplied by the enormous volumes of basic magma transported through the crust, resulting in the basic, followed by felsic, succession, of magmatic events found in the various evolutionary cycles of the group. The apparent lack of an extensive basic magmatic event initiating the first cycle could conceivably be attributable to emplacement of magma into a relatively cool crust and consequent rapid and early chilling, with only minor volumes of basic magma reaching the surface. Furthermore, the emplacement and deposition of the younger units has largely obliterated evidence for the early stages of the first cycle.

Cessation of magmatic activity within each cycle was followed by periods of intense erosion of local volcanic piles and exposed plutons with the deposition of immature clastic debris into local basins which began forming toward the latter stages of the felsic magmatic events. The basins were the result of vertical movement along extensive faults paralleling the general trend of the Rehoboth Magmatic Arc, which in the Sinclair Group type area, is approximately north-north-west.

Other parts of the arc provide evidence for similar evolutionary patterns to that of the Sinclair Group<sup>3,4,6-8</sup> although never as complete or as well preserved; the ENE trending sector has been involved to varying degrees in the younger Damara tectonism, with thrusting and shearing to the SSE. Sequences are typically of limited lateral extent with interfingering relationships, consisting of thick piles of basic, intermediate and felsic volcanics, and immature clastics; comagmatic intrusion is extensive. Granodiorite and quartz diorite (as opposed to highly siliceous granites) are, however, more common within the Nauchas-Rehoboth sector of the arc than in the Sinclair Group type area.

I regard the characteristics of the Rehoboth Magmatic Arc and its constituent units as reasonable evidence for the presence of a subduction zone active during late Precambrian times beneath the western and north-north-western margin of the Kalahari Plate. In terms of modern plate tectonics a requisite for continental margin tectonics is the presence of a stable plate, and the Kalahari Plate has certainly remained essentially undeformed since Sinclair Group times (since ~ 1,350 Myr), inferring that the craton had acquired its present stable and consolidated nature before the development of the Rehoboth Magmatic Arc.

The well-defined curvilinear shape, situated at the edge of a highly stable continental plate, thick piles of tholeiitic, calc-alkaline and shoshonitic extrusives and comagmatic intrusives, voluminous 'granite' batholiths and rhyolitic lava, intrusives and volcanoclastics, episodic or pulsing development, vertical tectonics paralleling the trend of the arc, and rapidly deposited immature clastic debris of local provenance, are all characteristics of the Rehoboth Magmatic Arc that are common to young continental margin plate tectonic regimes<sup>13,16</sup>.

It is suggested, therefore, that the presence of this volcano-plutonic arc can be used to define roughly the position

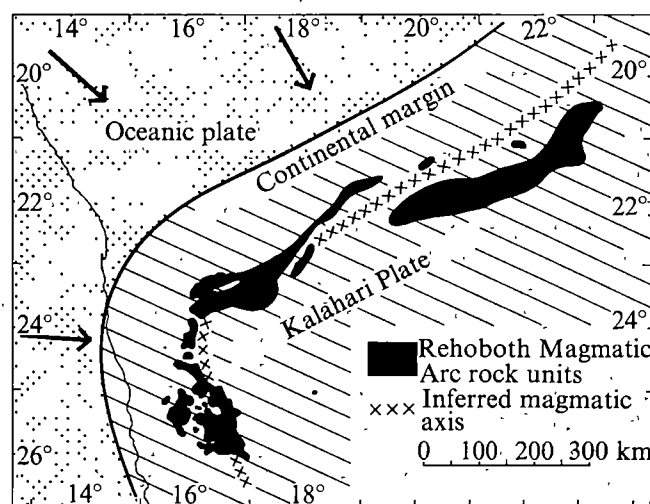

Fig. 3 Suggested reconstruction of the geotectonic setting that may have prevailed during the evolution of the late Precambrian Rehoboth Magmatic Arc, superimposed on a sketch map showing the present-day distribution of the Arc units. Arrows indicate the approximate directions of plate movement.

of the margin of the Kalahari Plate during immediately pre-Damara times. The distance between the continental margin and the axis of a volcano-plutonic arc developed above a subduction zone at a continental margin has been estimated to be in the order of  $225 \pm 50$  km (ref. 17). To the west of the Sinclair area (the southern sector of the Rehoboth Magmatic Arc (Fig. 1)) younger Damara rocks are encountered 180 km to the west along the present coastal regions of South West Africa. It is probable, therefore, that these younger rocks delineate fairly accurately the position of the continental slope regions of the Kalahari Plate during the late Precambrian. In the east-north-east trending sector of the arc, thrusting of the Damara Group units (during the Damara Orogeny) to the south-south-east over the magmatic arc units has occurred and the original position of the continental margin is a matter of speculation. A suggested reconstruction of the Kalahari Plate margin and prevalent geotectonic setting during evolution of the late Precambrian Rehoboth Magmatic Arc is presented in Fig. 3.

The model proposed here for the evolution of the Rehoboth Magmatic Arc may have far-reaching implications for the development of the Damara Belt, because it implies an oceanic crust during pre-Damara times in the area that is now overlain by the Damara Group. Oceanic crust in the area during the late Precambrian would be consistent with a paratectonic or collision origin for the Damara, as suggested for all pan-African orogenic belts by Burke and Dewey<sup>18</sup>. Such a model can, therefore, reconcile the apparently conflicting evidence for the origin of the Rehoboth Magmatic Arc by continental margin subduction, with the supposed ensialic character<sup>19</sup> of the following Damara orogenic event.

## A novel beryllsilicate phase containing 3-coordinate beryllium ( $\text{Rb}_2\text{Be}_2\text{Si}_2\text{O}_7$ )

BERYLLSILICATES are normally framework structures, with Be in tetrahedral coordination, similar to Si (ref. 1), and the structural role of Be can be compared with that of Al in the aluminosilicates. We report here on the preparation and X-ray crystal structure determination of  $\text{Rb}_2\text{Be}_2\text{Si}_2\text{O}_7$ , which contains planar  $\text{BeO}_3$  groups. Such coordination is unusual for beryllium, and, in complex oxides, has apparently been found previously only in  $\text{Y}_2\text{BeO}_4$  (ref. 2),  $\text{Ca}_{12}\text{Be}_{17}\text{O}_{29}$  (ref. 3), and  $\text{K}_2\text{BeO}_2$  (ref. 4).

The compound  $\text{Rb}_2\text{Be}_2\text{Si}_2\text{O}_7$  was prepared by solid-state reaction between appropriate quantities of  $\text{Rb}_2\text{CO}_3$ , BeO and quartz. A single crystal was selected from a sample which had been heated at 950 °C for three days. The orthorhombic cell dimensions are

$$a = 8.92 \text{ \AA}; b = 8.32 \text{ \AA}; c = 5.15 \text{ \AA}$$

The intensity data, obtained from a Hilger and Watts Y-190 linear diffractometer with  $\text{MoK}\alpha$  radiation, indicated a body-centred space group. The solution of the vector (Patterson) map indicated the space group to be  $\text{I}2\text{mm}$ . Later, a few, rather weak, additional reflections were observed on films, and the space group  $\text{P}2_1\text{nn}$  was adopted. The complete solution of the structure using vector and Fourier methods, followed by least squares refinement, has so far given values of  $R = 0.071$ , over 241 independent reflections.

The structure consists of  $\text{Si}_2\text{O}_7$  groups, linked at their corners by Be, to form an infinite framework anion of empirical formula  $[\text{Be}_2\text{Si}_2\text{O}_7]^{2-}$ . Large cavities contain two crystallographically distinct  $\text{Rb}^+$  ions, which have 13 and 14 nearest neighbour oxygen atoms (within 3.8 Å), respectively. In the planar  $\text{BeO}_3$  group, Be–O distances are around 1.54 Å, which is about 0.11 Å shorter than those in tetrahedral  $\text{BeO}_4$  (ref. 5); O–Be–O angles are close to 120°.

X-ray powder diffraction data suggest that  $\text{Cs}_2\text{Be}_2\text{Si}_2\text{O}_7$  is isostructural with  $\text{Rb}_2\text{Be}_2\text{Si}_2\text{O}_7$ .

## Coccolith blooms in the Kimmeridge Clay and origin of North Sea Oil

IN this paper I suggest that Kimmeridge Clay oil shales (and therefore much of the oil in the North Sea) were formed from algal blooms, in an environment between open ocean, and an enclosed marine basin. These conditions favour the production of such blooms, which by deoxygenating and poisoning the water, could temporarily create bottom conditions suitable for the formation of organic-rich sediment.

Thin coccolith-rich bands were first noted in the Kimmeridge Clay by Downie<sup>1</sup>, at four levels in the cliff sections near Kimmeridge Bay, Dorset. The most prominent of these bands, the White Stone Band, was subsequently recorded in boreholes in Hampshire, Surrey, Sussex<sup>2</sup> and Norfolk<sup>3</sup>.

Coccolith-rich bands of a similar nature have recently been recorded at three levels in a borehole at Donington on Bain, Lincolnshire, each level corresponding with one of the higher levels in Dorset. Re-examination of borehole material from Surrey and Norfolk has shown that the same three horizons are present in Surrey, and that the lowest two of these are present in Norfolk (Fig. 1). Thus, these coccolith-rich bands occur over an area where the Kimmeridge Clay varies in thickness from < 100 m to > 500 m, and which embraced both the stable margins and the more rapidly subsiding parts of the basin of deposition.

The coccolith-rich bands are readily recognisable in borehole cores by their pale colour and lightness in weight, and at outcrop by their almost white weathering patina. In Dorset the thickest band is ~ 0.5 m thick, but elsewhere the three bands are each generally < 0.1 m thick. The coccolith contents of these bands ranges from 60–98% of the calcium carbonate fraction of the rock (30–> 50% of the whole rock). Most other Kimmeridge Clay lithologies contain < 3% coccoliths/whole rock, although some of the more calcareous clays have yielded up to 12.5% coccoliths/whole rock.

The coccolith-rich bands are generally composed almost wholly of one species, *Ellipsagelosphaera britannica* (Stradner)<sup>3</sup>. Even now, seasonal blooms of coccoliths consisting largely of one species occur from time to time over large areas of the North Sea<sup>4</sup>. Such blooms characteristically form in seas which are rich in land-derived nutrients and are to some degree land-locked so that, although they remain a fully marine environment, their salinities are slightly lower than those of the open oceans. The persistence and composition of the thin coccolith-rich beds in the Kimmeridge Clay suggests that they were formed from similar blooms.

In addition to their usefulness as stratigraphical marker beds the coccolith-rich bands may provide an insight into the conditions of depositional environment in which the Kimmeridge Clay oil shales were deposited, since each of the coccolith-rich bands recorded to date occurs in close association (usually interlaminated) with oil shales.

Although they vary considerably in thickness, the Kimmeridge Clay sequences in Dorset, Surrey and Norfolk can be matched with one another in lithological and faunal detail<sup>3</sup>, suggesting that ecologically similar environments existed over much of southern England, in spite of great variations in rate of subsidence of the sea floor. The distribution of the Kimmeridge Clay lithologies and fauna, mostly pelagic ammonites and benthonic bivalves, including oysters, preserved in calcite, suggests accumulation in a relatively shallow marine environment on a broad continental shelf. The oil shales contain a richer and more abundant fauna than any other lithology in the Kimmeridge Clay. They are characterised by bedding planes crowded with one or two species of small bivalve or ammonite preserved in either calcite or pyrite, and by small gastropods, phosphatised fish debris and faecal pellets, abundant Foraminifera and, locally, by pyritised plates of the free-swimming crinoid *Saccocoma*.

In Dorset the oil shales contain ≤ 40% of brown organic matter which Forsman<sup>5</sup> has described as composed mostly of kerogen. This kerogen occurs largely as laths of amorphous organic matter (AOM) but is rich in palynomorphs such as dinoflagellates<sup>1</sup>. Cosgrove<sup>6</sup> recorded abnormally high iodine and bromine contents in some of the oil shales from the Kimmeridge Clay in Dorset, and has related this to the abundance of microplankton present.

According to Trask<sup>7</sup>, few modern typically marine sediments contain more than 10% of organic matter; near-shore sediments generally contain between 1% and 8% and open-ocean sediments ~ 1%. Kaplan and Rittenberg<sup>8</sup> state that the

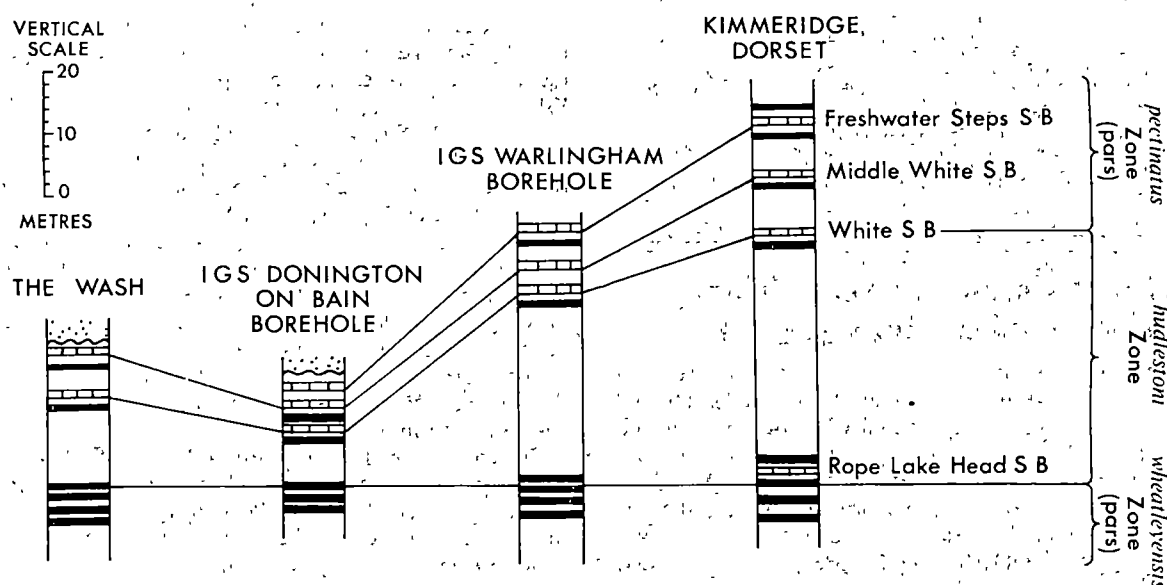

Fig. 1 Correlation of coccolith-rich bands referred to in the text

highest organic content recorded now in any marine environment is 23.4% in one of the Norwegian fjords. The oil shale fauna, although limited in variety, is fully marine, and clearly does not represent an anaerobic bottom environment comparable to that of any modern closed or restricted basin.

The apparent paradox of substantial amounts of organic material being preserved in sediments which, on general faunal and sedimentary grounds, seem to have been laid down in a shallow, marine environment was first recognised by Hallam<sup>9</sup> in the Lias. The solution he suggested was that of anaerobic bottom conditions developed beneath a layer of undisturbed, effectively stagnating, seawater<sup>9,10</sup>.

There are a number of difficulties in applying this suggestion to the oil shales in the Kimmeridge Clay. First, there is evidence of a plentiful benthonic fauna in the oil shales, both in the form of burrowfill structures and bivalve and gastropod shells. Second, the oil shales are thin seams (generally < 0.1 m-thick) which occur over a wide area (> 200,000 km<sup>2</sup>), apparently independent of distance from land and the overall shape of the sea floor. Thirdly, the oil shales occur in juxtaposition (commonly interburrowed) with a variety of lithologies which must represent a variety of differing bottom conditions.

The stagnant bottom conditions hypothesis could explain very local occurrences of oil shale within a single basin of

deposition containing variable bottom conditions, or could explain widespread occurrences within a basin containing uniform conditions. It does not, however, explain the widespread occurrences in the Kimmeridge Clay, which embrace several depositional basins containing variable conditions. Nor does it explain the characteristic association of these oil shales with the occurrences, in flood proportions, of the pelagic flora and fauna of coccoliths, Foraminiferida, ammonites and the crinoid *Saccocoma*.

Dinoflagellate blooms have been recorded from a number of present-day localities, mostly on continental shelves, where their relationship to modern AOM-rich sediments has been studied. The abundance and types of palynomorph present in any given area are governed by complex and interacting factors, such as water turbulence, distance from shore, availability and proximity of river effluence and upwelling<sup>11</sup>. Such blooms are generally dominated by one or two species and give rise to AOM-rich sediments. The ability of certain types of dinoflagellate bloom to poison the benthonic fauna of an area is well known<sup>12</sup>, and it seems likely that if such poisoning took place on a sufficiently large scale, anaerobic bottom conditions, conducive to the formation of pyrite and phosphate, would be temporarily created.

Thus, by analogy with the origin of the coccolith-rich beds,

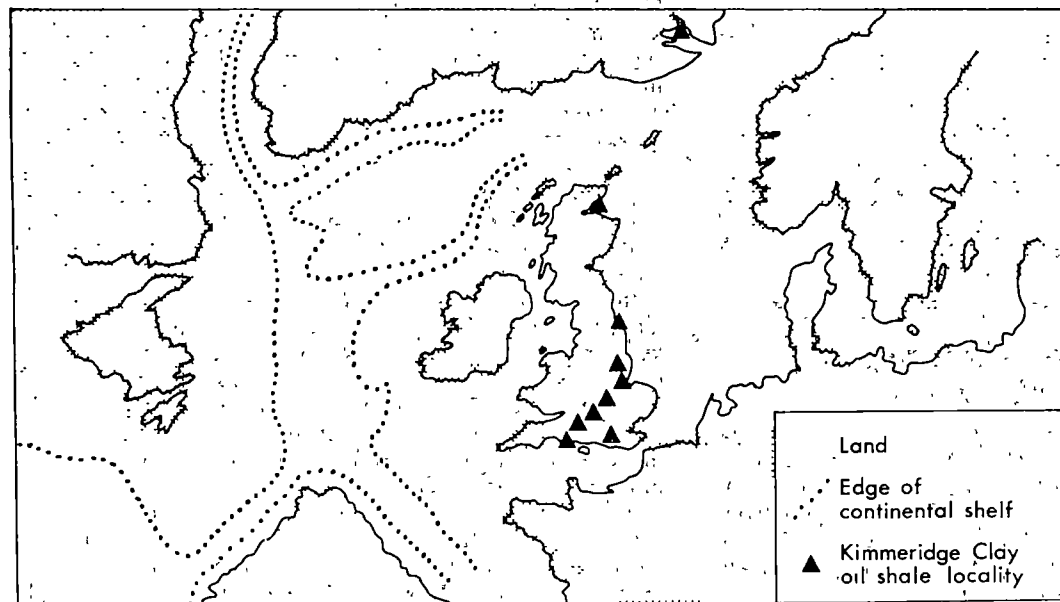

Fig. 2 Palaeogeography in middle Kimmeridge Clay times: continent fit after Laughton<sup>14</sup>.

with which they are so intimately associated, the Kimmeridge Clay oil shales appear to have resulted from algal (probably dinoflagellate) blooms. The combined faunal and sedimentary evidence suggests that the organic content of the shales is largely derived from blooms, and that the blooms themselves, by deoxygenating and poisoning the water, provided the temporary anaerobic bottom conditions required to ensure the preservation of their organic content. It is perhaps significant that one of the bivalves most affected by the 1968 toxic bloom off the east coast of Britain was *Lucinoma borealis* Linne<sup>12</sup>, and that the bivalve which forms the most extensive plaques in the Kimmeridge Clay oil shales is '*Lucina*' *minuscule* Blake.

Thick oil shale seams occur only in the upper part of the Lower Kimmeridge Clay and the lower half of the Upper Kimmeridge Clay. At these levels the fauna is less diverse than that at lower levels in the Kimmeridge Clay, and seems to represent a less open marine environment. The highest Kimmeridge Clay, above the Rotunda Nodule Bed, contains little bituminous matter and was probably deposited in an even more restricted basin which formed as a result of the Middle Volgian earth movements<sup>13</sup>.

The Kimmeridge Clay oil shales appear therefore to have been deposited in an environment intermediate between open ocean and restricted marine basin at a time when the delicate balance between palaeogeographical influences and nutrient supply was particularly favourable to the formation of algal blooms. The palaeogeography in Kimmeridge Clay times was probably not unlike that of the present-day North Sea, with a series of subsiding basins linked by relatively narrow straits between land areas of low relief (Fig. 2). In the Mesozoic rocks of the British land area, similar palaeogeographical conditions seem to have existed only in the Lias and the Oxford Clay, and the bituminous bands in those formations may have a comparable origin to those of the Kimmeridge Clay.

The likelihood of the Kimmeridge Clay being a major oil source rock off the western coast of Britain would seem to be largely dependent on the nature of the Kimmeridgian palaeogeography. If this area had access to a fully oceanic environment of a proto-Atlantic sea (Fig. 2), then the prospect of thick oil shale seams and a major oil source occurring at this stratigraphical level is unlikely to be high.

I thank Dr A. W. Medd who determined the coccolith percentages.

## Dichotic verbal transformations and evidence of separate processors for identical stimuli

AFTER listening for several seconds to a clear recording of any word or phrase repeated over and over, a listener experiences illusory changes called "verbal transformations" (VTs), and hears a series of abrupt transitions, sometimes to new forms, sometimes back to the actual stimulus or to

illusory forms reported earlier<sup>1</sup>. Considerable phonetic distortion may take place, so that with the repeated stimulus 'tress' listeners can believe they are hearing clearly words as far removed as 'purse' or 'florist'. The temporary receptive aphasia and perceptual reorganisation produced by VTs have provided access to mechanisms for speech processing not otherwise available for study<sup>2</sup>. Previous investigations have been restricted to one repeated statement at a time; we have extended this research with VTs to investigate dichotic presentation of separate stimuli to each ear.

Our initial observations of dichotic VTs involved presentation of a different repeated word to each ear. We found that subjects had no trouble monitoring both ears, and that VTs seemed to occur in an uncorrelated fashion on both sides. A more interesting condition was suggested by this observation. What if the dichotic stimulus consisted of the same word delivered asynchronously to each ear? By separating the presentation of the single repeated word to each ear by exactly half the duration of the word (a few hundred milliseconds), fusion into a single auditory image would be prevented, and identical stimuli with temporal cross-ear symmetry would be received by each ear. Would VTs occur independently for each side? The answer would have some theoretical interest.

If identical reorganisation to another word occurred at the same time in each ear, it would indicate that a single processor responsible for verbal identification was being used for the input to the two ears. Convergence of dichotic verbal input on the same speech processor has been suggested by some investigators working with the "right ear advantage" effect for speech perception. In studies demonstrating this ear advantage, different verbal messages delivered simultaneously to each ear were shown to be handled asymmetrically, with input to the right ear identified somewhat more accurately<sup>3,4</sup>. In explanation, it has been suggested that there is competition for access to a single speech processor (located in the left cerebral hemisphere for most right-handed subjects), and that the pathway from the contralateral right ear is favoured over the pathway from the ipsilateral ear<sup>5,6</sup>.

Alternatively, if VTs with the temporally dichotic but acoustically identical stimuli occurred independently (so that specific repetition-induced phonetic distortions were unilateral), it would suggest that functionally separate verbal decoders or processors were handling the identical input received by each ear. This outcome would raise the possibility that the results of the earlier studies on the right ear speech advantage do not reflect favoured competition for engaging a single processor, but might rather follow from different characteristics of functionally distinct verbal processors, each handling one of the simultaneous messages.

The experimental stimuli were prepared from a single statement of the word 'tress' repeated each 492 ms by a loop of recorded tape. A dual output digital delay line was used to split the repeated signal into two identical statements separated by half the word duration (246 ms), and a two-track recording was made with this fixed asynchrony. When played back through matched stereophonic headphones, the identical statements on the two sides were temporally symmetrical, including the contralateral accompaniment for each part of a lateral statement.

Separate groups of college students were used for each experimental condition shown in Table 1, and all (diotic control and three dichotic groups) heard the word 'tress' repeated for 5 min. The 20 subjects in the diotic group listened to the repeated word from one of the recorded channels delivered synchronously to each ear. These diotic subjects were unselected for handedness, but because of the correlation between handedness and the side of the dominant speech hemisphere<sup>7</sup>, the 100 subjects used for dichotic listening were all right-handed with no left-handed

Table 1 Verbal transformations with temporally dichotic presentation of a single stimulus

	n	Transitions mean (s.e.)	Forms mean (s.e.)	Proportion of simple changes*
'Tress' (diotic)	20	39.5 (4.90)	6.00 (0.62)	0.418 ± 0.035
'Tress' (dichotic, report one)†				
Right only	40	26.1 (3.38)	5.58 (0.49)	0.289 ± 0.028
Left only	40	23.0 (2.73)	5.50 (0.57)	0.371 ± 0.032
'Tress' (dichotic, report both)†				
Right response	20	14.7 (4.31)	4.15 (0.44)	0.186 ± 0.046
Left response	20	7.1 (1.25)	3.30 (0.26)	0.369 ± 0.086
Total (right + left)	20	21.8 (5.06)	4.85 (0.36)	0.242 ± 0.043

\*The range given for proportion of simple changes corresponds to the 95% confidence intervals.

†Delivery to each ear separated by half the duration of the repeated word.

siblings or parents. The instructions were similar to those used in earlier studies<sup>7</sup>. Subjects called out what the voice said, and any changes heard; the experimenter wrote down all responses, later checking the transcription against a tape recording. Forty dichotic subjects were instructed to report only words heard on the right side ('report right'); another 40 were instructed to report only words on the left ('report left'). The final (and most interesting) group consisted of 20 subjects who were instructed to monitor both ears ('report both') and to report all changes, using a hand-operated indicator to show the side on which each reported change occurred. This group did not find it difficult to monitor both ears.

The major finding was that VTs occurred independently on each side. Each of the 20 subjects listening dichotically and monitoring the identical stimuli on both sides reported hearing phonetically different words on the two sides at the same time for some period during the test. As an example, a listener reported hearing the stimulus change from 'commence' back to 'tress' in one ear while the other continued to hear 'tress' repeated over and over. Such independent changes demonstrate that separate speech processors operating up to the level of syllables or words were handling the identical input to each side.

By examining the characteristics of verbal reorganisations under the various experimental conditions, we can compare properties of these processors. In keeping with earlier studies, the results summarised in Table 1 are scored in terms of transitions (perceptual changes) and forms (different perceptual organisations). Individual scores for these two measures are not correlated: as long as an individual reports at least two forms he can achieve a high transition score by rapid changes from one form to the other. After logarithmic transformation<sup>7</sup>, analysis of variance showed that transition scores were significantly higher for diotic listening than for report left, and also significantly greater than left and right combined for report both ( $P < 0.05$ ). There was no appreciable difference between report right and report left only, and for report both, the difference between the right response and the left response, although sizeable, was not significant. The decrease in numbers of illusory changes observed for dichotic relative to diotic listening may involve attentional factors related to the greater complexity and difficulty of the dichotic task. An earlier study<sup>1</sup> indicated that making the task more difficult by the addition of masking noise to a diotic signal also decreased the rate of VTs.

An analysis of variance for numbers of forms showed no significant differences between any of the groups. But if we consider the nature of the changes made by individuals when going from one form to the next, an interesting difference is found. When a listener hears the stimulus word 'tress' change to 'dress' or the illusory word 'frazzle' change to 'trazzle', we have examples of a simple change with one phoneme transformed in each case. Complex changes involve two or more phonemes, and may be as

extreme as the transition reported from 'stress' to 'conniving' in which all phonemes change. The proportion of simple changes for group totals in each experimental condition is shown in Table 1, together with the 95% confidence limits for each proportion. The proportion of simple changes for diotic stimulation was significantly greater than right and left combined for the dichotic report both condition. Within the dichotic report both group, the proportion of simple changes was significantly greater for left than for right reports, as if the left side were more conservative.

Using the asynchronous identical stimuli, it was necessary to introduce each to separate ears to obtain independent VTs. If the outputs of the two stimulus channels were mixed and then introduced dichotically to both ears, the mixed signal was not intelligible. With continued listening, the mixed input became organised into a clearly heard single word which then underwent illusory changes characteristic of repeated single words.

Little is known concerning the nature of neural decoding of speech signals; our experiments with dichotic verbal transformations do not inform us of the spatial relation of the separate processors, but merely of their presence and characteristics. It seems that, since more than one processor can be used for identical auditory inputs, we need not consider that the right ear advantage, reported by many investigators for dichotic messages, reflects competition for a single processor as is commonly believed. It seems rather that, if one processor is occupied with a particular task, others may be assembled for similar analyses. The number of potential verbal processors may not be limited to two: in a preliminary experiment with James Bashford we delivered three asynchronous versions of one repeated word through headphones. Each version was preceded and followed by other versions separated by one-third the word duration, with one sequence of the repeated word heard on the left, one on the right and one in the medial plane (the centre signal was delivered dichotically; the lateral signals corresponded to separate monaural delays). Monitoring all positions was more difficult with three than with two statements, but all five experienced listeners tested heard the three versions each change independently.

This study was supported in part by the National Institutes of Health and by the University of Wisconsin-Milwaukee-Graduate School.

## Correspondence between sharp tuning and two-tone inhibition in primary auditory neurones

THE sharp frequency selectivity of single primary auditory neurones in mammals contrasts with the poor mechanical tuning of the basilar membrane<sup>1,2</sup>. This discrepancy has generally been explained by postulating some filter mechanism interposed between the basilar membrane and the excitation of auditory afferents<sup>3,4</sup>. A further property of these neurones which probably cannot be explained by basilar membrane behaviour alone is two-tone inhibition whereby the simultaneous presentation of a second tone reduces the response of a neurone to a first tone at the best, or characteristic frequency<sup>5-7</sup>. It has been suggested that this inhibition may also be a property of the additional cochlear mechanisms which follow the basilar membrane<sup>8</sup>. I now present evidence that the loss of sharp frequency selectivity of primary neurones is intimately linked to changes in two-tone inhibition and that the two phenomena might be related to a common mechanism which is vulnerable to perilymph removal.

In 15 guinea pigs anaesthetised with Nembutal, data were collected from 57 single primary neurones in the spiral ganglion of the cochlea<sup>9</sup>. The measure of frequency selectivity estimated from the conventional tuning curves was the  $Q_{10\text{ dB}}$  value (the characteristic frequency divided by the bandwidth of the tuning curve 10 dB above threshold at the characteristic frequency). Two-tone inhibition was studied in the same neurones by computing time histograms of the number of action potentials in response to tone bursts. The first tone at the characteristic frequency was presented for 50 ms while the second, inhibiting tone, started 10 ms after the first and lasted for 30 ms (see Fig. 1). Both tones had rise-fall times of 5 ms. The inhibitory regions on either side of the characteristic frequency were mapped out as completely as possible in the time available for each unit. Inhibition was designated "strong", "weak" or "absent" when the second tone, when maximally effective, could reduce the firing rate to the first tone by either more than 50%, by less than 50%, or not detectably, respectively. The first tone was fixed at an intensity of 10-15 dB above the characteristic frequency threshold.

For 33 neurones, the inhibitory regions were thoroughly studied and the strength of inhibition determined by the above criteria and compared with variations in the sharpness of the single-tone tuning curves found from one animal to another<sup>9,10</sup>. These data, shown in Fig. 1, reveal a close association between the sharpness of neural tuning and the strength of two-tone inhibition.

Furthermore, the removal of perilymph from the scala tympani caused a reversible loss of sensitivity of about 20 dB and a broadening of the tuning curve in cells held throughout the procedure<sup>11</sup>. In all the cells observed, this effect was accompanied by the disappearance of two-tone inhibition (Fig. 2). Complete data were obtained from four cells in three animals with partial confirmation from other cells. Allowing the perilymph to refill the scala tympani caused a rapid return of sharp tuning and two-tone inhibition. Intensities of characteristic frequency tone less than 10 dB above threshold were tried in the drained cochlea, to see if inhibition was perhaps still present but weak. No inhibition could be demonstrated. A complete range of intensities of the second tone were also used, also

Fig. 1. Tracing shows an example of strong two-tone inhibition in a single spiral ganglion. The approximate positions of the two-tone bursts are shown above the tracing. Three sweeps of the oscilloscope are superimposed. The graph shows the relationship between the sharpness of tuning curves (the  $Q_{10\text{ dB}}$ ) and the strength of two-tone inhibition (see text) for 33 cells in 15 animals.

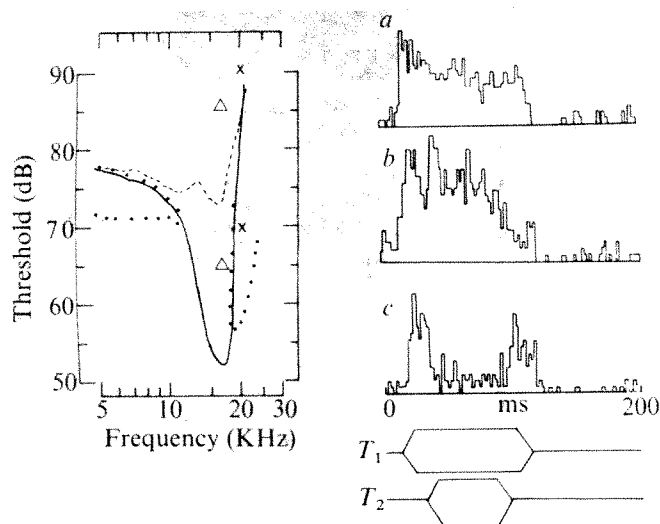

without demonstrating any appreciable inhibition. Thus two-tone inhibition was totally absent on both the high and low-frequency sides of the abnormally drained tuning curves.

One explanation that should be considered for these results is that the inhibition is lost because the lower slopes of the broadened tuning curves cause an encroachment of the excitatory areas into the inhibitory regions. This is certainly a possibility for the portion of the low frequency slope where the slope changes dramatically during drainage.

For the high frequency slopes, part of the inhibitory regions shown in the tuning curve of Fig. 2 would still fall outside the abnormally broad tuning curve, even if they too were elevated by 20 dB by perilymph drainage. All combinations of characteristic frequency and second tone failed to elicit inhibition. Figure 2b illustrates the only effect that can be produced by the second tone in the drained cochlea. This is an excitatory effect superimposed on the response to the characteristic frequency tone as the intensity of the second tone crosses the boundary of the abnormally broad tuning curve.

Though a more detailed mapping of inhibitory regions than was possible in the present study may reveal some encroachment of the broad tuning curve on to inhibitory regions on the high frequency slope, I believe the present results are sufficient evidence for a genuine loss of two-tone inhibition associated with loss of sharp frequency selectivity.

Thus, loss of sensitivity, loss of inhibition and loss of sharp frequency selectivity seem to go hand in hand. These parallel variations might be explained by alterations in the functioning of a common mechanism. The dramatic and reversible effects of perilymph removal on both frequency selectivity and two-tone inhibition throw some light on the cochlear mechanisms which follow the broad tuning of the basilar membrane. It has been known for some time that the frequency selectivity of primary auditory neurones cannot be related to neurochemical synaptic interactions between

**Fig. 2** Graph on left shows the effect of perilymph removal on the tuning curve of a single ganglion cell. Solid line is the tuning curve before drainage, broken line is the curve with perilymph removed. The dotted lines demarcate the inhibitory regions for the cell in the normal case. *a*, *b* and *c* are histograms of the response of the same cell to 20 presentations of characteristic frequency ( $T_1$ ) and inhibitory tone ( $T_2$ ). *a*, The initial response to  $T_1$  alone at 17 kHz, 67 dB. *b*, Response with perilymph removed to  $T_1$  now 85 dB and  $T_2$  at 20 kHz, 90 dB. The excitatory effect seen during  $T_2$  presentation is the only form of interaction seen. *c*, Response to the same two frequencies with perilymph replaced.  $T_1$  now 65 dB,  $T_2$  70 dB. Strong inhibition is seen. Sound pressure is measured at the tympanic membrane (dB referred to  $0.0002 \text{ dyne cm}^{-2}$ ).

afferents<sup>12</sup>. One has therefore to consider physical mechanisms which could restrict the extent of excitatory input to these neurones arrayed along the cochlear turns. It was originally suggested that the action of perilymph removal might be to alter the mechanical response of the basilar membrane to acoustic stimulation<sup>11</sup>. Several authors have argued against this<sup>1,13</sup> and support the alternative explanation; that the underlying mechanism is an increase in the resistance of the scala tympani pathway. Such a resistance change would be expected to interfere with the spread of receptor currents between neighbouring regions of the basilar membrane. Whatever the real explanation turns out to be, the present evidence suggests that both sharp tuning and two-tone inhibition arise from the functioning of such a common mechanism.

I thank G. A. Manley of the Department of Biology, McGill University, Montreal, for support during this work and E. F. Evans for criticism of the manuscript.

## The Red Sea coral *Stylophora pistillata* is an *r* strategist

MACARTHUR and Wilson<sup>1</sup> coined the terms *r* selection and *K* selection to describe two general kinds of selection they believed could be functioning in nature (*K* refers to carrying capacity and *r* to maximal intrinsic rate of natural increase,  $r_m$ ). As originally defined, the *r* and *K* selection concepts postulated that alternative genotypes within a species possessed somewhat divergent life history characteristics: genotypes with a high  $r_m$  were suggested to have a relatively low *K* and vice versa<sup>1</sup>. Thus, *r* selection occurs in a fluctuating environment when there is no crowding and it is more important to increase the size of the population. *K* selection occurs in stable environments when population size is always near the maximum and increasing efficiency in resource use is required for the production of a few but extremely fit offspring. Pianka<sup>2</sup> extended these concepts to include comparisons of individuals of different species. He postulated that no organism is completely *r* selected or completely *K* selected, but all must reach some compromise between the two extremes. Thus, a given species could be visualised along an *r*–*K* continuum and identified by a set of *r* and *K* characteristics<sup>2</sup>.

*Stylophora pistillata* (Esper), an important scleractinian coral in the Gulf of Eilat<sup>3</sup> has most of the *r* characteristics summarised by Pianka<sup>2</sup>—success in colonising unpredictable reef habitats, rapid development, great population turnover, early reproduction, high  $r_m$ , small body size, short life span, density independent mortality (often catastrophic), wide dispersal gradient and poor competitive ability. Most of the other scleractinian corals of Eilat have the opposite characteristics (*K* strategists), or are ranked below *S. pistillata* in their proximity to the *r* end of the *r*–*K* continuum.

The coral reefs of Eilat constitute a physically controlled coral community near the reef flat (the *r* end of the *r*–*K* continuum), existing side by side with the subtidal biologically accommodated community, increasing in diversity (and environmental predictability) to a depth of 50 m (ref. 3). The relative unpredictability of the reef flat at Eilat (in the sense of Slobodkin and Sanders<sup>4</sup> and Colwell<sup>5</sup>), compared with the deep reef, may be best demonstrated by the catastrophic and extremely low tides which occur periodically but unpredictably along the northern Gulf of Eilat. Thus, in September 1970, an unexpected and extremely low tide caused 80–90% mortality of the hermatypic coral communities on the reef flats of Eilat<sup>6</sup>. In spite of its small colony size<sup>3</sup>, *S. pistillata* is among the most important

**Fig. 1** *S. pistillata* colonies growing on the shell of the gastropod *Trochus dentatus*.

frame builders of the reef flat because of its abundance<sup>7</sup>. Before the catastrophic low tide of 1970, it composed ~25% of the total living coverage of the reef flat of the nature reserve at Eilat. During the low tide, 98% of *S. pistillata* colonies on the reef flat were killed, while other abundant species were somewhat less affected<sup>8</sup>.

In such uncertain conditions, the optimal strategy is to put all possible matter and energy into reproduction, and to produce as many progeny as possible<sup>8</sup>. Histological examination of gonads, in collections made every 2 weeks for a year, revealed that *S. pistillata* breeds during the 8 months from December to July. Colonies 4.0–5.0 cm in diameter already contained ripe eggs<sup>9</sup>. Three years of periodical observations of larval settlement, development and growth indicated that colonies of this size are between 2 and 3 yr old (unpublished). The only other coral species for which estimates have been made of the time required to reach sexual maturity are *Favia doreyensis* (8 yr) and *Fungia actiniformis* (10 yr) in the Great Barrier Reef<sup>10</sup>. In general, reduction of the age for first reproduction and an increase in progeny number tend to increase  $r$  (ref. 11). Envelopment of *S. pistillata* colonies with plankton nets facilitated the capture of the released planulae, and showed

that a moderate-sized colony may produce 100–400 planulae within 2 h after sunset<sup>9</sup>.

Perhaps the most important feature of *S. pistillata* as an  $r$  strategist is that it is usually the pioneer coral species colonising 'new environments' or unexploited habitats. Such species have variously been called 'fugitive'<sup>12</sup>, 'opportunistic'<sup>13</sup>, 'colonising'<sup>14</sup>, 'weedy'<sup>15</sup>, or ' $r$  selected'. The seawater system of the Marine Biological Laboratory at Eilat provided a good opportunity to examine the fast-colonising capabilities of this species. Ninety-five colonies of *S. pistillata* were counted in 1972 on the seawater pipe (installed in 1967, 20 m long, 30 cm in diameter), and about 100 colonies on the concrete blocks used to hold down the pipe. Other hermatypic species counted on the seawater system were *Millepora dichotoma* (ten colonies), *Favia fava* (five colonies), *Cyphastrea microphthalma* (two colonies) and *Acropora variabilis* (one colony). A new seawater pipe, installed parallel to the old pipe was colonised by 45 colonies of *S. pistillata* 8 months later. In April 1975, 92 colonies of this species were recorded, and in August 1975, 173 colonies of this species were counted on the same pipe. So far, no other scleractinian corals have settled on the new pipe. Another demonstration of the opportunistic colonising character of *S. pistillata* is the fact that it may be found growing in shallow lagoons attached to the roots of the mangrove tree *Avicennia maritima*, where water temperature during low tide reaches 36 °C and salinity 48‰. It may also be found attached to the shells of mobile animals, such as the gastropod *Trochus dentatus* (Fig. 1) or to any other newly introduced foreign matter on the reef.

The growth rate of *S. pistillata* is among the fastest of the scleractinian corals in the Gulf of Eilat (Y.L., unpublished and L. Fishelson, personal communication). The growth rate of 134 colonies, of various sizes, of *S. pistillata* was studied during 815 d (May 17, 1973–August 10, 1975). Each colony was numbered by a plastic tag and length, width and height were measured approximately every 3 months. Length is chosen as the distance across a coral between the tips of the branches which are furthest apart. Width is chosen as the distance perpendicular to the length axis. Height is chosen as a measure perpendicular to the length and width axes. When colonies died during the study, 1 tagged and measured new and healthy colonies of similar dimensions growing nearby. The shape of *S. pistillata* approximates a sphere. The colonies were, therefore, divided into size groups according to the geometric mean of their radius ( $\bar{r}$ ). Although the range of the mean increase in diameter per year ( $\Delta \bar{d} \text{ yr}^{-1}$ ) was very narrow (1.9–2.5 cm), among the size groups studied (Table 1), the

**Fig. 2** Healthy colonies of *S. pistillata* (branched colony) and *F. fava* (massive colony) were brought into physical contact on October 7, 1974 (left). On January 1, 1975, the terminal tissues of the branches of *S. pistillata* which touched the *Favia* colony were seen to be killed (right). *S. pistillata* branches within a distance of 2.0–2.5 cm from the *Favia* colony were also killed, which might indicate the furthest distance the mesenterial filaments of *F. fava* can reach. Note that the differences in magnification of the two photographs are due to the use of different lenses of the Nikonos II underwater camera. The left photograph was taken with a 35-mm lens, while the right photograph was taken with a 28-mm lens.

smallest colonies increased in absolute size significantly less compared with the larger ones ( $t$  tests,  $P < 0.05$ ). The rate of growth per year of the largest size category, however, was approximately eight times slower than that of the smallest category, which might indicate that like all other organisms they grow proportionately more slowly as they age. The largest colonies of *S. pistillata* do not reach a geometric mean diameter greater than 30–35 cm (ref. 3). It is possible that when a colony reaches the size of sexual maturity (diameter of 4.0–5.0 cm) much of its energy is channelled into the production of sexual cells rather than growth, which considerably lowers the growth rate. Regeneration in this species is also very fast: some accidentally broken branches grew 5.0–7.0 cm yr<sup>-1</sup>. During this study, 80–85% of the original population of *S. pistillata* died. The causes of mortality were mainly abiotic (winter storms or heavy sedimentation). Nevertheless, many new colonies settled in the same study area. Thus, *S. pistillata* has a short life span and high population turnover in comparison to the other coral species in the same area.

Although the vast majority of the hermatypic corals at Eilat are limited to the deep reef (20–50 m depth) and are rare, *S. pistillata* is very abundant and shows a wide range of dispersal, from the lagoon to the deepest point of the reef. When space becomes limiting, however, *S. pistillata* is the first to be competitively excluded by the deep reef coral specialists.

The area exposed to light is one of the most important limiting factors on a coral reef. Corals compete with each other for available space in various ways<sup>10</sup> one of which takes the form of aggressive behaviour<sup>10</sup>. Observations and experiments (Fig. 2) with *S. pistillata* rank this species among the lowest in aggressive hierarchy. That is, on physical contact with most of the other hermatypic corals it is competitively excluded. Abundant species which occur together with *S. pistillata* on the reef flat proved to be more aggressive. Thus, species such as *F. favus*, *Platygyra lamellina*, *Echinopora gemmacea*, *Goniastrea retiformis*, *Pocillopora danae*, *M. dichotoma*, and many others can be seen to extrude their mesenterial filaments and digest away the living tissue of the neighbouring *S. pistillata*. No damaging effects have been observed, however, when several colonies of *S. pistillata* were brought into physical contact with each other.

I thank Y. Schlezinger and Miss L. Horowitz for technical assistance and B. Rinkevich and Y. Benayahu for discussion and comments on the manuscript. This work was partially supported by the Israel Council for Research and Development, and the United States-Binational Science Foundation.

## Cell differentiation by 3',5'-cyclic AMP in a lower plant

Cyclic AMP evokes or mediates a multitude of responses in animals and microorganisms<sup>1,2</sup>. Whereas the occurrence and regulatory role of cyclic AMP in these organisms is well established, little is known about its role in plants. Cyclic AMP has been reported to mimic certain effects of gibberellins, indoleacetic acid (IAA) and phytochrome in higher plants but in no case has its endogenous presence been unequivocally demonstrated<sup>3,4</sup>. We describe here a new response of cyclic AMP at the cellular level in the moss protonema; the results show that it is involved in the differentiation of chloronema cells. The intracellular level of cyclic AMP in these cells is four- to sevenfold higher as compared with that in caulonema cells. In a leaky chloronema-repressed mutant isolated by us, cyclic AMP is shown to enhance the differentiation of chloronema filaments.

The protonema constitutes the juvenile phase in the life cycle of a moss and has been widely used for studies on cell differentiation<sup>5</sup>. In the moss *Funaria hygrometrica*, two distinct cell types are formed during protonema development<sup>6,7</sup>. A spore germinates producing a multicellular filament. Each chloronema cell contains a large number of chloroplasts and has septa at right angles to the longer axis. Later, caulonema cells are formed; these have fewer chloroplasts and show oblique septa. The buds (initials of moss plants) differentiate only on caulonema cells and their formation is enhanced by cytokinins<sup>7</sup>. The protonema can also be regenerated from any part of a gametophore or a sporophyte, but caulonema cells always differentiate only after the chloronema cells have been formed<sup>8,9</sup>.

The experiments were carried out with the wild-type cell line J-2 of the moss *Funaria hygrometrica* (L.) Sibth grown in axenic cell suspension cultures<sup>10</sup>. In the absence of

Table 1 Effect of cyclic AMP and IAA on the differentiation of chloronema and caulonema filaments

Cells were cultured in minimal medium (MM) at  $26 \pm 2^\circ \text{C}$  in continuous light at an initial cell density of  $20 \text{ mg l}^{-1}$  as described previously<sup>10</sup>. Cyclic AMP sterilised by filtration through membrane filters was added to the autoclaved MM  $\pm$  IAA. After 6 d, at least 500 filaments were scored to determine the proportion of chloronema filaments.

exogenous auxins, protonema grown in liquid culture consist predominantly of chloronema filaments. Auxins enhance the differentiation of caulonema filaments<sup>11</sup>. In cultures grown in the presence of IAA, adenine derivatives other than cytokinins were observed to enhance the differentiation of chloronema filaments, thus antagonising the effect of IAA.

Formation of chloronema filaments was profusely enhanced by cyclic AMP and at a concentration of  $100 \mu\text{M}$ , their percentage was restored equal to that in control (Table 1). This increase was due to initiation of a large number of new chloronema branches and not due to a dedifferentiation of existing caulonema filaments. The latter continued to produce caulonema cells and this result strongly suggests that caulonema differentiation is independent of cyclic AMP.

**Table 2** Effect of various nucleotides and inhibitors of phosphodiesterase on the formation of chloronema and caulonema filaments in wild-type and mutant *pg-1* protonema

Compound	% Chloronema filaments	
	Wild type	<i>pg-1</i>

ICI 58,301*	88	42

\*3-Acetamido-6-methyl-8-*n*-propyl-5-triazolo[4,3-*a*]pyrazine.

Mutant *pg-1* was isolated as follows. Spores ( $1.52 \times 10^5$  per 3 ml) suspended in MM+0.001% Tween-20 were exposed for 45 min to ultraviolet light from a Philips germicidal lamp (1.25% of the spores survived). After exposure, spore suspension was stored in dark (30 h) and then plated on complete medium. The protonema that grew 0.5 cm or more in diameter in 10 d (650) were screened for altered differentiation of various cell types. Three isolates behaved differently and only in one of these (designated *pg-1* here) caulonema filaments were found to be formed in the absence of IAA. The detailed method of isolating mutants will be published separately. Wild-type protonema was grown in MM+1  $\mu$ M IAA, whereas *pg-1* was cultured in MM+1% glucose. All nucleotides and inhibitors of phosphodiesterase were sterilised by filtration through membrane filters and then added to the autoclaved medium. A wide range of concentrations were tested; data are given only for 0.1 mM. Other details as in Table 1.

Mono- and dibutyl cyclic AMP, purine nucleotides and inhibitors of cyclic nucleotide phosphodiesterase also enhanced chloronema differentiation (Table 2). Theophylline and aminophylline, although active, inhibited the growth of cells at all the concentrations tested (0.01–1 mM). ICI 58,301 (an inhibitor of phosphodiesterase<sup>12</sup>) was not inhibitory and mimicked the effect of cyclic AMP. The pyrimidine derivatives were completely inactive. The compounds enhancing chloronema differentiation in the wild type may act by elevating endogenous levels of cyclic AMP, and an increase in the activity of adenylate cyclase by most of these has been shown in animal systems<sup>13,14</sup>.

Further evidence about the specific involvement of cyclic AMP in chloronema differentiation comes from the results obtained with the pale green mutant (*pg-1*), which we isolated by treating the wild-type spores (cell line J-2) with ultraviolet irradiation as described in Table 2. In suspension cultures, this mutant produced predominantly caulonema filaments (>70%) without the addition of an auxin (the

rest being the chloronema filaments). It may be recalled that in the wild type very few (<10%) or no caulonema filaments are formed in the absence of an auxin. In the mutant *pg-1*, cyclic AMP was quite active, whereas dibutyl cyclic AMP and phosphodiesterase inhibitors were marginally active (Table 2). Six days after addition of 0.1 or 1 mM cyclic AMP, a maximum of 66–70% chloronema branches were seen (control showed 27%). These branches arose as laterals on caulonema filaments and appeared similar in all respects to such branches from the wild-type protonema. Adenosine, 5'-AMP, 5'-GMP and other cyclic nucleotides did not alter the relative proportion of caulonema and chloronema filaments.

To elucidate the role of endogenous cyclic AMP, its intracellular levels were determined in the wild-type and the mutant protonema using the protein kinase assay<sup>15</sup> (Table 3). Detailed results concerning the characterisation of cyclic AMP in this moss will be published elsewhere. The endogenous concentration of cyclic AMP was four- to sevenfold higher in chloronema cells compared with a population of cells consisting of about 65–75% caulonema filaments. Cyclic AMP levels in the mutant and in the wild-type caulonema filaments were the same. A severalfold greater level of intracellular cyclic AMP in chloronema cells compared with that in caulonema filaments, and their enhanced differentiation by exogenous cyclic AMP, strongly suggest that cyclic AMP has a role in chloronema differentiation. The enhancement of chloronema filaments by adenosine and 5'-AMP in the wild-type protonema only (and not in the mutant) is a significant difference. Our results are consistent with the *pg-1* mutant being at least partially impaired in the synthesis of cyclic AMP.

Our results show that cyclic AMP enhances the differentiation of chloronema cells, whereas the auxins are already known to inhibit their growth and differentiation<sup>11,17,18</sup>. The chloronema cells contain IAA (M.M.J., unpublished), and a balance of endogenous cyclic AMP and auxin may in fact underlie the differentiation of chloronema cells. The results of the experiment in which the amount of cyclic AMP and auxin were altered in the medium support this suggestion; also, the percentage of chloronema filaments was greater at high cyclic AMP-IAA ratios.

The widespread occurrence of cyclic AMP among heterotrophic organisms<sup>4</sup> has led many investigators to test for its presence and function in plants<sup>3,4</sup>. So far, cyclic AMP or enzymes of its metabolism have been found in bacteria<sup>2</sup>; fungi<sup>19–22</sup> and an alga<sup>23</sup>, but not in higher plants. In the context of our results on the moss protonema, the situation in lower plants may indeed be different from that of higher plants. Based on available evidence, cyclic AMP seems to be a naturally-occurring regulator of growth and differentiation only in the lower plants.

**Table 3** Endogenous levels of cyclic AMP in wild-type and mutant protonema

Predominant cell type	Medium	% Chloronema	Cyclic AMP (pmol)	
			per g fresh weight	per mg protein
Wild type				
Chloronema	MM	100	56	2.05
	MM±1% glucose	100	44	2.23
Caulonema	MM±1 μM IAA	35	8	0.53
Mutant <i>pg-1</i>				
Caulonema	MM+1% glucose	25	5	0.53

Chloronema cells were grown in MM+1% glucose and collected in late exponential phase, whereas cultures of caulonema filaments were obtained by growing chloronema cells in MM+1  $\mu$ M IAA for 6 d. Mutant grew better in MM+1% glucose and cells were collected after 5 weeks. For cyclic AMP determination, cells were homogenised in 6%  $\text{Cl}_2\text{CCOOH}$  in a blender at 4 °C.  $^3\text{H}$ -cyclic AMP (3,000 c.p.m., specific activity  $20.8 \text{ Ci mmol}^{-1}$ ) was added as internal standard and homogenate was centrifuged at  $27,000g$  for 15 min. Pellet was saved for determination of protein<sup>15</sup> and cyclic AMP was determined in the supernatant. Supernatant was extracted five times with cold water-saturated diethyl ether and the resulting aqueous phase lyophilised after removal of ether. Dry material was dissolved in distilled water and chromatographed on BioRad Aminex MS cation exchange resin (mesh size 200–400). Cyclic AMP-containing fractions were freeze dried and chromatographed on thin-layer silica gel plates in *n*-butanol-methanol-ethylacetate-ammonia (7:3:4:4, v/v). Area corresponding to cyclic AMP was eluted with 50% ethanol and eluate lyophilised. Purified material was dissolved in distilled water and cyclic AMP determined using protein kinase assay as described by Kuo and Greengard<sup>16</sup> except that the source of protein kinase was rabbit skeletal muscle. Cyclic AMP levels in the samples of caulonema cells (wild type and *pg-1*) were three- to fivefold greater than the lowest amount of cyclic AMP detectable (0.5 pmol) in our assay conditions.

We thank Dr A. H. Todd, ICI, UK for ICI 58,301, and Miss R. Radha, Bhabha Atomic Research Centre, Bombay for histones.

## Adenylate cyclase activity and steroidogenesis in phenotypic revertants of an ACTH-insensitive adrenal tumour cell line

A LARGE body of evidence implicates adenylate cyclase and cyclic AMP as mediators of adrenocorticotrophic hormone (ACTH)-stimulated adrenal steroidogenesis (see ref. 1 for review). Recent observations, however, suggest that ACTH acts at separate sites to increase steroidogenesis and cyclic AMP accumulation, and that cyclic AMP may not be an important component of ACTH-stimulated steroidogenesis<sup>2-5</sup>. An ACTH-responsive adrenocortical tumour cell line<sup>6</sup> (clone Y1) and a derivative clone insensitive to ACTH<sup>7</sup> (clone Y6), have been used to examine the role of adenylate cyclase and cyclic AMP in adrenal steroidogenesis<sup>1,7</sup>. Y6 cells do not respond to ACTH with increased steroidogenesis but do respond to added cyclic AMP<sup>7</sup>. In addition, these cells have an adenylate cyclase system insensitive to ACTH, probably accounting for their variant phenotype<sup>1</sup>. Y6 cells, when grown as tumours, regain the ability to respond to ACTH with increased steroidogenesis, and continue to express the ACTH-sensitive phenotype after prolonged periods in culture and extensive dilution<sup>7</sup>. Y6 cells, after animal passage, provide a system of phenotypic revertants to examine the linkage of different biochemical events to ACTH insensitivity<sup>7,8</sup>. We have now examined adenylate cyclase activity in phenotypic revertants of Y6 cells induced by animal passage to assess the role of this enzyme in steroidogenesis. After animal passage, Y6 cells regained the ability to respond to ACTH both with increased steroidogenesis and with increased adenylate cyclase activity. These data indicate that the actions of ACTH on adenylate cyclase activity and steroidogenesis are closely linked.

Y6 cells were grown in monolayers or as tumours in isogenic mice (LAF<sub>1</sub>; Jackson Laboratories) as described previously<sup>7</sup>. For steroid assays, cells were incubated in growth medium containing 2.5 mM CaCl<sub>2</sub> and 0.1% trypsin inhibitor (from lima bean) for 1 h. At the end of the incubation periods steroids

were extracted from the growth medium in methylene chloride and measured against a corticosterone standard by fluorescence<sup>9</sup>. Adenylate cyclase activity was determined by measuring the conversion of labelled ATP to labelled cyclic AMP as described previously<sup>1</sup>. Labelled cyclic AMP was separated from other labelled compounds by chromatography on Dowex 50 and treatment with BaSO<sub>4</sub> (ref. 10). Cells were screened for aerobic and anaerobic bacteria to ensure that they were not contaminated. Mycoplasma infections were demonstrated by characteristic growth in broth and in agar<sup>11</sup>. Mycoplasma were determined by Dr P. Quinn, Hospital for Sick Children, Toronto.

Y6 cells infected with mycoplasma<sup>1</sup> tentatively identified as *M. arginini* (E. Bransome, personal communication) regained the ability to respond to ACTH with increased steroidogenesis when grown as tumours and plated as primary cultures (Table 1 and ref. 7). Concomitantly, the tumours and primary cultures recovered the ability to respond to ACTH with increased adenylate cyclase activity (Table 2). ACTH-sensitive adenylate cyclase activity was observed in intact cells, homogenates and membrane particles prepared from primary cultures of Y6 tumours (Table 2). Clonal isolates from primary cultures of Y6 cells after animal passage responded to ACTH and to cyclic AMP with increased steroidogenesis (Table 1). Homogenates and membrane particles prepared from these clonal isolates also responded to ACTH with increased adenylate cyclase activity (Table 2). Thus after animal passage, the same cell recovered the ACTH-sensitive phenotype both in steroidogenesis and adenylate cyclase activity. F<sup>-</sup> stimulated adenylate cyclase activity in preparations from primary cultures and to a greater extent in preparations from clonal isolates (Table 2). After animal passage, these cells no longer carried the mycoplasma infection.

Y6 cells cured of mycoplasma infection *in vitro* with kanamycin sulphate remained insensitive to ACTH<sup>1</sup>. After animal passage, the cells treated with kanamycin sulphate did not recover ACTH sensitivity with respect to steroidogenesis or adenylate cyclase activity (data not shown). When the cured cells were reinfected with mycoplasma and grown as tumours, they regained the ability to respond to ACTH with increased steroidogenesis (Table 1) and increased adenylate cyclase activity (Table 2). ACTH-responsive Y1 cells retained ACTH sensitivity when infected with mycoplasma and grown for several months (data not shown) or when treated with kanamycin sulphate<sup>1</sup>.

As demonstrated here, phenotypic reversion of Y6 cells requires the combination of mycoplasma infection and animal

Table 1 Steroidogenesis in Y6 cells after animal passage

Cell population	Steroids secreted (ng h <sup>-1</sup> per mg protein)		
	Unstimulated	+ACTH	+cyclic AMP
Experiment 1			
Primary culture	170 ± 15	710 ± 35	Not determined
Clone 1	80 ± 5	280 ± 30	215 ± 20
Clone 2	110 ± 5	580 ± 60	370 ± 15
Experiment 2			
Primary culture	200 ± 10	750 ± 50	Not determined

Y6 cells were grown as solid tumours in LAF<sub>1</sub> male mice and plated as primary monolayer cultures *in vitro*<sup>7</sup>. Clones were isolated by plating single cells from primary cultures in microwells for tissue culture. Where indicated, ACTH (ACTHar, Parke Davis) was added at 5 mU ml<sup>-1</sup> and cyclic AMP at 1 mM. In experiment 1 tumours were formed from Y6 cells infected with mycoplasma. Before animal passage, these cells secreted 180 ± 20 ng steroid per h per mg protein without ACTH; and 250 ± 15 ng steroid per h per mg protein with ACTH. In experiment 2 Y6 cells (approximately 10<sup>6</sup> cells per 75 cm<sup>2</sup> flask), cured of mycoplasma *in vitro* with kanamycin sulphate<sup>1</sup>, were reinfected by adding 0.1 ml of medium from mycoplasma-infected Y6 cells to 15 ml of culture medium. The infected medium was centrifuged at 200g to remove any floating cells before use. Cells were cultured for 2 weeks with mycoplasma titres reaching approximately 10<sup>7</sup> colony forming units in agar per ml of medium, and then injected into mice.

**Table 2** Cyclic AMP accumulation in Y6 cells after animal passage

Cell populations were obtained for experiments 1 and 2 as described in Table 1. Adenylate cyclase in intact cells was determined by measuring the conversion of endogenous labelled ATP to labelled cyclic AMP as described previously<sup>1</sup> but without theophylline. ACTH was added to intact cells at 500 mU ml<sup>-1</sup>. The results for cyclic AMP accumulation in intact cells are expressed as c.p.m. per 30 min per mg protein ±s.e.m. Cell homogenates and membrane particles were prepared and assayed for enzyme activity as described previously<sup>1</sup>. ACTH (ACTHar, Parke Davis; 625 mU ml<sup>-1</sup>) and NaF (15 mM) were added where indicated. The results for cyclic AMP accumulation with homogenates and membrane particles are expressed as pmol per 10 min per mg protein ±s.e.m. Adenylate cyclase activity in homogenates of Y6 cells before animal passage was 30±5 pmol per 10 min per mg protein without ACTH; and 40±5 pmol per 10 min per mg protein with ACTH.

passage. Although the mechanism of restoration of ACTH sensitivity is not understood, these results suggest an unusual mechanism for the regulation of phenotypic expression. The possibility that this phenomenon is related to true genetic reversion remains open, since previous studies have demonstrated that mycoplasma can induce permanent phenotypic and karyotypic changes in cell cultures<sup>12</sup>.

Nevertheless, the concomitant recovery of ACTH-sensitive phenotypes in steroidogenesis and adenylate cyclase activity after animal passage demonstrate that the two events are closely linked. These observations indicate that the inability of Y6 cells to respond to ACTH with increased adenylate cyclase activity and with increased steroidogenesis is the result of a common defect, and suggest that at least one component of the ACTH-sensitive adenylate cyclase system is essential for the action of ACTH on adrenal steroidogenesis.

I thank Drs I. B. Fritz, C. J. Ingles and A. Marks for critical discussions. This work was supported by the MRC of Canada.

## Inhibitory action of noradrenaline and cyclic AMP in explants of rat cerebellum

IZENTOPHORETICALLY applied noradrenaline (NA) produces sustained depression of spontaneous firing of rat cerebellar Purkinje cells<sup>1–3</sup> and this inhibition may be mediated by cyclic AMP<sup>1–3</sup>. This contention has been challenged by Godfraind and Pumain<sup>4</sup> as well as by Lake and Jordan<sup>5</sup> who failed to observe a depressant action of cyclic AMP. Because the results may be influenced by electrical current or pH artefacts, the kind of anaesthetics used or factors impeding the release of cyclic AMP from micropipettes<sup>7</sup> we have used cultured Purkinje cells from rat cerebellum<sup>8–10</sup> to test the hypothesis that cyclic AMP mediates the depressant action of NA on Purkinje cells. We found that high concentrations of cyclic AMP only slightly decreased the firing rate of Purkinje cells, but that low concentrations of inhibitors of phosphodiesterase strongly enhanced the inhibition induced by cyclic AMP and NA.

Explants of cerebellum were cultured from newborn rats by the roller tube technique<sup>11,12</sup>. All electrophysiological experiments were conducted during the third week in culture. Single unit spontaneous action potentials were recorded extracellularly from large nerve cells (presumably Purkinje cells) with microelectrodes filled with 2 M NaCl<sup>12</sup>. The drugs were added directly to Hanks' balanced salt solution which served also as control solution.

When the monoamine was added to the bathing fluid in low concentrations, NA, like isoproterenol<sup>8</sup>, altered the pattern of spontaneous discharges by selectively increasing the number of long interspike intervals. Higher concentrations (>10<sup>-5</sup> M) slightly decreased the firing rate and the cells stopped firing at a concentration varying between 10<sup>-4</sup>

**Table 1** Response of cultured Purkinje cells to various drugs applied in the bathing fluid

Substance	n	+	—	=
NA 10 <sup>-5</sup> M	14	29	14	57
NA 10 <sup>-4</sup> M	11	18	27	55
cyclic AMP 10 <sup>-4</sup> M	11	18	18	64
cyclic AMP 10 <sup>-3</sup> M	23	17	44	39
AMI 10 <sup>-4</sup> M	10	—	40	60
AMI 10 <sup>-3</sup> M	12	—	83	17

AMI 10 <sup>-4</sup> M + NA 10 <sup>-5</sup> M	10	—	70	30
AMI 10 <sup>-4</sup> M + NA 10 <sup>-4</sup> M	16	—	100	—
PAP 10 <sup>-6</sup> M + NA 10 <sup>-4</sup> M	6	—	100	—
cyclic AMP 10 <sup>-4</sup> M + NA 10 <sup>-4</sup> M	8	13	37	50
cyclic AMP 10 <sup>-3</sup> M + NA 10 <sup>-4</sup> M	8	—	75	25

Results are expressed as percentage of tested cells. n, Number of cells tested; +, excitation; —, inhibition; =, change in rate ≤ 10%; AMI, aminophylline; PAP, papaverine.

and 10<sup>-3</sup> M. The action of NA was, compared with other substances such as gamma aminobutyric acid<sup>8</sup> or glutamate<sup>10</sup>, slow in onset and only partially reversible. Only before the cessation of the activity did the amplitude of the spikes decrease.

Cyclic AMP had no effect at 10<sup>-4</sup> M. At 10<sup>-3</sup> M, the firing rate of 44% of the cells was decreased (Table 1), but no cells stopped firing. With monobutyl or dibutyl cyclic AMP, used on 14 cells (not shown in Table 1), there was no significant difference in response. Even in the absence of exogenous cyclic AMP, inhibitors of phosphodiesterase, believed to increase the intracellular cyclic AMP concentration, consistently depressed the firing of Purkinje cells (Fig. 1a). Papaverine was about 100 times more potent than aminophylline and caffeine in abolishing the

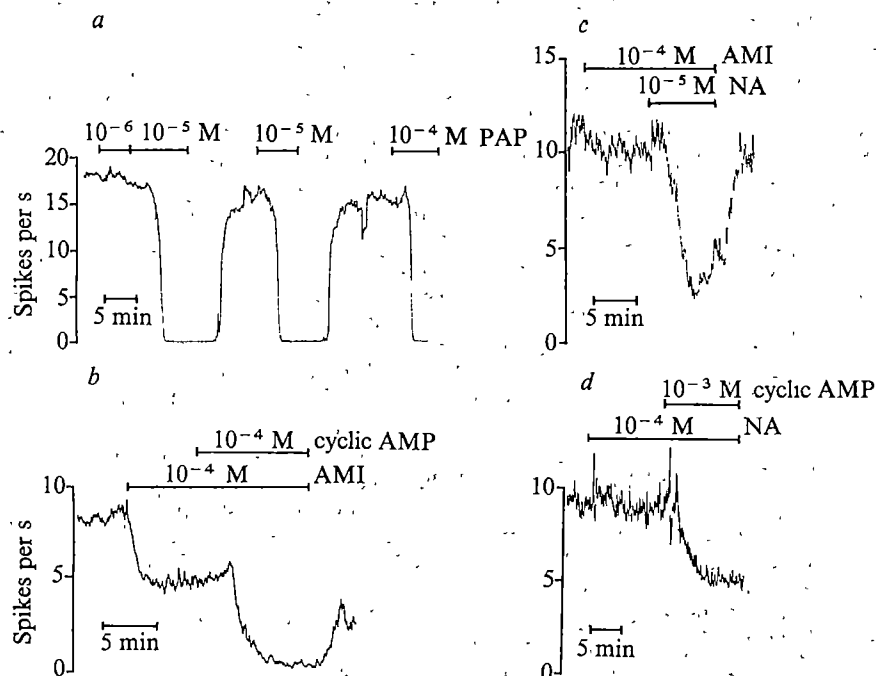

Fig. 1 Examples of the effects of various drugs on the rate of spontaneous discharge of Purkinje cells. *a*, Application of  $10^{-5}$  M papaverine abolished firing. After removal of the drug, the cells resumed firing. The effect of  $10^{-4}$  M papaverine was, however, only very slowly reversible. *b*, The inhibition induced by  $10^{-4}$  M aminophylline was enhanced by a subthreshold concentration of cyclic AMP. *c*, In the presence of aminophylline,  $10^{-5}$  M NA produced sustained depression of firing. In this cell, the rate of firing was not decreased by application of  $10^{-4}$  M aminophylline. *d*, High concentrations of NA and cyclic AMP slowed, but did not stop, firing of Purkinje cells.

spontaneous discharges ( $10^{-3}$  M of the latter were about equiactive with  $10^{-5}$  M papaverine).

The efficacy of various substances in potentiating the inhibitory effect is shown in Table 1 and examples of drug responses are illustrated in Fig. 1. The inhibition produced by  $10^{-4}$  M aminophylline was enhanced by a subthreshold concentration of cyclic AMP (Fig. 1*b*). On a cell which was virtually unaffected by  $10^{-4}$  M aminophylline, the addition of  $10^{-5}$  M NA caused sustained depression of firing (Fig. 1*c*). Surprisingly this inhibition was rather quickly reversed after removal of the drugs. Concomitant addition of  $10^{-4}$  M NA and  $10^{-3}$  M cyclic AMP inhibited Purkinje cells only to some degree (Fig. 1*d*), whereas most cells exposed to  $10^{-4}$  M NA and  $10^{-4}$  M aminophylline stopped firing.

Cultured Purkinje cells probably retain receptors for NA, and their activation could have been responsible for the inhibition in the presence of NA. The need for relatively high concentrations of NA to elicit an effect could be due to a relatively small number of intact receptors or, if the second messenger hypothesis of cyclic AMP is accepted, to high activity of phosphodiesterase. The latter might also be responsible for the failure of cyclic AMP to produce a clear, sustained depression of firing.

The fact that NA and inhibitors of phosphodiesterase produced similar electrophysiological results does not directly prove or disprove a link between their actions, but the hypothesis is strengthened because the action of NA was enhanced by inhibitors of phosphodiesterase. Substances that selectively inhibit brain adenylate cyclase might provide a means to determine whether cyclic AMP is the second messenger for NA in cerebellum. Lead was reported to inhibit selectively adenylate cyclase in rat cerebellum<sup>11</sup>. Unfortunately, application of lead ( $10^{-3}$ – $10^{-4}$  M) in our system led to ambiguous results, sometimes preventing, sometimes enhancing NA-induced inhibition.

In conclusion, phosphodiesterase activity seems to be high in cultured cerebellum. This might explain the weak effect of cyclic AMP (and possibly also of NA) on Purkinje cell firing. Inhibitors of phosphodiesterase strongly enhanced the inhibition produced by NA and cyclic AMP. The data reported support the hypothesis of Bloom *et al.*<sup>4,5,14</sup> that the intracellular level of cyclic AMP influences noradrenergic neurotransmission.

## Allergic sensitisation of human lung fragments prevented by saturation of IgE binding sites

PASSIVELY sensitised chopped human lung fragments release mediators of immediate hypersensitivity when challenged with appropriate antigens<sup>1</sup>. Antigen triggers the release of mediators from mast cells or basophils by coupling of neighbouring surface IgE antibody molecules sharing the same antigen specificity<sup>2</sup>. Release of mediators should therefore be unlikely if specific IgE molecules are sparsely distributed on cell surfaces, as in normal non-allergic people; or if surface receptors are densely occupied by IgE molecules with other specificities. Humans harbouring certain parasites develop high IgE levels<sup>3</sup>, and epidemiological evidence suggests that allergic disorders such as hayfever or pollen asthma are rare in heavily parasitised populations<sup>4,5</sup>. It is not known whether IgE induced in man by parasite infestation is directed specifically against parasite antigens, or whether it represents nonspecific potentiation of IgE production against many different antigens, as demonstrated in the rat *Nippostrongylus* model<sup>6</sup>. Here we show that human lung fragments first exposed to IgE-rich serum from West African residents become resistant to further passive

Table 1 Effect of IgE-rich serum on subsequent passive sensitisation and challenge

Preincubated with:	Lung fragments Sensitised with:	Challenged with:	No. of experiments	Mean histamine release (ng per g. tissue, mean ± s.d.)
West African IgE-rich serum	Allergic serum	Pollen antigen	13	282 ± 92
Cord* serum	Allergic serum	Pollen antigen	13	2,316 ± 435
Cord serum	Allergic serum	Cord serum	13	171 ± 27
Cord serum	Cord serum	Pollen antigen	13	222 ± 33
West African IgE-rich serum	Cord serum	Pollen antigen	3	165 ± 54

\*Cord serum used in control experiments contained less than  $1 \text{ U ml}^{-1}$  of IgE

sensitisation with serum containing grass pollen-specific IgE. Normal tissue obtained from peripheral lung lobes removed at operation was finely chopped, filtered on gauze and washed three times in Krebs solution. Aliquots (200 mg) were incubated for 90 min at  $37^\circ\text{C}$  in pooled serum, diluted 1:100 in Krebs solution, from 8 West African subjects, residents in Manduar, The Gambia. The IgE level of this pool was  $6,454 \text{ U ml}^{-1}$ , measured by double antibody radioimmunoassay<sup>7</sup> ( $1 \text{ U} = \text{approximately } 2.4 \text{ ng}$  (ref. 8)). The treated aliquots of lung tissue were washed three times in Krebs solution and resuspended in serum, diluted 1:100, from a patient with hayfever. The total IgE of this second serum was only  $60 \text{ U ml}^{-1}$ , but high specific IgE antibody activity to Timothy grass pollen was demonstrated by the

a 73% blocking effect, comparing histamine release from blocked lung fragments with that from challenged control fragments exposed only to cord serum before passive sensitisation. Similar results were obtained when other allergic sera from different patients were used for passive sensitisation.

Table 2 shows the results of experiments designed to confirm that the blocking effect was related specifically to IgE antibody. All inhibitory activity was lost after heating the IgE-rich serum at  $55^\circ\text{C}$  for 30 min, enough to denature IgE but not other immunoglobulins. Furthermore, lung fragments exposed to unheated IgE-rich serum, although refractory to further passive sensitisation, released histamine readily on treatment with anti-IgE.

Table 2 Effect of heat treatment, and of challenge with anti-IgE

Preincubated with:	Lung fragments Sensitised with:	Challenged with:	No. of experiments	Mean histamine release (ng per g. tissue, mean ± s.d.)
Cord serum	Allergic serum	Pollen antigen	3	2,164 ± 184
Untreated IgE-rich serum	Allergic serum	Pollen antigen	3	238 ± 21
Heat-treated IgE-rich serum†*	Allergic serum	Pollen antigen	3	2,170 ± 240
—	IgE-rich serum	Anti-IgE†	2	2,998 ± 536
—	Allergic serum	Anti-IgE	2	3,435 ± 697
—	Cord serum	Anti-IgE	2	238 ± 32

\*Heated at  $55^\circ\text{C}$  for 30 min.

†Anti-IgE was prepared in a sheep immunised against N.D. myeloma IgE; the IgG fraction was separated from sheep serum by 3 ammonium sulphate precipitations, followed by DEAE-cellulose chromatography

radio-allergo-sorbent technique<sup>8</sup>. After overnight incubation at room temperature and a further 60 min at  $37^\circ\text{C}$  the lung fragments were washed and challenged with freeze-dried extract of Timothy grass pollen in Krebs solution ( $100 \mu\text{g ml}^{-1}$ ) for 15 min. Histamine released into the supernatant was measured by bioassay, using strips of guinea pig ileum bathed in Krebs solution at  $37^\circ\text{C}$  containing atropine sulphate  $60 \mu\text{g ml}^{-1}$ .

Table 1 shows the combined results of experiments in which previous exposure of lung fragments to IgE-rich serum effectively blocked subsequent passive sensitisation. There was some variation in histamine released by different lung specimens, but in no experiment was there less than

Finally, the effect of altering the experimental sequence was studied (Table 3). When lung was first passively sensitised with serum containing grass-pollen specific antibody, subsequent exposure to West African IgE-rich serum failed to interfere with histamine release after challenge. Nor was significant blocking found when lung fragments were exposed to grass-pollen specific antibody and IgE-rich serum simultaneously, in spite of a total IgE level 100-fold higher in the West African serum than in the allergic serum.

These results support the hypothesis that IgE receptors, numbering up to 100,000 per mast cell<sup>10</sup>, can be saturated, thus making the cell unresponsive to further attempts at passive sensitisation<sup>11</sup>. In this model system blocking was

Table 3 Effect of altering the experimental sequence

Preincubated with:	Lung fragments Sensitised with:	Challenged with:	No. of experiments	Mean histamine release (ng g <sup>-1</sup> tissue)
IgE-rich serum	Allergic serum	Pollen antigen	3	238 ± 21
Allergic serum	IgE-rich serum	Pollen antigen	3	2,348 ± 295
—	Mixed allergic serum and IgE-rich serum*	Pollen antigen	4	1,841 ± 173

\*The final dilution of both sera was 1:100.

achieved only if IgE-rich serum was added to lung in a separate step before passive sensitisation with allergic sera, results which are in keeping with the known high affinity binding of IgE to mast cell surface receptors. Mast cell blockade through saturation of IgE receptors is also suggested by the failure of patients with IgE myeloma to accept passive sensitisation<sup>12</sup>, and by animal experiments<sup>13,14</sup>. Now it is necessary to know whether IgE produced actively by parasite infection or by the administration of parasite derived antigen can displace IgE against environmental allergens already existing in an allergic patient.

We thank Mr B. G. Overell of Beecham Pharmaceuticals for a gift of freeze-dried Timothy grass pollen.

## Suppression of bacterially-induced hypersensitive reaction and phytoalexin accumulation in bean by phaseotoxin

PHASEOTOXIN is a trivial name given to an exotoxin produced by *Pseudomonas phaseolicola*, which causes halo-blight of beans<sup>1</sup>. Although the mechanism of chlorosis induction in susceptible hosts is unknown, evidence indicates that chlorosis is casually related to inhibition of ornithine carbamoyltransferase (OCT; EC 2.1.3.3) by phaseotoxin, a potent and specific inhibitor of the enzyme<sup>2</sup>. Phaseotoxin may also be involved in the host specificity of the pathogen. We previously reported that in infected resistant bean plants (but not in infected susceptible ones) phaseotoxin production is suppressed in spite of substantial bacterial multiplication<sup>3</sup>. Further, in resistant beans treated with phaseotoxin, a larger number of bacteria are found than in non-treated plants<sup>4</sup>. These observations indicate that phaseotoxin may suppress the hypersensitive reaction (HR) in resistant hosts. The object of this study was to investigate whether pretreatment of resistant cultivars of bean with phaseotoxin suppresses the HR response of the host and phytoalexin accumulation on subsequent inoculation with *P. phaseolicola*, and our results seem to support this.

The term HR is applied to an acute, localised response of plant tissues to inoculation with incompatible pathogens. In plants infected (or inoculated) with incompatible fungal pathogens, HR is accompanied by accumulation of phytoalexins, compounds which are toxic to the invading pathogens. There are only two examples of HR induction and phytoalexin accumulation in plants infected with incompatible bacterial pathogens<sup>5,6</sup>. The compounds which occur in soybeans inoculated with *P. glycinea* have been identified<sup>5</sup> and we have recently identified some of those which accumulate in beans infected with *P. phaseolicola*<sup>8</sup> and determined their toxicity to the pathogen.

Seedlings (6 d old) of a resistant bean cultivar were

allowed to take up nutrient solution plus phaseotoxin ( $4,200 \text{ U ml}^{-1}$ ) or nutrient solution alone (controls), in a growth chamber for 24 h. At the end of the incubation period the leaves of treated plants contained approximately  $1,300 \text{ U}$  of phaseotoxin per  $2 \text{ cm}^2$  leaf area. The plants were then replanted in vermiculite and the abaxial surfaces of their primary leaves inoculated with a suspension of *P. phaseolicola*. Leaf disks ( $2 \text{ cm}^2$ ) were removed every 24 h from the toxin-treated and control plants and their bacterial populations determined as previously described<sup>3</sup>.

In control plants the number of bacteria found per disk were  $7.1 \times 10^7$  and  $1.2 \times 10^8$  cells 2 and 4 d after inoculation, whereas in toxin-treated plants the bacterial numbers were  $6.7 \times 10^6$  and  $3.3 \times 10^{11}$  cells for the same periods (Fig. 1). After 3 d, the control plants responded with HR, exemplified by tissue silvering, collapse and browning. Leaves from treated plants were usually 0-5% smaller in area than the non toxin-treated control leaves and after 3 d showed water-soaked infection centres typical of the susceptible response. To determine if HR suppression by phaseotoxin is accompanied by suppression of phytoalexin accumulation, an identical experiment was performed except that only one leaf sample was taken. Leaves of control and toxin-treated plants were collected after the appearance of HR in control plants (3 d after inoculation) and their phytoalexin content determined by thin-layer chromatography<sup>9</sup>.

Chromatograms of extracts from control tissues showed several prominent fluorescing bands when exposed to ultraviolet or when sprayed with diazotised *p*-nitroaniline. In extracts of the toxin-treated tissues, however, only faint bands were seen. The known phytoalexin bands were removed, eluted from silica gel with 95% EtOH and rechromatographed in chloroform-EtOH (100:3). The chromatographically pure compounds were quantitated by spectrophotometry. In control tissues, quantities of phaseollin, phaseollidin, phaseollinisoflaven and kievitone were 12.21, 7.67, 9.14 and  $16.70 \mu\text{g}$  per g leaf tissue; whereas in toxin-treated tissues the quantities were 6.42, 3.04, 5.79 and  $12.86 \mu\text{g}$  per g fresh weight of the tissue respectively.

The demonstration of suppression of phytoalexin accumulation in resistant bean tissues by phaseotoxin offers a mechanistic explanation for the suppression of HR in such tissues. That such suppression results at concentrations of toxin which are detected in infected susceptible tissues

Fig. 1 Phaseotoxin treatment suppresses the resistance response in GN Nebraska 27 bean plants to *Pseudomonas phaseolicola*. Six-day-old seedlings were allowed to take up, through the roots, either quarter-strength nutrient solution or nutrient solution + phaseotoxin ( $4,200 \text{ U ml}^{-1}$ ) for 24 h in a growth chamber at  $27^\circ\text{C}$ . Leaf disks were taken at the end of the 24-h period and their phaseotoxin level determined ( $1,300 \text{ U per } 2 \text{ cm}^2$ ). The toxin-treated (○) and control (●) plants were then replanted and their primary leaves infiltrated with a cell suspension ( $10^7$  cells  $\text{ml}^{-1}$ ) of *P. phaseolicola* and incubated in a growth chamber (16 h light,  $24,000 \text{ lx}$ ) at  $24^\circ\text{C}$ . Leaf disks ( $2.0 \text{ cm}^2$ ) were removed daily from the leaves and their bacterial populations determined as described<sup>3</sup>. Bars represent s.e.m.

indicates that phaseotoxin is involved in the initial establishment of the pathogen in the susceptible tissues. That no phaseotoxin is detected in inoculated resistant tissues of bean further implicates the toxin in pathogenic establishment, and suggests that phaseotoxin production is suppressed in resistant tissues. Thus, it seems that the factor which determines bean resistance to *P. phaseolicola* has to do with suppression of elaboration of phaseotoxin.

We thank Dr H. D. Van Etten for samples of phaseollin, phaseollinisoflavan and kievitone. A scholarship awarded by the East-West Center to S.S.G. is gratefully acknowledged. This work was supported in part by a grant from the National Institutes of Health.

## Collaboration between *in vivo* responses to LD and SD antigens of major histocompatibility complex

STUDIES using mixed leukocyte culture (MLC) and cell mediated lympholysis (CML) tests, have suggested a possible differential role for LD and SD antigens associated with the major histocompatibility complex (MHC, H-2 in mouse) in allograft reactions<sup>1-3</sup>. LD differences are primarily responsible for stimulating the proliferative response in MLC; the SD antigens are the major targets in CML<sup>1</sup>. The presence of LD differences on the stimulating cell in MLC enhances the cytotoxic response against the SD antigens. The cellular basis for this potentiation of CML is that two separate subpopulations of T lymphocytes are differentially reactive to LD and SD antigens<sup>1-3</sup>. A proliferating helper cell responds primarily to LD differences whereas cytotoxic T lymphocytes are more strongly activated by the SD antigens. Lafferty *et al.*<sup>7</sup> and Talmage *et al.*<sup>10</sup> have shown that allogeneic thyroids transplanted under the kidney capsule are rejected less rapidly if they are first cultured *in vitro*. Injection of peritoneal exudate cells from the thyroid donor into the recipient speeds up rejection. They suggest that the peritoneal exudate cells sensitise the recipient and that the sensitised cells can invade and reject the thyroid. A further refinement in the interpretation of their data might suggest that either in addition to the mechanism they propose or as an alternative to it the peritoneal exudate cells provide an LD stimulus to the recipient's proliferating helper T cells, and that these cells either by themselves or through a secreted helper factor potentiate the development of cytotoxic T lymphocytes directed at the SD antigens on the graft. Our experiments reported here are consistent with this model.

The mouse strains we used are primarily strains AQR, B10.A and B10.T(6R). B10.A and B10.T(6R) are congenic on a B10 background. AQR carries a substantial portion of the B10 background but is not congenic with the other strains. Two mouse strains are said to be LD-different if they are identical for the two SD loci but differ for the

Fig. 1 Thyroid transplantation has been performed as described by Lafferty *et al.*<sup>6</sup> and Talmage *et al.*<sup>10</sup>. Twenty-four hours before removal of the kidneys 0.5  $\mu$ Ci of <sup>125</sup>I was injected intraperitoneally. Both kidneys of each animal were counted in a gamma counter. The results are expressed as a ratio of the counts of <sup>125</sup>I in the thyroid-containing kidney to those in the contralateral control kidney. All thyroids were examined histologically for signs of rejection; the results are consistent with those expected based on the ratio. We have injected  $1 \times 10^4$  lymph node cells (instead of peritoneal exudate cells) intraperitoneally into thyroid graft recipients. The H-2 complex can be divided into four regions, K, I, S and D. The SD loci are in the K and D regions; the strong LD locus is in I. The MHC genotypes of these strains are the following: AQR (qkdd), B10.A (kkdd) and 6R (qqdd), where the lower case letter in parentheses refers to the H-2 haplotype from which each region for a given strain is derived. Each point represents at least five animals. Comparative histological studies showed that thyroids with a ratio of 4 or lower reveal severe signs of rejection. The curves are keyed as follows: (recipient) (thyroid donor) (LNC donor). a, (AQR) (AQR) (none); b, (AQR) (AQR) (6R); c, (AQR) (B10.A) (AQR); d, (AQR) (B10.A) (B10.A); e, (AQR) (B10.A) (none); f, (AQR) (B10.A) (6R); g, (AQR) (B10.A) [(B10.A  $\times$  6R)(F<sub>1</sub>)].

strong LD locus in the I region, and SD-different if a difference exists for either the K and/or D region but they are identical for the H-2 I region. Thus, AQR and 6R are LD-different, and AQR and B10.A are SD-different (being identical for the strong LD locus (loci)). We have used lymph node cells (LNCs) instead of peritoneal exudate cells.

The results are presented in Fig. 1. B10.A thyroids transplanted into AQR recipients with or without injection of AQR LNCs show prolonged survival compared with grafts differing for both H-2 LD and SD factors which in our experiments never show ratios above 4 (data not shown) tested on day 5 and later<sup>6,10</sup>. Rejection is markedly more rapid when 6R LNCs are injected at the time of thyroid transplantation. Various controls are included in the figure. To rule out that the injected 6R cells themselves reject the thyroid rather than provide an LD stimulus to the recipient, in some experiments we have used [B10.A  $\times$  (6R)] F<sub>1</sub> LNCs instead of the 6R LNCs, similar enhancement of rejection was seen. (AQR  $\times$  B10) F<sub>1</sub> recipients gave results (not shown)

similar to the AQR recipients demonstrating that rejection is due to MHC differences (since AQR is not yet congenic with B10). Injection of B10.A LNCs into AQR recipients receiving a B10.A thyroid results in some acceleration of rejection. The potentiating effect is much less than that seen when 6R LNCs are injected and consistent with *in vitro* findings: B10.A stimulating cells not only induce a weak proliferative response in AQR responding cells, suggesting the presence of weak LD-like differences in the SD region of B10.A, but also lead to killing in CML<sup>7</sup>. Likewise, the fact that B10.A thyroids are rejected by AQR is consistent with these *in vitro* findings.

The most likely explanation of these findings is that LD-SD interaction similar to that seen *in vitro* can occur *in vivo*. When both an LD antigen on injected LNCs and SD differences on the B10.A thyroid are presented to the recipient's immune system, the B10.A grafts are rejected like LD+SD-different allografts. At the cellular level, this could be interpreted as follows. Injected LNCs from the LD-different 6R strain activate proliferating helper cells of the recipient. These cells, or soluble products secreted by them, amplify the response of the cytotoxic lymphocytes directed against the SD antigens in the thyroid.

B10.A thyroids are rejected in 20–25 d when no additional LNCs are injected. This delayed rejection is, presumably due to the absence of strong LD-like differences in this combination. We suggest that the prolonged survival of allogeneic cultured thyroids, at least in part, is likewise due to the removal of the LD stimulus in the passenger leukocytes.

AQR recipients recognise H-2<sup>I</sup> region associated antigens on the 6R LNCs; it could be argued that these antigens cross react with the SD antigens of B10.A recognised as foreign by AQR. *In vitro* data argue against this interpretation: AQR cells sensitised to 6R lyse 6R target cells but not B10.A<sup>11</sup>. We thus consider this a very unlikely explanation for our findings and suggest, instead, that LD-SD collaboration occurs *in vivo* as well as *in vitro*.

Davies and collaborators<sup>8,9</sup> have demonstrated that anti-I region (anti-Ia) antisera lead to prolongation of graft survival. Our studies suggest that, at least in part, I-region disparity is important in allograft rejection in terms of activating the T-helper system; they thus provide a potential mechanism for explaining the effect of the enhancing anti-Ia antisera as well as extrapolating the *in vitro* findings of LD-SD collaboration to the *in vivo* system. This work was supported by grants from the National Institutes of Health and the National Foundation—March of Dimes. H.W.S. is a recipient of a Max Kade postdoctoral research exchange grant. We thank Drs Kevin Lafferty and David Talmage for showing us the thyroid transplantation procedure and for discussion.

## Association of high affinity stereospecific binding of <sup>3</sup>H-propranolol to cerebral membranes with $\beta$ adrenoceptors

*IN VITRO* binding of <sup>3</sup>H-catecholamines to plasma membranes from a variety of tissues has been reported<sup>1–4</sup>. In none of these studies, however, has the binding satisfied criteria necessary for identification of true  $\beta$  adrenoceptors (for example, stereospecificity and high affinity for potent  $\beta$ -adrenoceptor antagonists). On the other hand, studies using labelled  $\beta$ -adrenoceptor antagonists have demonstrated binding sites on erythrocyte ghosts and cardiac membranes that seem to satisfy fully the criteria associated with  $\beta$  adrenoceptors<sup>5–7</sup>.

The presence of  $\beta$  adrenoceptors in cerebral tissue has been confirmed by electrophysiological techniques<sup>8,9</sup>, and further characterisation of a central  $\beta$  adrenoceptor has come from biochemical approaches. For example, as is clearly the case in extracerebral tissue<sup>10</sup>,  $\beta$  adrenoceptors seem to mediate catecholamine-induced cyclic AMP formation in the brain<sup>11,12</sup>. Catecholamines have also been shown to interact with a  $\beta$  adrenoceptor and markedly stimulate cyclic AMP formation in neonate chick cerebral hemispheres<sup>13</sup>. Since it was felt that this tissue may represent a rich source of central  $\beta$  adrenoceptors, I have examined the characteristics of DL-<sup>3</sup>H-propranolol binding to membranes prepared from chick cerebral hemispheres.

Specific binding of DL-<sup>3</sup>H-propranolol to cerebral membrane fragments was saturable (Fig. 1) and half-maximal specific binding occurred at about 11 nM. On the other hand, nonspecific binding of DL-<sup>3</sup>H-propranolol (binding in the presence of 200  $\mu$ M isoprenaline) was not saturable over the concentration of propranolol examined. The amount of DL-<sup>3</sup>H-propranolol specifically bound at saturation provides an estimate of the number of binding sites on the membranes. The mean  $\pm$  s.e. for five experiments was 0.23  $\pm$  0.015 pmol per mg protein. DL-<sup>3</sup>H-propranolol bound rapidly and reversibly to cerebral membranes. Binding was 75% complete at 10 s and equilibrium was reached at 2 min, at which time the addition of unlabelled isoprenaline (200  $\mu$ M) resulted in a dissociation of bound DL-<sup>3</sup>H-propranolol with a half time of about 45 s.

The displacement of DL-<sup>3</sup>H-propranolol by non-radioactive stereoisomers, D- and L- and DL-propranolol is shown in Table 1. The D isomer was almost 100-fold less potent than the L isomer, and DL-pindolol proved to be the most potent  $\beta$ -adrenoceptor antagonist examined. The displacement of DL-<sup>3</sup>H-propranolol by catecholamines and salbutamol is also

Table 1 Effect of adrenergic antagonists and agonists on DL-<sup>3</sup>H-propranolol binding to crude synaptic membranes

Compound	Half-maximal inhibition of <sup>3</sup> H-propranolol binding
Antagonists	
DL-Propranolol	$9.5 \times 10^{-8}$ M
DL-Propranolol	$2.0 \times 10^{-8}$ M
D-Propranolol	$8.2 \times 10^{-7}$ M
DL-Pindolol	$6.1 \times 10^{-9}$ M
DL-Pronethalol	$1.4 \times 10^{-6}$ M
Agonists	
L-Isoprenaline	$1.2 \times 10^{-8}$ M
L-Adrenaline	$5.9 \times 10^{-6}$ M
L-Noradrenaline	$4.3 \times 10^{-5}$ M
Salbutamol	$1.1 \times 10^{-6}$ M
Dopamine	No binding at $10^{-4}$ M

For binding studies DL-<sup>3</sup>H-propranolol (15 nM) was incubated with various concentrations of compounds shown and membrane protein equivalent to 0.6–0.7 mg for 15 min at room temperature. Results are means of triplicate determinations from four separate experiments using at least six different concentrations of drugs indicated, s.e.m. all  $\leq 10\%$ .

shown in Table 1. Clearly the order of potency of the catecholamines was isoprenaline > adrenaline > noradrenaline. Salbutamol was about fourfold more potent than noradrenaline and dopamine was inactive at concentrations up to 100  $\mu$ M.

The results presented here demonstrate in a crude synaptic membrane preparation DL-<sup>3</sup>H-propranolol-binding sites that possess characteristics associated with true  $\beta$  adrenoceptors. Thus the binding is of high affinity, saturable, rapid, reversible and clearly stereospecific. Moreover, the cerebral membrane sites show high affinity for both  $\beta$ -adrenoceptor agonists and antagonists, and the order of potency of these compounds parallels their potency as agonists or antagonists on adenylate cyclase activity in various tissues<sup>5,7,15</sup>. The potency of isoprenaline, adrenaline, noradrenaline and salbutamol in displacing DL-<sup>3</sup>H-propranolol binding from chick cerebral hemisphere membrane sites closely approxi-

mates the potencies of these compounds in stimulating cyclic AMP formation in slices of cerebral hemispheres of this species<sup>13</sup>.

The data reported in cerebral membranes agree with extensive studies examining DL-<sup>3</sup>H-propranolol and L-<sup>3</sup>H-alprenolol binding to erythrocyte and cardiac membranes<sup>5,6</sup>, and suggests that the sites studied are indeed truly representative of  $\beta$  adrenoceptors. Earlier failures to detect stereospecific binding sites with DL-<sup>3</sup>H-propranolol in brain<sup>16</sup> and heart<sup>17</sup> probably relates to the use of high concentrations (100 nM) of DL-<sup>3</sup>H-propranolol rather than to the 'membrane' effects<sup>18</sup> of this drug.

The use of high specific activity  $\beta$ -adrenoceptor antagonists should make it possible to quantitate and further characterise this cerebral receptor. In addition it should allow for a more definite cellular localisation of the  $\beta$  adrenoceptor since their presence on both neurones and glia has been suggested<sup>9,19</sup>. Moreover, the use of DL-<sup>3</sup>H-propranolol should facilitate investigation of altered affinity and/or number of cerebral  $\beta$  adrenoceptors in conditions in which an apparent altered sensitivity to catecholamines has been demonstrated<sup>20,21</sup>.

I thank Mr J. Anson for assistance and the Wellcome Trust for financial support.

**Fig. 1** Binding of DL-<sup>3</sup>H-propranolol to cerebral membranes. Male Ranger chicks (2–4 d old) were decapitated and their cerebral hemispheres homogenised in 20 volumes ice-cold 0.32 M sucrose and the homogenate centrifuged at 1,000g for 10 min. Resulting supernatant was centrifuged at 17,000g for 30 min to obtain a crude mitochondrial pellet. This pellet (P<sub>2</sub>) was lysed by resuspending in 20 volumes ice-cold water and briefly rehomogenising. The suspension was centrifuged at 10,000g for 20 min and the resulting pellet, a bilayer with a soft buffy upper layer washed carefully to collect this upper layer. Supernatant was centrifuged at 48,000g for 20 min and final membrane pellets stored in liquid nitrogen until use. Protein estimations by the method of Lowry *et al.*<sup>14</sup>. In the binding assay, membrane suspensions (0.5–1 mg protein) were incubated in all experiments except where indicated, with 15 nM DL-4n-<sup>3</sup>H-propranolol (specific activity 21 Ci mmol<sup>-1</sup>, Radiochemical Centre, Amersham), in buffer containing 50 mM Tris-HCl, pH 8.1, 15 mM MgCl<sub>2</sub> for 15 min at room temperature. Total volume of incubations 0.5 ml. Samples were filtered under pressure through Whatman glass-fibre circles (GFC) and immediately washed once with 10 ml buffer (filtering and washing required less than 6 s). Filters were dried and shaken in the cold with 5 ml Triton X100-toluene scintillator and radioactivity determined by liquid scintillation spectrometry. In every experiment 'nonspecific' binding was determined by measuring radioactivity obtained when incubations were carried out in presence of 200  $\mu$ M L-isoprenaline. Nonspecific DL-<sup>3</sup>H-propranolol binding (●) was subtracted from total radioactivity to obtain 'specific' binding (■). DL-<sup>3</sup>H-propranolol bound refers to 'specific' binding. At 15 nM DL-<sup>3</sup>H-propranolol, 'specific' binding was 40–50% total radioactivity. Results are means of triplicate determinations from five separate experiments; s.e.m. all < 10%.

## Synaptic transmission reversibly conditioned by single-gene mutation in *Drosophila melanogaster*

ONE way to advance current physiological and biochemical understanding of the mechanism of synaptic transmission at the molecular level is to alter synaptic function by means of single gene mutations. Among the various behavioural mutants of *Drosophila melanogaster*, those which express a mutant phenotype only in certain conditions and otherwise behave normally are of particular interest. If the mutant phenotype appears at the synapse, the mutant might enable a reversible modification of synaptic function by way of experimentally controlling the expression of the

mutant phenotype. Such a mutant would provide a useful tool for the study of synaptic function.

Temperature-sensitive mutants which express their mutant phenotype only at a certain temperature are one class of conditional mutants. A single gene mutant of *D. melanogaster*, *shibire* temperature-sensitive (*shi<sup>ts1</sup>*), shows reversible paralysis at 29 °C, but behaves normally at 22 °C. Genetic and behavioural studies were previously done in Suzuki's laboratory<sup>1-4</sup>. We report here that the paralysis results primarily from a blockade of neuromuscular transmission.

The material used was *shi<sup>ts1</sup>*, one of the six alleles of the *shibire* locus. The mutant *shi<sup>ts1</sup>* not only shows a reversible temperature-sensitive paralysis but also expresses morphological changes on the epidermal structure if it is exposed to high temperature during development<sup>2</sup>. To avoid the latter effect, we have maintained the temperature during culture at 17 °C. Control wild-type Oregon-R flies were raised in the same conditions. Adult 4-d-old females of *shi<sup>ts1</sup>* and Oregon-R were used. For the physiological experiments, a fly was mounted in wax and immediately covered with saline solution<sup>5</sup> which was maintained at 19 °C by a thermoelectric unit placed under the bath. Artificial respiration was given through undamaged thoracic spiracles described previously<sup>6</sup>.

To confirm the temperature-sensitive paralysis, the mechanogram of the mesothoracic sterno-coxal muscle was recorded at various temperatures. For this purpose, the fly was placed ventral side up and the mesothoracic preepisternum was dissected out to expose the thoracic ganglion and the left mesothoracic leg nerve. The nerve was cut at about 20  $\mu$ m from the thoracic ganglion, and the distal cut end was sucked into a suction electrode for electrical stimulation. The left mesothoracic leg was cut at the coxal-trochanter joint, and a mechanoelectric transducer was attached to the proximal cut end of the leg. The other legs were held by wax at the femur to prevent disturbance to the record. The sterno-coxal muscle of *shi<sup>ts1</sup>* responded to a single electric pulse with a vigorous twitch, as shown in Fig. 1a (*shi<sup>ts1</sup>*) at 19 °C. When the temperature was increased to 27 °C, the magnitude of the response diminished. At 28 °C, only a small response was observed, and at 29 °C, the response was completely absent. The elimination of the mechanical response at 29 °C was

Fig. 1 Mechanical (a), junctional (b), and electrogenic (c) responses of mutant, *shi<sup>ts1</sup>*, and control, Oregon-R, flies. a, Tension developed in mesothoracic sterno-coxal muscle on stimulation of mesothoracic leg nerve. b, Junctional and action potentials of third dorsal longitudinal muscle fibre in response to stimulation of posterior dorsal mesothoracic nerve. Upper trace in each record shows reference potential level. c, Muscle membrane responses of third dorsal longitudinal muscle fibre for transmembrane depolarising current. Upper trace: potential recording; lower trace: current recording, outward, current downward. Temperatures are indicated at left of figures. Top 19 °C, beginning of experiment; bottom 19 °C, recovery after exposure to high temperature. Calibration for a: 2 mg, 250 ms; b: 50 mV, 10 ms; c: 50 mV,  $1 \times 10^{-7}$  A, 50 ms.

very specific and confirmed the previously reported behavioural results on paralysis<sup>3</sup>. When the temperature was lowered to 19 °C, the response returned almost completely. The change of temperatures from 19 to 29 and back to 19 °C was applied many times with consistently similar results, whereas the response from the control Oregon-R fly showed no appreciable change in mechanogram within this temperature range (Fig. 1). In several cases, the response of control flies remained unaffected even when the temperature was increased to 35 °C.

Our results indicated that the possible cause of paralysis is the excitability of the nerve, conduction of the impulse along the nerve, neuromuscular transmission, excitability of the muscle membrane, or contractile elements in the muscle fibre. From further studies, however, it seems that nerve excitability and conduction are not affected by the temperature change. To show this, the nerve was stimulated at the same location as described above, and nerve impulses were recorded at the femo-tibial joint as described previously<sup>5</sup>. The recorded nerve impulses from *shi<sup>ts1</sup>* showed no appreciable diminution at 29 °C, nor did those from the control fly Oregon-R.

For further study of the neuromuscular properties of these mutants, we used the dorsal longitudinal flight muscle because a fibre of this muscle was known to be innervated by a single excitatory neurone<sup>7</sup>. For this purpose, a fly was mounted laterally and dissected as described previously<sup>7</sup>. The entire lateral surface of the dorsal longitudinal muscle and the thoracic ganglion was exposed to saline solution by making an opening at the lateral cuticle and removing the dorso-ventral and tergo-trochanter muscles. The posterior dorsal mesothoracic nerve innervating the exposed dorsal longitudinal muscle was cut about 50  $\mu$ m from the ganglion. The distal cut end was stimulated with a suction electrode. Intracellular recordings were made from the third muscle fibre. At 19 °C, both control Oregon-R and *shi<sup>ts1</sup>* flies showed membrane potentials of -88 to -93 mV. The preparations showing resting potentials less negative than this range were discarded. In the remaining preparations, a single square current pulse of 0.1 ms was applied to the nerve every second, and the muscle membrane response was recorded continuously as the temperature was changed.

The muscle membrane response of *shi<sup>ts1</sup>* is shown in Fig. 1b (*shi<sup>ts1</sup>*). The top record of Fig. 1b (*shi<sup>ts1</sup>*) shows the response at 19 °C. The response consisted of a rapidly increasing and overshooting action potential followed by the remaining slowly decreasing junction potential. When the temperature was raised, the action potential began to fail, leaving a junction potential of diminished size. At 28 °C only the junction potential was recorded. At 29 °C the junction potential was markedly reduced; and when the preparation was kept at 29 °C for longer than 5 min, no trace of junction potential was observed. Lowering the temperature to 19 °C restored the response completely. The effects of these changes of temperature were consistent and repeatable. During the change of temperature, the resting membrane potential showed no appreciable change and stayed at -90 mV. The response of the muscle membrane on stimulation of the nerve of the control fly Oregon-R is shown in Fig. 1b. The response at 19 °C was similar to that of *shi<sup>ts1</sup>*. When the temperature was raised, the time course of the action potential became faster but never failed to respond even up to 35 °C. The results suggest that the possible cause of the paralysis in *shi<sup>ts1</sup>* could be at the neuromuscular junction or more distal part of the system, possibly the muscle fibre membrane.

The excitability of the muscle membrane was tested by passing electric current through an intracellular microelectrode while observing the response by another intracellular electrode. As shown in Fig. 1c, the muscle membrane of both *shi<sup>ts1</sup>* and Oregon-R flies responded with a train of

Fig. 2 Current-voltage relationship at different temperatures obtained from mutant, *shi<sup>ts1</sup>*, and control, Oregon-R, flies.  $\Delta$ , 19 °C, beginning;  $\bullet$ , 29 °C;  $\nabla$ , 19 °C, recovery. Depolarisation and outward current are plotted in positive direction on y and x axes, respectively. Resting potential located at origin.

action potentials after local depolarisation. At high temperatures, the amplitude of the action potential became smaller and a larger depolarising current was required to initiate action potentials. All of these effects of temperature, however, appeared similarly in both *shi<sup>ts1</sup>* and Oregon-R flies. The current-voltage relationship of the muscle fibre membrane was analysed by applying hyperpolarising and depolarising currents to the fibre. As shown in Fig. 2, the input conductance increased by a factor of about 1.7 when the temperature was raised from 19 to 29 °C. The input conductance returned essentially to the original level when the temperature was lowered. These changes were common to both *shi<sup>ts1</sup>* and Oregon-R flies. Thus, the capacity of electrogenesis of the muscle membrane was found to be unaffected by the *shi<sup>ts1</sup>* gene.

So far, we have not investigated the effect of this mutation on the excitation-contraction coupling mechanism or the contractile protein. Therefore, we cannot eliminate the possibility that these and related properties necessary for the contraction of the muscle are affected by mutation. If the neural information carried by the nerve fails to be transmitted, however, to the muscle membrane at the neuromuscular junction, as shown by *shi<sup>ts1</sup>* at high temperature, the failure of muscle contraction is independent of the state of the contractile mechanism. Thus, the major cause of paralysis induced by the *shi<sup>ts1</sup>* gene is the blockade of neuromuscular transmission.

We have not determined whether the failure of transmission is presynaptic or postsynaptic. Kelly and Suzuki<sup>8</sup>, however, reported that the loss of the on-off transient of electroretinogram of *shi<sup>ts1</sup>* at high temperature was attributable to both pre- and postsynaptic defects. It is likely that not only the neuromuscular junction but other synapses are affected by the *shi<sup>ts1</sup>* gene. At the presynaptic terminal, if the potential-dependent calcium permeability<sup>9</sup> is affected, the transmitter release mechanism may be altered. The action potential of the muscle fibre is produced by the potential-dependent increase in calcium permeability (unpublished data on *Drosophila* by the present authors and also on *Sarcophaga* by J. B. Patlak). Note that the calcium permeability of the muscle fibre membrane is not affected in *shi<sup>ts1</sup>*.

At the postsynaptic membrane, one possibility is the direct effect on the receptor protein; it is known that the change of a single amino acid in a polypeptide could result in altering the temperature sensitivity of the protein<sup>10</sup>.

Membrane permeability changes at the subsynaptic membrane also should be investigated. Although we have not determined these points, the present results are the first to reveal that a temperature-conditioned neuromuscular transmission can be induced by a single gene mutation. Siddiqui and Benzer reported similar results (unpublished) with another allele of *shi<sup>ts</sup>*.

We thank Dr D. T. Suzuki, University of British Columbia, for *shi<sup>ts1</sup>* flies, and Dr M. Letinsky and Mr J. B. Patlak for help in preparing the manuscript. Supported by the US Public Health Service NIH grants to K.I. and S.H.

## Ca<sup>2+</sup> influx across the excitable membrane of behavioural mutants of *Paramecium*

THE ciliate protozoan *Paramecium* has an excitable surface membrane, which depolarises in response to a sudden increase in the Na<sup>+</sup> or K<sup>+</sup> concentration of the medium. An influx of Ca<sup>2+</sup> during depolarisation raises the internal Ca<sup>2+</sup> concentration, which in turn causes the cilia to reverse their direction of beating, and the cells to swim backwards<sup>1</sup>. The swimming behaviour of *Paramecium* is therefore a direct and readily observable correlate of the electrophysiological state of the membrane.

We have developed (unpublished results) a method of measuring <sup>45</sup>Ca<sup>2+</sup> influx and shown that in wild-type cells, the rate of <sup>45</sup>Ca<sup>2+</sup> influx increased five- to tenfold when 10 mM Na<sup>+</sup> or K<sup>+</sup> was added. This stimulated influx correlated with the observed backward swimming which in turn is correlated with Ca<sup>2+</sup> movement down an electrochemical gradient through a Ca<sup>2+</sup> "gate". This gating mechanism is a major component of membrane excitability in *Paramecium*<sup>1,2</sup>.

By selecting for behavioural defects, Kung *et al.* isolated several classes of mutant *paramecia* defective in various components of membrane excitability<sup>2</sup>. We have measured <sup>45</sup>Ca<sup>2+</sup> influx in all the major classes of mutants. Cells that showed no backward movement in Na<sup>+</sup> or K<sup>+</sup>, also showed little Na<sup>+</sup>- or K<sup>+</sup>-stimulated Ca<sup>2+</sup> influx.

Ca<sup>2+</sup> influx was measured essentially as before (to be described elsewhere). A low Ca<sup>2+</sup> concentration was used to minimise Ca<sup>2+</sup> binding, and the assay was performed at 0 °C to inhibit an active Ca<sup>2+</sup> extrusion. Cells were separated from the assay solution by centrifugation in a Pasteur pipette with one end sealed<sup>3</sup>.

Both behaviour and cell survival at 0 °C were examined. In the assay solution (legend Table 1) at 0 °C the cells

Influx was measured as nmol  $\text{Ca}^{2+}$  per 10 min per mg protein. Mutants were derived from 51s and were homozygous for mutations at the designated gene loci. Strain numbers are given in parentheses. —, No backward swimming observed; +, cells show repeated backward jerks; ++, cells swam backwards continuously.

*Paramecium aurelia* (syngen 4) was grown in cerophyl medium<sup>7</sup> (supplemented with  $\beta$ -sitosterol ( $1 \text{ mg l}^{-1}$ ) and inoculated 16 h previously with *Enterobacter cloacae*, the food source). Cells were collected by centrifugation at mid to late logarithmic phase, washed once in the assay solution and transferred into the assay solution. The assay solution consisted of: 10% v/v cerophyl medium (prepared without  $\text{Na}_2\text{HPO}_4$ ), 1 mM HEPES, 50  $\mu\text{M}$   $\text{CaCl}_2$ , 20  $\mu\text{M}$  EDTA and Tris base to pH 7.0. This solution contained 40  $\mu\text{M}$  free  $\text{Ca}^{2+}$ . Cells (30–90,000 per ml) were left in the assay solution for 30 min at room temperature. Then, the cells were placed on ice for 20 min before  $^{45}\text{Ca}^{2+}$  influx was measured and were left on ice for the rest of the experiment.  $^{45}\text{CaCl}_2$  (New England Nuclear, titrated to a phenol red endpoint with Tris base) was added to a specific activity of  $\text{Ca}^{2+}$  of 1,000 c.p.m.  $\text{nmol}^{-1}$ . Duplicate samples of cells were collected by layering 0.5 ml of the cell suspension over 1.0 ml of wash solution (assay solution with 1% sucrose), in a chilled, siliconised Pasteur pipette centrifuge tube. The tube was centrifuged for 0.5–1.0 min at 500g in an oil testing centrifuge and the tip containing the cell pellet was broken off. The tips were crushed and counted by liquid scintillation in a Triton-toluene mixture<sup>8</sup>. Uptake was approximately linear over the first 20 min. Rates were determined at 10 and 20 min and the average was taken. A large amount (30–50%) of the total  $\text{Ca}^{2+}$  in the assay mixture had been taken up after 30 min at  $0^{\circ}\text{C}$  when cells were stimulated by 10–15 mM KCl or NaCl. When the number of cells in the assay was decreased, however, we found no appreciable difference in uptake rates, expressed as nmol  $\text{Ca}^{2+}$  per 10 min per mg protein.

swam; though more slowly than at  $25^{\circ}\text{C}$ , for at least 1 h. When  $\text{Na}^{+}$  or  $\text{K}^{+}$  (10–15 mM) was added, 20–80% of the cells swam very slowly or stopped after 10–30 min. These cells swelled slightly, yet lysis was never observed. Naitoh<sup>4</sup> has shown that cilia cease to beat when the intracellular  $\text{Ca}^{2+}$  concentration rises above 0.1 mM. Cells stopped swimming at the end of the experiment only when  $\text{Na}^{+}$  or  $\text{K}^{+}$  was added, at a final concentration of 10 mM or higher. Pawn mutants, which did not show stimulated  $\text{Ca}^{2+}$  influx, also did not stop swimming in the presence of  $\text{Na}^{+}$  or  $\text{K}^{+}$ . For these reasons, we believe that the poor condition of the cells at the end of the experiment is a result of a large accumulation of intracellular  $\text{Ca}^{2+}$  in our assay conditions, which were chosen to prevent normal  $\text{Ca}^{2+}$  expulsion. The increased intracellular  $\text{Ca}^{2+}$  concentration apparently affects cell motility and shape.

Wild-type cells at  $0^{\circ}\text{C}$  swam backwards or showed repeated backward jerks in solutions containing  $\text{Na}^{+}$  or  $\text{K}^{+}$ , as they did at room temperature. The response of mutant cells to  $\text{Na}^{+}$  and  $\text{K}^{+}$  at  $0^{\circ}\text{C}$  was also qualitatively the same

as the response at room temperature. In the absence of  $\text{Na}^{+}$  or  $\text{K}^{+}$ , spontaneous avoiding reactions were more frequent at  $0^{\circ}\text{C}$  than at room temperature. These spontaneous reversals were probably due to an abnormal accumulation of  $\text{Ca}^{2+}$ , which occurred when the  $\text{Ca}^{2+}$  efflux system was inhibited by low temperature.

$\text{Ca}^{2+}$  influx in wild-type cells was stimulated by both  $\text{Na}^{+}$  and  $\text{K}^{+}$ , with  $\text{K}^{+}$  more effective than  $\text{Na}^{+}$  (Table 1). This trend was observed in each of approximately 20 experiments with wild-type cells. The absolute rate of stimulated  $\text{Ca}^{2+}$  influx varied over a range of 6–20 nmol per mg protein per 10 min in different experiments. This variability may be due to differences in the nutritional state of the cells which are difficult to control. In starved or slowly growing cells,  $\text{Na}^{+}$  generally stimulated  $\text{Ca}^{2+}$  influx only weakly.

$\text{Ca}^{2+}$  influxes were measured for 10 behavioural mutants of *Paramecium*, each with a different, single gene mutation. These mutants belong to the following classes: pawns, paranoiacs, fast-1, fast-2, and TEA (tetraethyl ammonium)-insensitive.

Pawn mutants always swim forward and do not reverse their swimming direction in  $\text{Na}^+$  or  $\text{K}^+$ . This behaviour has been attributed to a mutation in a voltage-sensitive  $\text{Ca}^{2+}$  gate, which cannot open properly to allow  $\text{Ca}^{2+}$  down its electrochemical gradient<sup>2</sup>.  $\text{Na}^+$  and  $\text{K}^+$  failed to stimulate  $\text{Ca}^{2+}$  influx in the unconditional pawn, *pwB*, and in the temperature-sensitive pawns, *pwA*<sup>2</sup>, and *pwC* grown at 35 °C (Table 1).  $\text{Ca}^{2+}$  influx in the pawn mutant *PwA* was weakly stimulated by  $\text{Na}^+$  and  $\text{K}^+$ . This mutant is somewhat leaky

(C. Kung, personal communication). Temperature-sensitive pawns exhibit wild-type behaviour when grown at room temperature and pawn behaviour when grown at 35 °C (ref. 6). Figure 1 shows the effects of  $\text{Na}^+$  and  $\text{K}^+$  on  $\text{Ca}^{2+}$  influx in wild-type and temperature-sensitive pawns grown at 24–26 °C and at 35 °C. Temperature-sensitive pawns require 2–4 h of growth at the permissive temperature to shift from pawn to wild-type behaviour<sup>3</sup>, so cells grown at 35 °C could not have shifted into a new phenotype during the assay at 0 °C.

The pawn mutant *pwC* (d4-131) has reproducibly lower rates of  $\text{Ca}^{2+}$  influx when grown at the permissive temperature (24–26 °C) (Table 1) and may therefore be somewhat abnormal even when grown at the permissive temperature. Kung has presented genetic evidence that one or both of the gene products of *pwA*<sup>1</sup> and *pwC* do not function normally even at the permissive temperature. Although both *pwC* and *pwA*<sup>1</sup> are temperature-sensitive pawns, the double mutant *pwA*<sup>1</sup>/*pwC* is temperature independent<sup>3,6</sup>.

Paranoiac mutants swim backwards for abnormally long periods in  $\text{Na}^+$ , yet swim backwards normally in  $\text{K}^+$  (ref. 2). The biochemical nature of the defect is not known.  $\text{Na}^+$  was as effective as  $\text{K}^+$  in triggering  $\text{Ca}^{2+}$  influx in the paranoiac *PaA*, and in another paranoiac strain, *PaC*,  $\text{Na}^+$  stimulated  $\text{Ca}^{2+}$  influx even more effectively than  $\text{K}^+$  (Fig. 1 and Table 1). The rates of  $\text{Ca}^{2+}$  influx in the paranoiacs were correlated with the behaviour of paranoiacs, since  $\text{Na}^+$ -stimulation caused increases in both the duration of backward swimming and the rate of  $\text{Ca}^{2+}$  influx.

Fast-1 and fast-2 mutants swim faster than normal cells. Fast-1 responds normally to  $\text{Na}^+$  and  $\text{K}^+$ , while fast-2 reverses only in  $\text{K}^+$  but not in  $\text{Na}^+$  (ref. 2). Fast-2 cells seem to have an abnormally large resting  $\text{K}^+$  permeability (Y. Satow, and C. Kung, personal communication).  $\text{Ca}^{2+}$  influx in fast-1 cells was stimulated normally by  $\text{Na}^+$  and  $\text{K}^+$ , while only  $\text{K}^+$  stimulated  $\text{Ca}^{2+}$  influx in fast-2 (Table 1 and Fig. 1). Again, there was a direct correlation between  $\text{Ca}^{2+}$  influx and ciliary reversal.

The mutant *fna*<sup>p</sup> behaves as a paranoiac, but the mutation is located in the fast-2 gene (*fna*) (J. Van Houten, S.-Y. Chang, and C. Kung, personal communication).  $\text{Na}^+$  stimulated  $\text{Ca}^{2+}$  influx in this cell line to a rate similar to that in wild type (that is, intermediate between fast-2 and paranoiac).  $\text{K}^+$ -stimulated  $\text{Ca}^{2+}$  influx normally in the *fna*<sup>p</sup> mutant (Table 1).

The mutant *TEA*<sup>-</sup> swims forward instead of reversing in the presence of TEA (which causes backward jerking in wild-type cells). The *TEA*<sup>-</sup> mutant responds almost normally to  $\text{Na}^+$  and  $\text{K}^+$  (ref. 2), but it apparently has a membrane defect resulting in a low resting resistance, most likely due to an increase in conductance to potassium (Y. Katow, and C. Kung, personal communication). *TEA*<sup>-</sup> cells had normal  $\text{Na}^+$ - and  $\text{K}^+$ -stimulated  $\text{Ca}^{2+}$  influx (Table 1).

There was an excellent correlation for all the cell lines studied between an increased  $\text{Ca}^{2+}$  influx triggered by  $\text{Na}^+$  and  $\text{K}^+$  and backward swimming stimulated by  $\text{Na}^+$  and  $\text{K}^+$ . These results further document that the three pawn genes, *pwA*, *pwB* and *pwC* are involved with the  $\text{Ca}^{2+}$  "gate", since these are the only mutants that show little  $\text{Ca}^{2+}$  influx in both  $\text{Na}^+$  and  $\text{K}^+$  solution. Our results suggest that fast-2 and paranoiac mutants, which show altered behaviour in  $\text{Na}^+$ , have normal  $\text{Ca}^{2+}$  "gates", since they show normal  $\text{Ca}^{2+}$  influxes in  $\text{K}^+$  solution. The abnormal response to  $\text{Na}^+$  in these strains is apparently the result of other factors. The variation between wild type, paranoiac and fast-2 phenotypes could be explained by postulating separate  $\text{Na}^+$ - and  $\text{K}^+$ -triggered  $\text{Ca}^{2+}$  "gates". We consider separate gates unlikely, since a single mutation in pawns can eliminate all  $\text{Ca}^{2+}$ -mediated depolarisations<sup>2</sup>.

This work was supported by grants from the Graduate School of the University of Wisconsin (to D.N.) and the

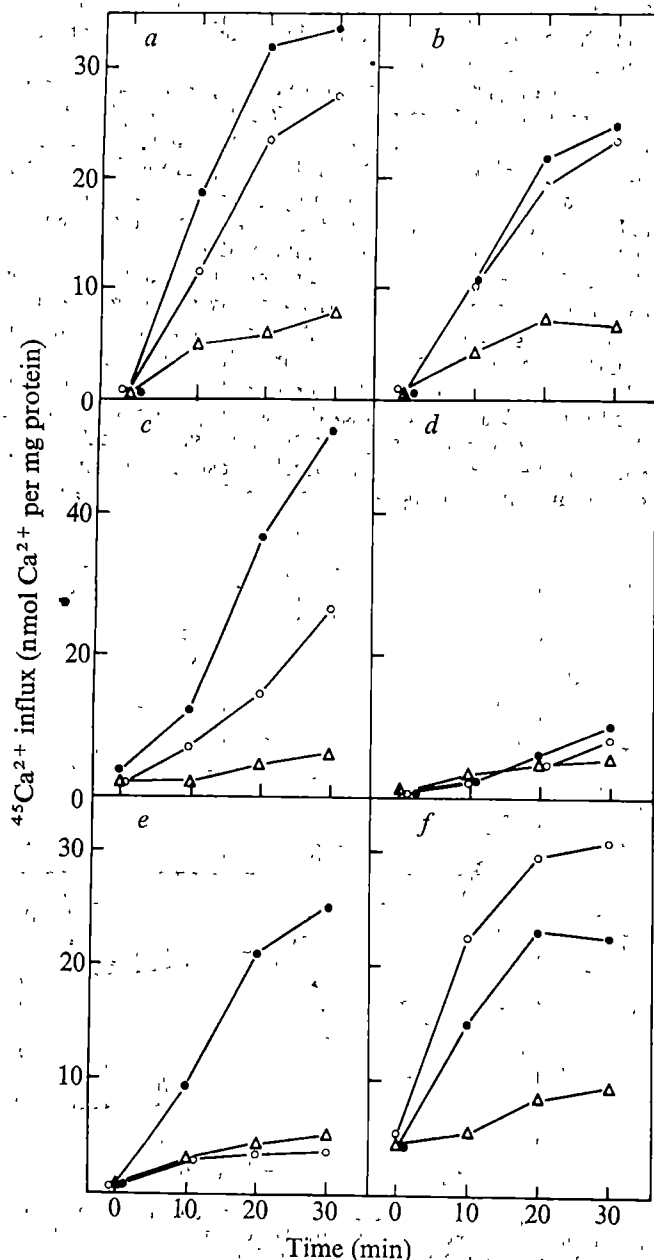

Fig. 1  $^{45}\text{Ca}^{2+}$  influx in wild type and behavioural mutants of *Paramecium*.  $\text{Ca}^{2+}$  influx was assayed as described in the legend to Table 1. Cell cultures were grown at 24–26 °C as described in the legend to Table 1. Cells were fed with fresh cerophyl medium which had been inoculated 12 h previously with *Enterobacter cloacae*. Half of the culture was left at 24–26 °C and the other placed at 35 °C.  $\text{Ca}^{2+}$  influx was assayed after 20 h or more. Each point represents the average of duplicate samples. The difference between duplicate values averaged 0.7 nmol  $\text{Ca}^{2+}$  per mg protein, for 40 separate points.  $\text{Ca}^{2+}$  influx was measured with 15 mM KCl (●), 15 mM NaCl (○), and the control (no addition) (△). a, wild type (25 °C); b, wild type (35 °C); c, *ts-pwA*<sup>2</sup> (d4-133, 25 °C); d, *ts-pwA*<sup>2</sup> (d4-133, 35 °C); e, *fna* (d4-91, 25 °C); f, *PaC* (d4-150, 25 °C).

## Synthesis of ATP coupled with action of membrane protonic pumps at the octane-water interface

ATP SYNTHESIS in mitochondria is one of the most important energy-producing processes in the cell. We have studied the main stage of this process, the coupling of ATP synthetase to the action of membrane protonic pumps at an octane-water interface.

Two hypotheses exist concerning this coupling of respiration to phosphorylation. That of Williams<sup>1</sup> suggests direct proton transfer in lipid phase from respiration enzymes to ATP synthetase, whereas that of Mitchell<sup>2</sup> postulates an essential additional stage of transmembrane proton transfer, resulting in the formation of a membrane potential. We have carried out ATP synthesis in non-equilibrium conditions (acidic concentration in the hydrophobic phase), thus supporting William's hypothesis.

We had previously shown that the mitochondrial ATPase can transfer protons from water to octane by ATP hydrolysis<sup>3</sup>. We therefore carried out the reverse reaction, and observed ATP synthesis coupled to the action of purified mitochondrial ATPase adsorbed at an octane-water interface. The proton flow through the ATPase complex from octane to water was caused by an excess concentration (with respect to that of the equilibrium) of the undissociated acid or Lewis form in the octane phase.

The excess concentration of acid was produced by oxidation of the reduced form of nicotinamide adenine dinucleotide (NADH) by ferricyanide with the participation of the enzymes comprising the initial step in the respiratory chain of mitochondria. For this purpose, submitochondrial particles (SMP) (for isolation techniques, see refs 4 and 6), were introduced into the octane-water system, to which was added one of the ATPases to be examined and rotenone, an inhibitor of NADH oxidase which prevents respiration and thus the synthesis of ATP in SMP. If NADH is added to the octane-water system containing a proton acceptor 2,4-dinitrophenol (DNP),  $K_3Fe(CN)_6$ , SMP and rotenone, the maximum shift in the positive direction of the potential difference measured in the chain, Au-air-octane, proton acceptor ( $RO^-$ ,  $ROH$ )-water, enzyme, substrate-water, saturated  $KCl-Hg_2Cl_2/Hg$ , was 0.52 V. ATP synthesis at the interface was detected by a decrease in potential difference measured in this chain on addition of ADP and inorganic phosphate to the system. Equilibrium octane-water systems containing 50 mM Tris-HCl (1 mM) and DNP were used.

Enzyme and substrates were added just before measuring the potential differences by the dynamic capacitance method<sup>3,8-10</sup>. Voltages plotted in the figures are referred to the initial value.

When 0.2 mM NADH was added to the system containing SMP,  $K_3Fe(CN)_6$  and oligomycin-sensitive ATPase, a potential shift in the positive direction was observed at the octane-water interface. Subsequent addition of 1 mM ADP and 1 mM inorganic phosphate caused the potential difference to shift in the negative direction. At sufficiently high ADP concentrations this negative shift was below the initial value (Fig. 1). Addition of oligomycin (points C and C', Fig. 1) eliminated almost completely the action of ADP and phosphate on the potential difference in the oligomycin-sensitive ATPase system.

Instead of SMP, another proton pump, such as bacteriorhodopsin sheets (obtained from *Halobacterium halobium*), was used. As we have shown previously<sup>8</sup>, bacteriorhodopsin sheets are also capable of transferring protons from water to octane by the action of light. Figure 2 shows that when light is switched on, bacteriorhodopsin sheets cause a potential change (0.5 V) at the octane-water interface. When the ATPase reaction starts, however, the potential returns to its initial value. When oligomycin is added in the presence of oligomycin-sensitive ATPase of *p-N,N*-di(2-chloroethyl)aminophenylacetic acid, an alkylating agent and inhibitor of soluble mitochondrial ATPase, bacteriorhodopsin sheets again generate the photopotential. Figure 2 shows the change in potential difference in the above chain in the presence of bacteriorhodopsin sheets on illumination and in the dark, as affected by the concentration of

Fig. 1 Shift in negative direction of potential difference in the chain (see text) as affected by the concentration of substrate ADP+Pi. Composition of incubation medium: a 0.1 mg ml<sup>-1</sup> oligomycin-sensitive ATPase, 0.1 mg ml<sup>-1</sup> SMP (isolated by the technique used in ref. 4), 2.5 µg ml<sup>-1</sup> rotenone, 50 mM Tris-HCl, 1 mM DNP, 1 mM MgSO<sub>4</sub>, 1 mM  $K_3Fe(CN)_6$  and 0.2 mM NADH. b, As a except SMP was isolated by the technique used in ref. 2. At points C and C' 2 µg ml<sup>-1</sup> oligomycin was added. The following experiments were run as controls: (1) Oligomycin-sensitive ATPase was excluded from the complete system. In these conditions, addition of ADP and Pi does not affect the potential difference. (2) SMP was excluded from the complete system. Addition of ADP and inorganic phosphate does not affect the potential difference. (3) NADH is excluded from the complete system. A very small potential change (no more than 25 mV) was observed on addition of 1 mM ADP and 1 mM Pi. Inorganic phosphate was excluded from the complete system. A very small potential change (no more than 25 mV) was observed on addition of 1 mM ADP.

Table 1 ATP synthesis at the octane-water interface due to the excess concentration of PCP in octane

ATPase	Experimental conditions	Amount of ATP in sample ( $\times 10^{-8}$ M)	Mean amount of ATP synthesised ( $\times 10^{-8}$ M)
Oligomycin-sensitive ATPase (100 $\mu\text{g ml}^{-1}$ ) + ADP ( $10^{-4}$ M)	-PCB	3.1	—
	+PCB	4.2	—
	+PCB + oligomycin (1 g $\text{ml}^{-1}$ )	2.9	—
	-PCB	2.5	—
Soluble mitochondrial ATPase before heat treatment (130 $\mu\text{g ml}^{-1}$ ) + ADP ( $3 \cdot 10^{-5}$ M)	+PCB	3.7	1.1

the substrate ADP and inorganic phosphate. When ADP and inorganic phosphate are added to a system with an active proton pump, the potential rapidly decreases.

ATP synthesis by oligomycin-sensitive ATPase, adsorbed on the octane-water interface, also takes place after addition of pentachlorophenol-octane solution to the octane phase. The system contained 1 ml octane and 2 ml 20 mM phosphate buffer ( $\text{pH}=7.5$ ) to which were added 40 g hexokinase protein,  $10^{-4}$  M ADP, 20 mM glucose, 2 mM  $\text{MgSO}_4$  and 100  $\mu\text{g}$  protein of oligomycin-sensitive ATPase isolated from the mitochondria of ox heart by Racker's method<sup>2</sup>. After introduction of 0.02 ml PCP into octane, its concentration in the complete system was  $5 \times 10^{-5}$  M. After 1 min. the reaction was stopped by perchloric acid and neutralised with NaOH. The amount of ATP formed was determined fluorimetrically by the glucose-6-phosphate dehydrogenase method. In the control tests PCP and octane were excluded from the system. The results of these tests (Table 1) show that in the control tests ATP is present as an impurity in the reactants used and can be formed according to the equation  $2\text{ADP} \rightarrow \text{ATP} + \text{AMP}$ , because of the presence of myokinases in the enzymes used. In the complete system the amount of ATP formed was 30–50% higher than in control tests in which PCP was not added. The experimental error was no greater than 10%. In the experiments with oligomycin-sensitive ATPase, oligomycin lowered the ATP level to the control value.

Figure 3 shows a scheme for the action of ATPase at the interface, based on the experimental data described above. It is clear from this scheme that under the action of light, in the presence in the non-aqueous phase of a proton acceptor (such as a weak acid, ROH), bacteriorhodopsin transfers protons to this phase. Of course, protons do not exist in the free form in the non-aqueous phase, but are

captured by  $\text{RO}^-$  or ROH to form ROH or  $\text{ROH}_2^+$  (Lewis acid form<sup>10</sup>).

If the charged Lewis acid form alone acted in this process as proton donor, the potential would always be positive and equal to, or less than, the initial positive charge of octane obtained in the case of SMP (Fig. 1). The change in the potential sign in the negative direction observed in the experiment with SMP must mean that ATP synthesis is also brought about by the elimination of protons from the neutral ROH form of DNP. In this case the anion remains in the non-aqueous phase and the proton goes into water. To verify this assumption, we used dimethoxybenzene

Fig. 3 Scheme for ATP synthesis at octane-water interface brought about by action of bacteriorhodopsin sheets.

Fig. 2 Dependence of potential difference measured in the chain (see text) on the concentration of substrate ADP + Pi. Composition of incubation medium: a, 30  $\mu\text{g ml}^{-1}$  bacteriorhodopsin sheets, 1 mM DNP, 50 mM Tris-HCl, and 1 mM  $\text{MgSO}_4$  in the dark; b, as c plus  $10^{-8}$  M soluble mitochondrial ATPase; c, as a, b and c under illumination.  $\text{pH} = 7.9$ . At A, 1 mM *p*-N,N-di-(2-chloroethyl)aminophenylacetic acid has been introduced into the cell

instead of DNP as Lewis-type proton acceptor in the non-aqueous phase. In this case, when NADH is added to the system containing soluble mitochondrial ATPase and SMP, the potential shifts in the positive direction by 0.2 V. At high ADP and inorganic phosphate concentrations it does not shift in the negative direction.

The interpretation of our experimental data obtained from measurements of the potential difference in the above chain is being verified by direct determinations of the amount of ATP synthesised. Our data show that the presence of a transmembrane potential is not a necessary condition for ATP synthesis by ATPase. The energy of proton (acid) solvation can be used for ATP synthesis.

We thank A. N. Frumkin, V. P. Skulachev and Dr I. A. Kozlov for discussions and S. A. Ostroumov for bacteriorhodopsin.

## Antiviral, immunosuppressive and antitumour effects of Ribavirin

THE compound 1- $\beta$ -D-ribofuranosyl-2,2,4-triazole-3-carboxamide (Ribavirin) has been reported to inhibit the replication of both RNA and DNA viruses *in vitro*, and to inhibit influenza virus infection of tissue cultures and mice<sup>1-3</sup>. The compound acts by interfering with guanine monophosphate formation and subsequent nucleic acid synthesis; at a concentration which completely inhibited influenza viral polypeptide production in tissue culture, however, there was no demonstrable effect on cellular protein synthesis<sup>4</sup>. To test the activity of Ribavirin further, we examined the effect of this compound on influenza virus

**Table 1** Response of ferrets to infection with influenza virus A/Port Chalmers/73

infection of ferrets. Four adult ferrets were inoculated intraperitoneally with 100 mg kg<sup>-1</sup> d<sup>-1</sup> of Ribavirin each for 7 d, this dose although it did not cause deaths or other signs of toxicity, was probably close to the toxic level as judged by standard tests in mice. Two hours after the second inoculation of drug, these animals and four

untreated ferrets were lightly anaesthetised and inoculated intranasally with 10<sup>3.0</sup> ferret-infective doses of egg-grown influenza virus A/Port Chalmers/73 (H3N2). Following virus infection, the drug-treated ferrets were given 5 further doses of Ribavirin. The response of the animals to virus infection was measured, as described previously<sup>5,6</sup>. The results are shown in Table 1. Ribavirin had a marked effect on the response of ferrets to influenza virus infection; compared with control ferrets, influenza virus-infected animals treated with Ribavirin did not exhibit a febrile reaction to infection, did not develop a significant increase in nasal wash protein and did not develop either local or serum antibody. In addition, the titre of virus in nasal washings collected 3 d after virus infection from drug-treated animals was 100-fold less than that found in control ferrets.

The absence of both a serum and a local antibody response in Ribavirin-treated ferrets infected with influenza virus may have been due to the antiviral activity of the compound which reduced virus replication to a level that did not induce antibody production (Table 1). Alternatively, Ribavirin may also have an immunosuppressive effect. To test this latter possibility, a group of guinea pigs was inoculated intraperitoneally with 100 mg kg<sup>-1</sup> d<sup>-1</sup> of Ribavirin for 10 d. On the second day, the drug-treated animals and a group of untreated guinea pigs were inoculated intramuscularly with 400 IU of inactivated influenza virus A/England/42/72 (H3N2) vaccine in an equal volume of Freund's complete adjuvant (FCA). Serum samples were collected before and 10 d after immunisation, and tested for serum haemagglutination inhibiting (HI) antibody. Some guinea pigs in each group were inoculated intraperitoneally with 10 ml of sterile paraffin 4 d after immunisation and were killed 6 d later; the peritoneal macrophages were collected from these animals and tested for cell-mediated immunity to influenza virus by the macrophage migration inhibition test. Ten days after immunisation, peripheral blood specimens were collected from the guinea pigs, and the buffy coat cells incubated with 2.0  $\mu$ g ml<sup>-1</sup> of phytohaemagglutinin and tested for lymphocyte transformation. The results are shown in Table 2. Guinea pigs immunised with influenza virus vaccine in FCA produced serum HI antibody by 10 d, post-inoculation (geometric mean titre g.m.t.=1:124); at this time however, no antibody was detectable in serum from Ribavirin-treated animals. The migration of peritoneal macrophages from both control and drug-treated guinea pigs was significantly inhibited in the presence of 40 IU of influenza virus A/England/42/72 vaccine. Furthermore, lymphocytes from drug-treated and control animals were both transformed by PHA to approximately the same degree (Table 2). The results indicate that Ribavirin, at

the concentration and by the route of inoculation used, inhibited the serum antibody response to influenza virus vaccine, but did not inhibit the cellular immune response.

Previous studies have shown that several compounds, such as ethidium bromide, rifamycin and Tilorone inhibit the RNA-dependent DNA polymerase of oncornaviruses and have an antitumour activity<sup>7-10</sup>; indeed, if oncornaviruses are important in maintaining the cancerous properties of transformed cells, the two properties may be related. Thus, Tilorone has a chemotherapeutic action against a wide range of viruses, and is an interferon inducer<sup>11</sup>; however, the antitumour activity of different analogues of this compound correlated more closely with the inhibitory activity on viral DNA polymerase, than with the ability to induce interferon<sup>12</sup>. From these observations, it is possible that many antiviral compounds, such as Ribavirin, may have antitumour activity. To test this possibility, groups of CBA mice were inoculated subcutaneously with 100 mg kg<sup>-1</sup> d<sup>-1</sup> of Ribavirin. Two hours after the second drug inoculation, these animals, together with a group of untreated mice, were inoculated subcutaneously at a different site with 5 × 10<sup>5</sup> transplanted adenovirus 12-induced CBA mouse tumour cells; the tumour cell inoculum used represented ten (50%) tumour doses<sup>13</sup>. Ribavirin was given to the treated mice for a further 20 d, and the incidence and size of tumours in the animals was recorded twice weekly for 4 weeks. Two identical experiments were carried out, and the results are shown in Table 3. In both experiments, the incidence of tumours and the size of palpable tumours was greater in control mice than in Ribavirin-treated mice; thus, Ribavirin inhibited the growth of transplanted adenovirus 12 tumours.

It is not certain from these studies that the antitumour activity of Ribavirin was due to the action of the drug on oncornaviruses present in the tumour cells; there are alternative mechanisms. The immune response of animals and man to either experimental or natural tumours has been shown to be cell mediated<sup>14,15</sup>, and factors which promote the cellular immunity of the host may enhance tumour immunity<sup>16</sup>. In contrast, sera from tumour-bearing animals may contain blocking factors which interfere with the cell-mediated immune response, and the production of humoral antibody could enhance tumour growth<sup>17</sup>. By allowing a cell-mediated response to transplanted tumour cells and inhibiting the humoral antibody response, as shown in the present studies in guinea pigs, the antitumour activity of Ribavirin may be due to the effect of this compound on the immune response of the host, and an enhancement of the mechanism of tumour cell rejection. By which mechanism or combination of mechanisms Ribavirin exerts an antitumour activity is not known; however, it is possible that the effectiveness of the compound is a result of a direct action on the oncornavirus present in tumour cells. If this is so, other antiviral compounds may share this property, and this should be investigated.

These studies were supported by grants from the Yorkshire Branch of the Cancer Research Campaign.

## Relationship between the oncornavirus gene product gp70 and a major protein secretion of the mouse genital tract

SEVERAL investigators have postulated that endogenous oncornaviruses play a role in development and differentiation, and that neoplasia is an unfortunate consequence of an otherwise important symbiosis<sup>1,2</sup>. Although attractive on theoretical grounds, these concepts remain unproven. Nevertheless, it is possible to study the relationship between viral gene expression and normal host functions. Evidence from several laboratories has suggested that expression of endogenous oncornavirus genes are under differentiation control in the mouse<sup>3-6</sup>. The clearest example of this is the case of gp70, the major envelope glycoprotein of the murine leukaemia viruses (MuLV)<sup>7-11</sup>. This protein which is coded for by the viral genome<sup>12</sup> may be a component of the surfaces of cells which follow certain pathways of differentiation. Further, the thymocyte differentiation marker, G<sub>1x</sub>, has been shown to be a type-specific antigenic determinant of some gp70 molecules<sup>4,5</sup>.

Although, as studies of G<sub>1x</sub> suggested, expression of gp70 is linked to cellular differentiation, we have shown already that its control is more relaxed than previously recognised. By immunofluorescence, gp70 was detected in various cell types, particularly lymphoid and epithelial

**Fig. 1** Characterisation of MuLV gp70 in secretions of epididymis and ductus deferens. Secretions of the epididymis and ductus deferens of an NZB mouse and disrupted MuLV (Scripps) were radioiodinated by the chloramine T method<sup>11</sup>. MuLV-producing lymphoblastoid cells (SCRF 60 A) were surface radioiodinated using lactoperoxidase as described previously<sup>8,12</sup>. After washing, cells were disrupted with 0.5% Nonidet P-40 and sonication, then centrifuged at 100,000g for 1 h. The resulting supernatant was used for immune precipitation. Labelled preparations were analysed by indirect immune precipitation as described in detail before<sup>8,9</sup>. Either goat anti-gp70 (Scripps) or normal goat serum was used as the primary antibody and rabbit anti-goat IgG was the second antibody. Resulting immune precipitates were dissociated in 8-M urea, 1% SDS, 2%  $\beta$ -mercaptoethanol, and then analysed on 6  $\times$  100 mm SDS polyacrylamide using the Laemmli system<sup>16</sup>. <sup>125</sup>I-radioiodinated  $\mu$ ,  $\gamma$ , and  $\kappa\lambda$  marker proteins from human IgG were included in each gel. Gels were sliced and counted as described before<sup>8</sup>. Results were corrected for crossover and counting efficiency and were plotted with a Hewlett-Packard system. Position of the marker protein is indicated by arrows. *a*, Radioiodinated SLV proteins reacted with goat anti-gp70 ( $\Delta$ ) or with normal goat serum ( $\square$ ). This figure shows that the goat anti-gp70 reacts primarily with MuLV gp70. The gp45 in this gel is a breakdown product of gp70, a subject which is now being studied. *b*, Radioiodinated SCRF 60 A cell surface proteins reacted with goat anti-gp70 ( $\Delta$ ) or with normal goat serum ( $\square$ ). Again, the specificity of the goat anti-gp70 for MuLV gp70 is shown. *c*, Radioiodinated secretions from the genital tract of a NZB mouse reacted with goat anti-gp70 ( $\Delta$ ) or with normal goat serum ( $\square$ ). This figure demonstrates that gp70 is a component of the secretions of the male genital tract. The approximate molecular weight of the gp70 from each source is 67,000.

cells<sup>13</sup>. We now report that a protein related immunologically to gp70 is present in the secretions of the epididymis and ductus deferens of the mouse. This protein has a molecular weight of 67,000, comprises up to 10% of these secretions, and is associated with the surface of sperm. Apart from its biological importance, identification of a major site of expression of an oncornavirus-related protein allows us to complement serological analysis with a structural study in which a virion structural protein is compared with a differentiation antigen of the mouse.

The molecular properties of the gp70 molecules of MuLV and of the secretions of the epididymis and ductus deferens were compared by sodium dodecyl-sulphate (SDS) polyacrylamide gel electrophoresis of indirect immune precipitates and by analysis of peptide maps of proteins eluted from gels. The data in Fig. 1 show that the anti-gp70 antibody reacts specifically with a single component from each of three sources: (1) purified MuLV (Scripps), (2) surface radioiodinated MuLV-producing lymphoblastoid cells (SCRF 60 A) or (3) secretions from the epididymis and ductus deferens. The molecular weight of the protein was approximately 67,000 in all three cases. A comparison of the tryptic peptides of AKR virus gp70 and genital tract protein from AKR mice showed significant differences (B.C.D.V. *et al.*, in preparation). We do not yet know if the observed differences are due to glycosylation or change in the amino acid composition.

Antigenic cross reactivity between MuLV gp70 and the gp70 of the genital tract was confirmed by double diffusion studies. Antibodies against purified MuLV gp70 gave a reaction of partial identity between MuLV gp70 and a molecule in the secretions of epididymis and ductus deferens. MuLV gp70 has antigenic determinants not present on the genital tract protein, resulting in a 'spur' in the Ouchterlony plate. After absorption of anti-gp70 antibody with a crude preparation of secretions from the epididymis and ductus deferens, the reaction between the absorbed antiserum and the genital tract protein was abolished whereas the reaction between the absorbed antiserum and the viral gp70 was not. Conversely, we showed that absorption of the anti-gp70 with virus abolished reaction to both viral and genital tract protein.

The amount of gp70 in preparations of the secretions from the genital tract was determined by competition radioimmunoassay using the interspecies assay. As discussed by Strand and August<sup>9</sup>, such competition curves are the result of three parameters of the reaction: first, the concentration of the competing proteins; second, the relative affinity of the antibodies for the proteins; and, third, the composition of the antigenic determinants of the proteins and of the

**Fig. 2** Competition radioimmunoassay for MuLV gp70. Reaction conditions were similar to those of Strand and August<sup>9</sup> in which the interspecies determinants of gp70 are measured, goat anti-FeLV (1:700) and <sup>125</sup>I-gp70 (Friend) (1 ng). Competing proteins were from MuLV (Scripps) ( $\circ$ ) and from secretions of epididymis and ductus deferens of an NZB mouse ( $\bullet$ ). Similar curves for the genital tract gp70 were obtained for NZB (NZB  $\times$  NZW)F<sub>1</sub>, NZW and 129 G<sub>1</sub>X<sup>+</sup>.

Fig. 3 Association of MuLV gp70 with sperm. NZB sperm were purified from epididymis and ductus deferens by differential centrifugation. Sperm were surface radioiodinated with lactoperoxidase, then extracted and analysed. SDS polyacrylamide gel electrophoresis of radioiodinated sperm proteins reacted with goat anti-gp70 (Scripps) ( $\Delta$ ) or with normal goat serum ( $\square$ ). Position of  $^{131}\text{I}$  marker proteins is indicated by arrows. The approximate molecular weight of the sperm gp70 is 67,000.

antibodies. A set of representative binding curves is shown in Fig. 2. The relative amount of gp70 in the secretions of the genital tract varied considerably from preparation to preparation, ranging from 2 to 10% of the protein. This variation may reflect different amounts of gp70 in the secretions from mouse to mouse, and from strain to strain, but was also undoubtedly influenced by the extent to which the secretions were recovered and/or contaminated by other proteins, especially serum proteins.

The relative slope of the inhibition curves for MuLV gp70 and that of the genital tract proteins are different, indicating differences in the affinities of the interspecies antigenic determinants for the antibodies. At high concentrations the genital tract proteins compete completely for antibody with the labelled viral gp70. Thus, most of the viral interspecies determinants are present in the genital tract protein. These studies show that the MuLV gp70 and the molecules from the genital tract are immunologically similar, but not identical.

Proteins of epididymal secretions are known to associate with the surface of sperm where they may play a role in capacitation. To determine whether gp70 associated with the sperm surface, epididymal sperm were purified and then surface radioiodinated. Figure 3 shows that in this strain, a gp70 molecule is associated with the sperm surface. It is interesting that studies (to be reported elsewhere) have shown that the gp70 of the epididymal secretions and that associated with the sperm surface may be the product of different genes.

The basic question relating to the proteins studied here is whether the host and viral proteins are transcripts from a single gene and are modified after synthesis as by glycosylation, or whether they are products of different genes. The differences in peptide maps strongly suggest that they are different gene products. A possibility not excluded by our studies is that MuLV gp70 and the genital tract protein are unrelated gene products modified so as to cross react immunologically. But a trivial cross reactivity seems un-

likely for several reasons. First, three different antisera prepared against purified gp70 from three different FMR viruses all reacted with the genital tract protein. Second, we know from previous studies that at least one protein of the male genital tract shows a mode of inheritance identical to that of  $G_{IX}$  and is lost in congenic  $G_{IX}^-$  mice<sup>13</sup>. Third, the interspecies determinants of viral gp70 are completely represented in the genital tract protein. Finally, the cross reactivity between viral and genital tract gp70 is not simply due to common carbohydrate groups. Unpublished results from our group and Bolognesi's group (personal communication) show that proteolysis destroys the antigenicity of gp70 whereas removal of the carbohydrate does not.

The data presented here indicate that several distinct genes for gp70 can be found in the mouse genome, some of which code for proteins made by certain differentiated cells; and others which code for proteins which are incorporated into virus.

We thank Drs S. J. Kennel, D. P. Bolognesi, M. Strand, and J. T. August for antibodies against purified gp70, Dr J. Ihle for AKR virus, Ms Barbara Nave for technical assistance, and Dr Frank J. Dixon for help and encouragement. This research was supported by grants from the National Foundation-March of Dimes, the National Cancer Institute, and a Basil O'Connor Starter Research grant from the National Foundation. R. A. L. is a recipient of a US Public Health Service career development award.

## Isolation of nucleic acid-binding protein: stimulation of reverse transcriptase-catalysed DNA synthesis

RNA tumour viruses transfer their genetic information from a single-stranded RNA genome found in their virions to a double-stranded DNA covalently integrated into chromosomes of the infected host<sup>1,2</sup>. A series of nucleic acid intermediates must therefore exist between the single-stranded RNA and the integrated viral DNA genome. The discovery of RNA-directed DNA polymerase (reverse transcriptase) associated with RNA tumour viruses fulfilled a critical requirement for synthesis of viral DNA<sup>3,4</sup>. The initial product in this information transfer is a RNA-DNA

hybrid which is converted into free, unintegrated DNA-DNA<sup>8</sup>. The double-stranded DNA (provirus) is then integrated into chromosomes of the infected host. We report here the isolation of a nucleic acid-binding (unwinding) protein from chick fibroblasts transformed by Rous sarcoma virus (RSV) and its stimulatory effect on DNA synthesis catalysed by reverse transcriptase. A protein capable of unwinding RNA-DNA hybrid and DNA-DNA duplex would not only conserve the input viral RNA strand for further reverse transcription, but also facilitate replication of the double-stranded viral DNA into many copies of provirus before integration.

Binding protein was isolated by affinity chromatography from chick embryo fibroblasts chronically transformed by Schmidt-Ruppin RSV, subgroup D after 2 weeks of virus infection. Cellulose containing covalently linked single-stranded calf thymus DNA was purchased from P.L. Biochemicals. All radioactive polynucleotides were purchased from Miles Laboratories. In a typical run, about 2 wet g transformed cells were washed, sonicated and centrifuged to obtain debris-free supernatant. The supernatant was treated with polyethylene glycol and centrifuged to remove nucleic acid. After dialysis the supernatant was

**Fig. 1** Isolation of DNA-binding protein using DNA-cellulose column. Frozen chicken embryonic fibroblasts (2 g), completely transformed by RSV, subgroup D, were suspended and washed twice with phosphate-buffered saline. Cells suspended in 4 ml sonicating buffer (20 mM Tris-HCl, pH 8.0, 1 mM EDTA, 1 mM 2-mercaptoethanol, 1.7 M NaCl) and disintegrated for 45 s at 4 A in a Branson Sonifier. Cell debris removed by centrifugation at 10,000g for 10 min. Polyethylene glycol (MW 6,000–7,500, 30% in 1.7 M NaCl) was stirred into supernatant to a concentration of 10%. After stirring for 30 min, suspension centrifuged at 27,000g to remove nucleic acid precipitate. Resulting clear supernatant fraction dialysed against 2 l Tris buffer (20 mM, Tris-HCl, pH 8.0, 1 mM EDTA, 1 mM 2-mercaptoethanol, 50 mM NaCl, 40% glycerol) for 20 h. Precipitate formed during dialysis removed by centrifugation (27,000g for 20 min) and supernatant passed through (4 ml h<sup>-1</sup>) a column (1 × 1 cm) of single-stranded DNA-cellulose (P.L. Biochemicals) that had been washed with the Tris buffer. Column washed with 10 ml Tris buffer and eluted with 2.5 ml each of 0.2 M, 0.6 M, 2.0 M NaCl in Tris buffer. Fractions (0.5 ml) were collected. <sup>3</sup>H-poly d(AT)-poly d(AT) (2 nmol, 25 mCi mmol<sup>-1</sup> P) or <sup>3</sup>H-poly(rA)-poly(dT) (2.8 nmol, 18 mCi mmol<sup>-1</sup> P) incubated with fractions (10 µl) in binding buffer (20 mM Tris-HCl, pH 8.0, 1 mM EDTA, 2 mM mercaptoethanol, 50 mM NaCl and 5% glycerol) in total volume 0.1 ml at 35 °C for 10 min. Solution chilled and diluted with 2 ml binding buffer and filtered through Millipore filter. Filter washed 3 times with 3 ml binding buffer; dried and radioactivity determined in toluene-based scintillation fluid.  $\Delta$ , Binding of <sup>3</sup>H-poly d(AT)-poly d(AT);  $\circ$ , binding of <sup>3</sup>H-poly(rA)-poly(dT).

**Table 1** Effect of binding protein (BP) on DNA synthesis by reverse transcriptase

Template	pmol <sup>3</sup> H-dTMP incorporated per h*		Ratio +BP
	–BP	+BP	–BP
Native calf thymus DNA	0.86	1.50	1.7
Nicked calf thymus DNA†	0.88	2.62	3.0
Heated calf thymus DNA‡	0.80	11.0	13.7

\*Reaction conditions as in Fig. 2 except 0.9 U reverse transcriptase were used. Binding protein, when present, was 0.5 µg per incubation. DNA concentrations were 50 µg ml<sup>-1</sup>.

†Calf thymus DNA nicked by treatment with DNase I (ref. 11).

‡Calf thymus DNA was heat-denatured at 100 °C for 15 min and chilled immediately<sup>11</sup>.

passed through a DNA-cellulose column (1 × 1 cm) pre-equilibrated with Tris buffer (20 mM, Tris-HCl, pH 8.0, 1 mM EDTA, 1 mM 2-mercaptoethanol, 50 mM NaCl and 10% glycerol). The column was washed with the Tris buffer and then eluted stepwise with 0.2, 0.6 and 2.0 M NaCl in the buffer. Resulting fractions were assayed for nucleic acid binding activity as described previously<sup>7</sup> using either <sup>3</sup>H-poly d(AT)-poly d(AT) or <sup>3</sup>H-poly(rA)-poly(dT) as substrate. Fig. 1 shows the results obtained from the DNA-cellulose column. There were three peaks of binding activity when the radioactive templates were used. All the fractions containing binding activity were combined and dialysed against the binding protein buffer (20 mM Tris-HCl, pH 8.0, 1 mM EDTA, 1 mM 2-mercaptoethanol, 20 mM NaCl and 30% glycerol).

**Table 2** Effect of binding protein (BP) on reverse transcription of RSV 70S RNA

Template	Binding protein	pmol <sup>3</sup> H-dTMP incorporated*	+BP % –BP
70S†	0	0.65	—
70S	0.8 µg	1.08	1.6
70S	2.0 µg	1.54	2.4
—	2.0 µg	0	—

\*Reaction conditions as in Fig. 2, except 0.5 U purified reverse transcriptase from RSV B77 used.

†RSV 70S RNA (4.5 µg ml<sup>-1</sup>) isolated from RSV B77 by sucrose density centrifugation<sup>24</sup>. 70S peak showed a single band of high molecular weight material in gel electrophoresis<sup>25</sup>.

The effect of the isolated binding protein on polymerase activity was studied in a reaction in which reverse transcriptase<sup>8</sup> catalysed DNA synthesis using heat-denatured calf thymus DNA as template. DNA synthesis as represented by TCA-insoluble counts<sup>9</sup> was linearly proportional to the amount of binding protein<sup>10</sup> present in the reaction with a maximum stimulation of about tenfold increase with 1 µg of the protein (Fig. 2). Heating of the binding protein at 100 °C for 5 min completely abolished the stimulatory effect and the binding protein itself contained no polymerase activity (Fig. 2).

It is clear from Figs 1 and 2 that the isolated protein binds to DNA and stimulates reverse transcriptase in DNA synthesis. We explored the possibility whether the binding protein enhances DNA synthesis by promoting denaturation (unwinding) of double-stranded DNA. When native calf thymus DNA was used as template the binding protein stimulated DNA synthesis by reverse transcriptase about twofold, which is not inconsistent with the unwinding of the template (Table 1). When the template was native DNA nicked slightly with DNase<sup>11</sup>, the protein stimulated DNA synthesis even greater (threefold), suggesting easier unwinding of the double-stranded DNA after nicking. When heat-denatured DNA was used as template, denatured DNA in the absence of the protein was a poor template for

Fig. 2 Stimulation of reverse transcriptase DNA synthesis by binding protein. Reaction mixture in total volume of 120  $\mu$ l contained: purified reverse transcriptase<sup>8</sup> (phosphocellulose fractions, eluted with 0.22 M phosphate buffer), 0.3 U; dATP, dGTP, dCTP, 0.1 mM each; MgCl 5 mM; dithiothreitol, 3 mM; NaCl, 50 mM; heat-denatured calf thymus DNA, 6  $\mu$ g (Sigma, type 1; boiled at 100 °C for 15 min and chilled); <sup>3</sup>H-dTTP, 8  $\mu$ Ci (20  $\mu$ Ci nmol<sup>-1</sup>); and specified amount of binding protein as determined by Lowry *et al.*<sup>10</sup>. Incubation carried out at 35 °C for 60 min and TCA-insoluble radioactivity determined by filter paper method. One unit of reverse transcriptase activity was defined as ability to incorporate 1 pmol <sup>3</sup>H-dTTP into TCA-insoluble precipitate per h in experimental conditions described above. ○, Reverse transcriptase activity in presence of binding protein; Δ, in presence of heated binding protein; □, polymerase activity of binding protein alone.

reverse transcriptase, which is in agreement with the observation that reverse transcriptase did not prefer single-stranded DNA<sup>12</sup>. Binding protein, however, stimulated greatly (14-fold) DNA synthesis when heat-denatured DNA template was used. We suggest that the protein binds strongly and cooperatively to single-stranded DNA and thus promotes unwinding of the small region of undenatured, double-stranded segment to which reverse transcriptase is attached. When bound to single-stranded DNA, it prevents intrastrand annealing and maintains the DNA in an extended conformation, thereby making the template more transcribable.

That the binding protein can unwind double-stranded DNA was studied in a separate experiment. When an excess of the binding protein (78  $\mu$ g) was added at 24 °C to 8  $\mu$ g double-stranded DNA, poly d(AT):poly d(AT),  $A_{260}$  of the DNA increased as a function of time until a plateau 35% greater than the original absorbance was reached (Fig. 3). Similar results were obtained using poly(rA):poly(dT), poly(A):poly(U) and 70S RSV RNA as substrates; the hyperchromic effects were about 29%, 19% and 20%, respectively, in the conditions used (not shown here). This hyperchromic shift is characteristic of the helix-coil transition which has been observed with the binding protein from bacteria<sup>13-15</sup>.

The binding protein reported here was capable of binding to all forms of nucleic acids: double-stranded DNA, <sup>3</sup>H-poly d(AT):poly d(AT), single-stranded DNA (affinity

column), double-stranded RNA (<sup>3</sup>H-poly(A):poly(U)), single-stranded RNA (<sup>3</sup>H-poly(A)) and DNA-RNA hybrid (<sup>3</sup>H-poly(rA):poly(dT)). The binding affinity in preliminary studies indicated about the same preference by the protein for double-stranded DNA or RNA-DNA hybrid. The affinity to single-stranded RNA (<sup>3</sup>H-poly(U)), however, was greater than double-stranded RNA (<sup>3</sup>H-poly(A):poly(U) or <sup>3</sup>H-poly(I):poly(C)).

The protein isolated by the DNA affinity column contained some DNase activity. Details of purification and properties will be described elsewhere. As in the case of the reported specificity of binding proteins to polymerases from the same source<sup>13,15-18</sup>, the binding protein stimulated greatly reverse transcriptase but little, if any, polymerase from *M. lysodeikticus* (data not shown). Although the binding protein stimulated sevenfold DNA synthesis by bacterial polymerase using native DNA as template, it stimulated little, if any, DNA synthesis after the template was heat denatured, suggesting that the stimulation was attributable to unwinding of the template by the protein instead of interaction between the binding protein and the bacterial polymerase. In contrast to this, the binding protein stimulated 14-fold DNA synthesis by reverse transcriptase on the heat-denatured template, suggesting that the binding protein, in addition to unwinding DNA, may also bind to reverse transcriptase during synthesis in such a way that the enzyme does not dissociate from the template and thus prolongs synthesis. We are studying the possibility of such an interaction between reverse transcriptase and the binding protein analogous to that of polymerase II and the binding protein in *Escherichia coli*<sup>13,16</sup>.

We have yet to determine the exact relationship of the binding protein reported here to viral RNA replication. We have also isolated a binding protein from chick embryo fibroblasts similar to that from RSV-transformed cells. Therefore, it seems that the binding protein is not coded by the virus. Intramolecular hydrogen bonding of 70S RSV genome is well known<sup>19</sup>. In the presence of the binding protein in a preliminary study, we have observed in electron microscopy an extended form of RSV RNA instead of the usual, collapsed structure, similar to the observation of

Fig. 3 Hyperchromicity of poly d(AT):poly d(AT) in presence of DNA-binding (unwinding) protein. Reaction mixture contained alternating copolymer (8.0  $\mu$ g) and binding protein (78  $\mu$ g) in 1.2 ml buffer (20 mM Tris-HCl, pH 8.0, 1 mM EDTA, 1 mM mercaptoethanol, 20 mM NaCl, 30% glycerol).  $A_{260}$  determined with a recording Gilford spectrophotometer at 24 °C immediately after mixing of copolymer and binding (unwinding) protein at 24 °C. Cuvettes containing copolymer or binding protein alone in buffer were also scanned to calculate increase in absorbance.

RSV RNA in the presence of gene 32 protein<sup>18</sup> Probably due to the collapsed RNA structure, a disturbing feature of reverse transcriptase reaction *in vitro* has been the relatively small size (5–7S) of the product and the faster initial rate of DNA synthesis<sup>20–23</sup>. In the presence of the binding protein, however, the rate of synthesis and the size of the DNA product would be expected to increase. In our preliminary studies using RSV 70S as template, increasing amounts of the binding protein stimulated linearly the rate of DNA synthesis in a homologous reverse transcriptase reaction (Table 2). A detailed study of the influence of the binding protein on the size of DNA products and the kinetics of synthesis is under way.

## Eukaryotic DNA replication complex

We postulate that eukaryotic DNA replication occurs at discrete intranuclear macrostructures, replication complexes, which might be separable from the bulk of nuclear material. A complex composed of DNA, protein and other nuclear constituents could have a different intrinsic density from nucleic acids or protein alone, and this might be the basis for its isolation. Replication complexes would characteristically contain nascent DNA<sup>1–4</sup> and DNA polymerase. If they are functionally intact, they should also have the intrinsic capacity to synthesise DNA. We have used a previously reported method for the fractionation of sonically disrupted nuclei on gradients of  $\text{Cs}_2\text{SO}_4$  (ref. 5). The results indicate that replication complexes may be partially purified by this method, and that ATP-dependent DNA synthesis is a characteristic of the complexes.

Isolated nuclei from regenerating rat liver were sonicated carefully and the sonicate was banded in equilibrium density gradients of  $\text{Cs}_2\text{SO}_4$  (ref. 5). Three principal bands were observed in the gradients: light band (LB), middle band (MB) and heavy band (HB) (average densities: 1.21, 1.26, and 1.32  $\text{g cm}^{-3}$ , respectively). These bands possess different relative concentrations of DNA, RNA and protein<sup>5</sup>. To demonstrate nascent DNA, rats were labelled with tritiated thymidine for 5, 30 or 120 min *in vivo* 23 h after partial

Fig. 1. Distribution of radioactivity in DNA of nuclear sub-fractions after 5, 30 or 120 min of labelling *in vivo*. Female Osborne-Mendel rats weighing 120 g were injected intraperitoneally with tritiated thymidine 23 h after partial hepatectomy. Nuclei were isolated from the livers by the method of Lynch *et al.*<sup>10</sup> Nuclear pellets were suspended in 5 mM Tris-HCl, pH 7.5 containing 5 mM Na<sub>2</sub>EDTA and then sonicated in precisely defined conditions<sup>5</sup>.  $\text{Cs}_2\text{SO}_4$  was added to this suspension to achieve a 1.3  $\text{g cm}^{-3}$  solution, and nuclear constituents were allowed to concentrate at their characteristic intrinsic buoyant densities in the gradients generated during a 66-h centrifugation at 35,000 r.p.m. in an SW40 rotor at 25 °C. The gradients were fractionated into 1-ml portions, and processed as follows: precipitating and washing with cold dilute TCA and PCA to remove  $\text{Cs}_2\text{SO}_4$  and unincorporated radioactivity; treatment with 0.3 M NaOH at 37 °C for 1 h followed by further washing with acid, and hydrolysis of DNA with 1.2 M PCA at 60 °C for 1 h. Radioactivity and DNA content were quantified in this hydrolysate. Nearly all radioactivity recovered after our standard processing was present in DNA and in thymidine residues when this DNA was subjected to enzymatic hydrolysis and chromatography (unpublished observation). The percentage of the total gradient d.p.m. present in each fraction was plotted to demonstrate the distribution of radioactivity after 5 (○), 30 (□), and 120 (△) min of labelling. The total d.p.m. incorporated were 129,191 at 5 min, 357,586 at 30 min and 1,749,712 at 120 min. The portions of the gradients corresponding to the light band (LB), middle band (MB) and heavy band (HB) are marked at the bottom of the figure.

hepatectomy (DNA synthesis peak<sup>6</sup>). The percentage distribution of radioactivity incorporated into DNA of gradient fractions changes with duration of labelling (Fig. 1) and this suggests a precursor-product relationship. LB (which contains 4.9% of the total DNA) has 11.1% of the radioactivity incorporated into DNA after 5 min and this decreases to 3.9% after 120 min; MB (which contains 7.9% of the total DNA) has 21.6% after 5 min and only 3.4% after 120 min; in contrast, HB (which contains 86% of the total DNA) has 44.9% at 5 min and this increases to 88.0% at 120 min. Much of the incorporated radioactivity is found in a small fraction of the total DNA after a short labelling period. With time there is a reduction in the proportion of radioactivity associated with the MB and LB DNA, and an increase in the proportion of radioactivity associated with the bulk DNA.

Previous reports<sup>1–4</sup> indicate that nascent eukaryotic DNA

is partially "destabilised" and seems to have partial single-stranded character because of its ease of denaturation. To evaluate this property, DNA was purified from the  $\text{Cs}_2\text{SO}_4$  gradient bands by rebanding in  $\text{CsCl}$  gradients. The purified DNA was then analysed by hydroxyapatite chromatography<sup>7</sup> and gel electrophoresis<sup>8</sup>. For both LB and MB, a sizeable proportion (15–20%) of the DNA labelled for 5 min *in vivo* demonstrated limited mobility in acrylamide–Agarose gels, consistent with the limited mobility demonstrated for replication forks from *Escherichia coli*<sup>9</sup>. In addition, a larger proportion of LB and MB DNA than HB DNA was more readily eluted from hydroxyapatite than native double-stranded DNA, which suggested a greater partial single-stranded character to LB and MB DNA.

The intranuclear localisation of the labelled product of DNA replication and repair *in vitro* in isolated rat liver nuclei was evaluated in  $\text{Cs}_2\text{SO}_4$  gradients. DNA replication (semi-conservative) in isolated S-phase liver nuclei is ATP dependent<sup>10–11</sup> whereas DNA repair (non-semi-conservative) is ATP independent and best observed in non-S-phase nuclei<sup>11–12</sup>. Analysis of  $\text{Cs}_2\text{SO}_4$  gradients of sonicated nuclei after DNA replication *in vitro* showed the labelled DNA product of the ATP-dependent process to be largely confined

**Fig. 2** Distribution in  $\text{Cs}_2\text{SO}_4$  gradients of DNA product of semi-conservative and non-semi-conservative DNA synthesis *in vitro*. Nuclei were isolated<sup>10</sup> from normal rats and from partially hepatectomised rats 23 h after operation. Nuclei from normal liver were treated with DNase I to stimulate non-semi-conservative, ATP-independent DNA synthesis<sup>11</sup>. Regenerating liver nuclei were incubated with and without ATP in conditions previously used to demonstrate ATP-dependent DNA replication<sup>11</sup>. For non-semi-conservative DNA synthesis DNase-treated normal liver nuclei were assayed in the same conditions, but with ATP omitted. After 5 min incubation at 37 °C, nuclei were cooled in an ice bath, pelleted by centrifugation at 600g and then resuspended in 5 mM Tris-HCl, pH 7.5 containing 5 mM  $\text{Na}_2\text{EDTA}$ . Nuclei were sonicated and the sonicates were banded in  $\text{Cs}_2\text{SO}_4$  equilibrium density gradients<sup>5</sup>. The gradients were then fractionated into 1-ml portions and the fractions were processed as described in the legend to Fig. 1. DNA content and radioactivity were determined for each fraction. ATP-dependent DNA replication in regenerating rat liver nuclei was determined as the activity of nuclei incubated with ATP minus the activity without ATP<sup>11</sup>. The d.p.m. in each fraction were normalised to the DNA content of the fraction and the specific activities were plotted for ATP-dependent DNA replication (○) and DNase I-activated DNA synthesis (□). The total d.p.m. was 76,800 for ATP-dependent DNA replication and 44,800 for ATP-independent DNase-activated DNA synthesis.

to the MB and LB (Fig. 2). In contrast, the labelled DNA product of non-semi-conservative DNA synthesis in isolated nuclei roughly paralleled the total distribution of DNA in the gradient and thus did not show specificity of localisation (Fig. 2). In previous experiments<sup>7</sup> we have shown the presence of DNA polymerase activity (primed with exogenous activated DNA) in gradient fractions of unlabelled liver nuclei and have shown the greatest quantities to be in MB and LB. In other experiments gradient fractions from unlabelled regenerating rat liver nuclei were evaluated for endogenously-primed, ATP-dependent DNA synthesis in assay conditions used for comparable nuclei. In the approximately 50% of these studies in which ATP-dependent DNA synthesis was detected in the gradient fractions, the MB was consistently shown to have the highest levels of this activity (unpublished observation).

The presence of ATP-dependent DNA synthesis and partially single-stranded, rapidly labelled DNA containing replication forks in the same fractions from  $\text{Cs}_2\text{SO}_4$  gradients indicates that this procedure partially purified eukaryotic DNA replication complexes from S-phase rat liver nuclei. This result extends the observation of ATP-dependent DNA replication in isolated mammalian cell nuclei<sup>10,11,13</sup> and complements the observation of ATP-dependent DNA synthesis in MB fractions isolated from sea urchin embryo nuclei<sup>14</sup>. Since nuclear membrane is largely confined to the LB (unpublished observation), the result reported here differs from studies involving the MB technique<sup>14–16</sup> because a sizeable proportion of nascent DNA is in the MB as well as in association with the nuclear membrane (in the LB). The property of ATP-dependent DNA synthesis seems to provide a characteristic *in vitro* assay with which the replication complex can be purified. In future experiments we will attempt to determine whether other enzymes, such as deoxyribonuclease, DNA ligase, DNA-dependent RNA polymerase, RNase H, as well as DNA-unwinding protein are intrinsic constituents of the DNA replication complex. Identification of constituents of the replication complex and preparation of appropriately labelled antibodies to them may allow unambiguous localisation of DNA replication sites in the nucleus by direct visualisation.

## Evidence for defined lengths of DNA replication units in 'satellite' DNA from *D. ordii*

EUKARYOTIC DNA can be isolated as long fibres on which replication has occurred at several locations<sup>1-9</sup>. These replicating units are arranged in tandem and spaced at intervals which vary in length from 1- to 100  $\mu\text{m}$ <sup>2-5, 7-9</sup>. Although it can be determined that at any time replication has been initiated from a particular position on a fibre, it is not known whether that position remains fixed from one round of replication to the next, nor whether replication terminates at fixed locations on the DNA fibre. Attempts to resolve these questions have used experiments in which replicated units are visualised and their length and spatial distribution reconciled with models of fixed<sup>4,5</sup> or varying<sup>3,8</sup> sites of initiation and termination. Different studies have reached the different conclusions that these sites are variable<sup>3,8</sup> or fixed<sup>4,5</sup> (particularly with respect to termination of replication). All of these studies have been complicated by the observation that the length of replicated regions seems to vary in a manner consistent with a broad but continuous distribution

for the length of the replicating unit. Such a distribution could reflect variation in the position of fixed termination sites or the fact that termination is not at a fixed position on the DNA fibre.

We have isolated and visualised a set of DNA fibres in which the length and spacing of tandem-replicated units are distributed as multiples of a single fundamental unit. These measurements were made on 'satellite' DNA of *D. ordii*<sup>10,11</sup> which had been isolated by CsCl centrifugation. The material to be described was prepared in a series of experiments reported previously<sup>5</sup>.

We have already presented evidence that satellite DNA with a buoyant density heavier than that of main band DNA<sup>10</sup> and characteristically replicated late in S phase<sup>11</sup> (6 to 8 h after release of fluorodeoxyuridine (FUDR) block) can be visualised as multiple short segments of replicated DNA arranged in tandem and interspersed with non-replicated material<sup>5</sup>. In that study we prepared DNA from cells which had been continuously labelled with <sup>3</sup>H thymidine for 8 h after release from FUDR inhibition of DNA synthesis. This DNA was fractionated by CsCl centrifugation and autoradiographs prepared from the different fractions. An outstanding characteristic of this material was the pattern of very long DNA fibres with small replicated and non-replicated regions occurring as tandem arrays on one fibre. We have quantitatively re-examined the material from the densest of these satellite fractions and obtained the distribution of non-radioactive and radioactive regions shown in Fig. 1a and b. A detailed description of the isolation and preparation of this DNA has been published<sup>5</sup> and a summary of this experiment is presented in the legend to Fig. 1.

Both non-radioactive (Fig. 1a) and radioactive (b) regions are grouped into distinct size classes which seem to be the same. That this is the case is apparent when the data for both replicated and non-replicated material are combined (Fig. 2a). In this larger mixed population the discrete length classifications are even more apparent.

It is interesting that the frequency of any particular size class seems to decrease as an exponential function of its size Fig. 2b. This relationship is apparent for all of the more heavily populated classes. The distribution in Fig. 2a was compared with the null hypothesis that pieces are distributed as a continuous function of their length according to the equation: number of any length,  $L = Ae^{-\lambda L}$ . The probability of obtaining the result in Fig. 2a assuming the null hypothesis to be correct is  $P < 0.001$  ( $\chi^2 = 93$ , 27 d. f.). These data are based on a sample of 350 units distributed in tandem arrays on 31 fibres isolated after lysis of a population of  $10^5$  cells and fractionation of the DNA on a CsCl density gradient. During this process, the sample was thoroughly mixed and it is extremely unlikely that any two fibres were isolated from the same cell. A fraction of the same relative density isolated from cells labelled for 10 h instead of 8 h, did not yield tandem arrays, but only long stretches of continuously radioactive material<sup>5,11</sup>. This suggests that the tandem arrays found at 8 h are due to replicated (radioactive) and non-replicated (non-radioactive) regions and that the non-radioactive regions are replicated between 8 and 10 h.

The data in Figs 1a and b and 2a are readily explained by assuming the existence of tandemly arranged replication units of defined length only some of which have been replicated after 8 h incubation in label.

The distribution of sizes is interesting. The size classes approximate one-, two-, four-, six-, eight- and tenfold multiples of a unit the length of which is about 7  $\mu\text{m}$ . Figure 2c compares the distribution of size classes in Fig. 2a with the distribution generated by a computer assuming that size classes are normally distributed ( $\sigma = 3.27 \mu\text{m}$ ) around a mean length which is one-, two-, four-, six-, or eightfold multiple of 6.93  $\mu\text{m}$  assuming a declining amplitude (peak height) equal to  $50e^{-0.037L}$ , where  $L$  is the piece size in  $\mu\text{m}$ . Distributions which fit the data better than that in Fig. 2c can be generated if one assumes that s. d. of each size class is a function of the size, being least for the class of shortest pieces.

Fig. 1 Frequency of 'a', non-replicated regions (GAPS) and b, replicated (radioactive) regions assorted with respect to length. Cells of *D. ordii* grown as monolayers were inhibited with FUDR ( $1 \mu\text{g ml}^{-1}$ ) for 12 h. Inhibition was reversed by addition of <sup>3</sup>H-thymidine ( $50 \text{ Ci mmol}^{-1}$ ;  $1 \mu\text{g ml}^{-1}$ ) and labelling continued for 8 h. DNA was isolated as described previously and autoradiographs prepared. The density profile of this material has been published (ref 5, Fig. 2). These data were obtained from the fractions designated as S\* in that publication. All of the radioactive units were taken from tandem arrays and only internal units were scored.

**Fig. 2** Combined distributions of replicated and non-replicated regions assorted with respect to length. *a*, linear; *b*, logarithmic frequency scales; *c*, comparison of observed frequency distribution with that generated on assumption that pieces are distributed in classes of one-, two-, four-, six- or eightfold multiples of 6.93  $\mu\text{m}$  (see text for details).  $\blacktriangle$ , Observed frequency;  $\circ$ , best fit distribution generated by computer.

The distribution in Fig. 2*a* and *c* cannot be explained by the simple association of units of the smallest size class because odd multiples are missing. Thus absence of lengths corresponding to three, five or seven times this basic unit requires that the population be composed of at least two categories of units: that corresponding to a single 7- $\mu\text{m}$  unit and those corresponding to groupings of basic units each one of which is approximately twice that size. We have observed that 25% of the smallest units are distributed on two fibres, whereas the rest are distributed on some 17 fibres and are found in every instance as isolated units (that is, 7- $\mu\text{m}$  units, either radioactive or non-radioactive, are separated from each other by larger units). No other clustering of any size class was apparent.

To our knowledge, distributions similar to that in Fig. 2 have not been observed in other material. It seems likely that this distribution reflects the regular spacing of replication units in satellite DNA and that this regularity may be generated by the repetition of particular sequences. On this assumption, it is possible, to construct models which can account for the evolution of the distribution seen in Fig. 2.

We thank Dr R. Bjorklund for generating the 'best fit' distribution of sizes. Supported by grants from the American Cancer Society and the US Public Health Service to K.G.L.

## Low temperature specific heat anomalies in melanins and tumour melanosomes

THE melanins are of great interest because of their widespread presence in biological systems. In humans, melanin is found in nearly all areas where energy transduction occurs, for example, skin, inner ear, retina, as well as in several other areas such as the midbrain. The loss of melanin in the substantia nigra (midbrain) has been correlated with Parkinson's disease, and melanin-drug interactions in the stria vascularis (inner ear) have been implicated in deafness (ototoxicity)<sup>1-3</sup>. Study of the physical properties of the melanins has yielded considerable insight into possible functional roles in biological systems<sup>3-5</sup>, and has led to the design of possible new treatments for the human malignant disease, melanoma, based on interactions between ultrasound and melanin binding drugs<sup>6,7</sup>. These observations have indicated that the melanins play an active, rather than passive, role in biological systems and intensive study of their properties should lead to better understanding of their functions *in vivo*. Such studies are also lending some insight into problems associated with the solid-state physics of amorphous materials<sup>2,5</sup>.

Studies of the physical properties of melanins show them to be highly stable structures, with a large density of free spins ( $10^{18} \text{ g}^{-1}$  (ref. 8)), and also amorphous<sup>9</sup>. These properties seem to be relatively insensitive to the method of preparation<sup>10</sup>. Experiments have shown that melanins exhibit rather exotic electrical characteristics similar to those found in some amorphous structures.

Low temperature specific heat measurements on amorphous solids have led to the observation that in many such materials the temperature-dependent linear term in the specific heat is much larger ( $7-50 \text{ erg g}^{-1} \text{ K}^{-2}$ ) than in the corresponding crystalline state, in which a linear term is negligibly small<sup>11,12</sup>. Data presented here indicate that melanins also exhibit a large linear term ( $50-200 \text{ erg g}^{-1} \text{ K}^{-2}$ ) and that they seem to undergo a phase transition as indicated by the heat capacity near 1.9 K. These effects occur in synthetic as well as natural melanins, but they are most pronounced in the melanosomes isolated from a human melanoma.

Table 1 Low temperature specific heat data for melanin samples

		$\gamma$ (erg g <sup>-1</sup> K <sup>-2</sup> )	$\beta$ (erg g <sup>-1</sup> K <sup>-4</sup> )	$\delta$ (erg g <sup>-1</sup> K <sup>-6</sup> )	$T_0$ (K)	$\Delta C$ at $T_0$ (erg g <sup>-1</sup> K <sup>-1</sup> )
Melanin	1% H <sub>2</sub> O	50 ± 9	120 ± 2	1.64 ± 0.09	1.87	940
Melanin	20% DEA	95 ± 9	99 ± 2	1.84 ± 0.09	1.92	770
Melanosomes	10% H <sub>2</sub> O	220 ± 20	99 ± 4	2.0 ± 0.20	1.95	2,530

All values were determined by data points above approximately 2 K using the normal fitting equation  $C = \gamma T + \beta T^3 + \delta T^5$ .

Melanins can be prepared by the auto-oxidation of L-dopa<sup>5</sup> and also by adding 20% (by weight) of diethylamine (DEA) to the starting mixture of L-dopa and twice-distilled water. Since the melanins exist in the cell as part of a cell organelle, the melanosome, a comparison of the properties of the intact melanosome with that of synthetic melanins was necessary to evaluate the function of the melanins in the intact organelle. The isolation of melanosomes for specific heat measurements was as outlined in Fig. 1. Human malignant melanoma cells obtained at autopsy were used.

Each calorimetric run involved a succession of heat inputs to the sample of a predetermined amount of calories, followed by measurement of temperature increases, using well-calibrated germanium thermometers. The measurements were repeated three times, particularly for the two synthetic melanins, to obtain enough data points for an accurate determination of the electronic specific heat coefficient. The data were fitted to the usual equation  $C = \gamma T + \beta T^3 + \delta T^5$  by the least squares method. The results are shown in Fig. 1 and Table 1, in terms of  $C/T$  as a function of  $T^2$ , where  $C$  is the specific heat in the units of g<sup>-1</sup> K<sup>-1</sup>, and  $T$  is absolute temperature.

The values of the  $\beta$  coefficient in Table 1 indicate that the three materials are quite similar in their lattice contribution to the specific heat. The values of  $\delta$  are also similar but considerably smaller. The linear term  $\gamma$  values, however, are surprisingly large and show a consistent increase as the material

approaches the biologically relevant form. The smallest  $\gamma$  occurs in the highly synthetic melanin, which was polymerised in twice-distilled water. The melanin polymerised with diethylamines shows a higher  $\gamma$  value. (Amines were chosen since they are likely to be present in cellular conditions.) The highest  $\gamma$  value occurs in the biological extract from a human tumour. The increase in  $\gamma$  between the synthetic and the biological material is of clear interest. Although the reason for this is not understood at present, the close agreement in the phonon contributions for the different melanins suggests that the change in the linear term coefficient is unlikely to be due to a change in the phonon spectrum.

An interesting anomalous feature of the data is the observation of a discontinuity at about 1.9 K for all melanins measured in the present experiment. As can be seen in the inset to Fig. 1, this anomaly, though relatively small, is significant beyond the scatter of the data points. The shape of the anomaly seems to be different from that expected from an ordinary Schottky, or  $\lambda$  type, transition. Blois *et al.*<sup>8</sup> measured electron spin resonance for both natural and synthetic melanins and showed the  $g$ -value to be close to 2, and a paramagnetic behaviour following the Curie law over a wide temperature range from 500 K down to 4.2 K. They concluded that the observed paramagnetism was due to unpaired electrons associated with free radicals in the amorphous melanin polymers, rather than an accidental contamination by some ferromagnetic impurities. The presence of

Fig. 1 The usual  $C/T$  against  $T^2$  plot for the melanosome sample. The discontinuous change in the range of 1.9 K is shown for synthetic melanin in the inset. The corresponding plot for copper shows a similar value of the linear coefficient, but substantially different higher term coefficients. The tumour was dissected to remove connective tissue, passed through a fine mesh screen and then vortexed for 15 s in an isotonic salt solution containing 8% sucrose. Phase microscopy examination indicated that most cytoplasmic membranes were ruptured, but most nuclei remained intact. The suspension was centrifuged at 500g for 10 min to remove unlysed cells, cell nuclei and cell debris. The supernatant containing a mixture of cytoplasmic remnants and melanosomes, was spun at 8,000 r.p.m. in a Beckman SW27 Rotor for 20 min. The resultant supernatant was then discarded and the pellet resuspended in 5 ml of an 8% sucrose solution by sonification at about 50 W cm<sup>-1</sup> at 10<sup>4</sup> cycles s<sup>-1</sup>. The material was then layered on an exponential sucrose density gradient (5% sucrose at the top) and spun at 10<sup>4</sup> r.p.m. for 20 min in an SW27 Rotor. The top two-thirds was then fractionated off and the remaining material resuspended and washed twice by centrifugation. The final pellets were found to contain about 3.5 g of material which, in the dehydrated state, was reduced to about 1.6 g, containing approximately 1% water. To prepare specimens suitable for calorimetric work, both synthetic melanins and melanosomes were compressed and cast into cylindrical moulds. After removal from the mould, a thermometer and heater wire were attached directly to each sample. Following the measurement, their contribution to the specific heat was corrected in the usual manner<sup>13</sup>. The DEA melanin sample was also made in the same way as above, but using a small amount of water. After the calorimetric experiment, this water was removed by heating in a vacuum and was found to constitute about 10% of the total weight of the sample. The weights of the synthetic melanins, melanosomes, and the DEA melanin samples were 2.30, 1.68 and 3.20 g respectively. The specific heat was measured in a semi-automatic calorimeter system in the <sup>4</sup>He range in the usual manner<sup>13,14</sup>.

the paramagnetism at 4.2 K strongly suggests that the specific heat data above the anomaly temperature to ( $\sim 1.9$  K) should also correspond to a paramagnetic state, since no specific heat anomaly is observed between 1.9 and 4.2 K. Thus, the anomaly at  $\sim 1.9$  K is probably associated with a magnetic transition, possibly from paramagnetism to antiferromagnetism. The apparently good fit to the equation  $C = \gamma T + \beta T^3$  of the few data points below 1.9 K may indeed be due to the presence of antiferromagnetism in the amorphous melanins. It is also possible that the large linear term is of magnetic origin rather than due solely to the amorphous structure. Antiferromagnetism in amorphous structures has been studied both experimentally and theoretically in amorphous glasses containing some transition elements<sup>15,16</sup> where, however, no sharp magnetic transition was reported.

The melanosome has long been considered a passive cellular organelle. Its considered role as a photoprotective agent in the skin and other illuminated areas, could not explain its presence and function in the non-illuminated areas (for example, the midbrain). A single hypothesis was developed, on the basis of a quantum mechanical model of disordered materials (amorphous semiconductivity) to explain the functional role of the melanosome in both illuminated and non-illuminated areas<sup>2,4,7</sup>. This hypothesis was based on electron-phonon interactions, which seems to be particularly strong in melanins, and on the large density of available energy states.

A particularly useful probe for determining the nature of these states is a measurement of low temperature specific heat. The measurements presented here include two anomalies, a transition and an unusually high linear contribution. The observed anomalies probably arise as a result of the electron-phonon coupling and high density of unpaired spins, which until now were difficult to correlate. Further experimental measurements at near the transition temperature may yield a detailed quantum mechanical description of the states, which will then afford a more precise understanding of the biological functions of melanosomes than has been possible to date.

This work was supported in part by a grant from the US Public Health Service and a contract from the Energy Research and Development Administration.

## <sup>3</sup>H-concanavalin A binding of X-irradiated human fibroblasts

STUDIES on the lectin-binding capacity of plasma membranes form a valuable approach for the detection of various alterations in the glycoprotein components of membrane structures. In studying the effect of ionising radiation on the Golgi complex as one of the main structures for glycoprotein biosynthesis or assembly<sup>1</sup>, we wanted to obtain quantitative data for the characterisation of the possible radiation-induced changes of plasma membrane glycoproteins. Using <sup>3</sup>H-concanavalin A (<sup>3</sup>H-con A), specific lectin for glucose- and mannose-containing receptors<sup>2</sup>, we observed a temporary change in the binding capacity of X-irradiated human fibroblasts.

Human WI38 fibroblasts were grown on coverslips in Bellco tubes with 10% heat-inactivated calf serum and 90% Parker solution containing penicillin (100 IU ml<sup>-1</sup>) and streptomycin (100 µg ml<sup>-1</sup>). Cultures were irradiated with a THX250 machine (200 kV, 20 mA, 0.5-mm copper filter, SSD 60 cm). Total absorbed doses were 90, 226 and 905 rad. After irradiation the medium was changed for an unirradiated one collected from cell cultures of the same age. At various times after irradiation the coverslips were washed three times with cold phosphate-buffered saline (PBS) solution and incubated for 5 min at 0 °C (ref. 3) with PBS containing <sup>3</sup>H-con A (1 µCi ml<sup>-1</sup>) (New England Nuclear, 60 Ci mM<sup>-1</sup>). Unbound tritiated lectin was washed out five times from the coverslips with a cold PBS. Coverslips were fixed in Carnoy solution, coated with liquid emulsion by the dipping method (Ilford Nuclear Research Emulsion, Type G5), exposed for 5 d at 4 °C, and fixed and stained with 5% Giemsa solution. Grains were counted in 100 cells for each dose and time point.

In the conditions specified above the number of grains developed in cells were counted. Irradiation resulted in an early (up to 30-60 min) and temporary increase in the amount of bound lectin at the doses applied; the amount of lectin bound to the plasma membrane returned to control level (Fig. 1). Maximum increase was about 60%

Fig. 1 Dose- and time-dependent changes in grain numbers of X-irradiated WI38 human fibroblasts labelled with <sup>3</sup>H-con A. Bars represent s.e.m. Diagonal hatching, control level; open columns, after 90 rad; vertically hatched columns, after 226 rad; solid columns, after 905 rad.

of control. Similar results were obtained when we considered radioactivity per cell, using the liquid scintillation method with labelled cells.

Our result may provide a new way of detecting early structural and functional changes in the plasma membranes because of radiation treatment. The temporary disturbances in membranes which can be detected by this method may lead to elucidation of other phenomena. Further investigations using different labelling conditions for concanavalin and other lectins may also provide promising radiobiological methods or practical tests for the early detection of the extent of radiation injury in animals or humans using their lectin-binding capacities, for example, blood cells. A similar increase in  $^{125}\text{I}$ -con A binding *in vitro* by irradiated (500 rad) porcine lymphocytes was detected after 30 min. Further experiments are in progress to measure the lectin binding capacity *in vivo* and *in vitro* of irradiated blood cells using autoradiographic and liquid scintillation methods.

We thank Dr L. Sztanyik for his interest and support.

## Detection of bound ferulic acid in cell walls of the Gramineae by ultraviolet fluorescence microscopy

THE phenolic acids, ferulic and *p*-coumaric, are bound to cell walls of plants of the Gramineae (which include grasses and cereals) and it was thought that these acids were esterified to lignin and so occurred only in lignified cell walls<sup>1-4</sup>. But it has been shown recently that in cell walls of *Lolium multiflorum* Lam., which contain ferulic acid and a small amount of *p*-coumaric acid mainly as their *trans* isomers, the acids are esterified at their carboxyl groups to polysaccharides<sup>5-7</sup>. The digestibility of grasses by ruminants can be predicted by estimating the amounts of the acids released from the plant cell walls after treatment with a commercial cellulase preparation<sup>8</sup>. The acids could be important in influencing the degradation of plant organic matter in the rumen or in soil and may act as growth inhibitors of plant pathogens<sup>9</sup>. We now report results obtained by ultraviolet fluorescence microscopy, which indicate that ferulic acid is bound to polysaccharides of the walls of a wide variety of cell types of the Gramineae; these walls give a negative phloroglucinol-HCl test for lignin<sup>10</sup>.

Phenolic acids and their ester derivatives often show changes in fluorescence intensity and colour in ultraviolet radiation when treated with ammonia<sup>11</sup>. Ultraviolet fluorescence microscopy of transverse sections (mounted in glass distilled water, pH 5.4) from the middle of an immature internode of *Lolium temulentum* L. showed that all the walls fluoresced blue. This fluorescence was intensified by exposure to ammonia vapour or treatment with 0.1 M ammonium hydroxide solution (pH 10.3), which caused the fluorescence colour of the walls of many cell types to change to green (Fig. 1 and Table 1). This change was dependent on pH and reversed by 0.1 M sodium acetate buffer, pH 4.0. A similar change was shown by carbohydrate esters of ferulic acid obtained from ryegrass cell walls and separated by thin-layer chromatography<sup>5,6</sup>,

suggesting that the walls which fluoresced green contained ferulic acid units esterified to polysaccharides.

Further evidence that the green fluorescence of the cell walls is associated with ferulic acid was obtained by treating sections of immature internode with 1.0 M sodium hydroxide solution at 20 °C for 16 h, which removes esterified phenolic acids from cell walls<sup>1-4</sup>. Cells which previously fluoresced green showed little fluorescence after treatment.

In addition to a negative phloroglucinol-HCl test, the absence of lignin from the walls of most cell types which fluoresced green was indicated by their complete degradation by a crude cellulase (Fig. 2). But the walls of the sub-epidermal sclerenchyma, although they fluoresced green and gave a negative phloroglucinol HCl test, were not degraded by cellulase, apparently because they were partially lignified.

Fig. 1 Transverse section (100  $\mu\text{m}$  thick) from the middle of an immature internode 11.8 cm long (internode below point of insertion of flag leaf) of *Lolium temulentum* L., cut under water using a Vibratome (Oxford Laboratories, San Mateo, California) and mounted in 0.1 M ammonium hydroxide. Photograph taken on a Zeiss Large Universal Fluorescence Microscope (HBO 200 Hg vapour lamp, UGI exciter and No. 41 barrier filters). Plants were grown in controlled environmental conditions (day 23 °C, night 18 °C, light intensity 130  $\text{W m}^{-2}$ , photoperiod 16 h). ( $\times 168$ .)

Cellulase did not alter the fluorescence behaviour of the walls of the cell types which were not degraded. Contrary to earlier suggestions<sup>12</sup>, these observations show that blue fluorescence in ultraviolet radiation does not necessarily indicate the presence of lignin. But those walls which remained blue after treatment with ammonia, and gave a positive phloroglucinol-HCl test, were not degraded by cellulase, which suggested that they were lignified. Some esterified ferulic acid may also have been present in such walls, its green fluorescence being masked by the blue fluorescence of the lignin.

Cell walls of other parts of *L. temulentum* showed fluorescence behaviour similar to that of the immature internode (Table 1). Usually those walls which continued to fluoresce blue after treatment with ammonia gave a positive

**Table 1** Fluorescence colour of *Lolium temulentum* cell walls of different cell types after treatment with ammonia

Plant part (transverse section)	Blue	Green
Immature stem	Xylem vessels, xylem tracheids and bundle sheath	Xylem parenchyma, phloem, sclerenchyma, epidermis, parenchyma and chlorenchyma
Fully elongated stem	Xylem vessels, xylem tracheids, bundle sheath, sclerenchyma, epidermis and parenchyma (adjacent to sclerenchyma)	Xylem parenchyma, phloem, parenchyma (adjacent to central cavity) and chlorenchyma
Leaf lamina	Xylem vessels, xylem tracheids and inner bundle sheath	Xylem parenchyma, phloem, outer bundle sheath, sclerenchyma (blue middle lamella), epidermis and mesophyll
Leaf sheath	Xylem vessels, xylem tracheids, inner bundle sheath, sclerenchyma and upper epidermis	Xylem parenchyma, phloem, outer bundle sheath, lower epidermis, parenchyma and mesophyll
Glume	Xylem vessels, xylem tracheids, bundle sheath, sclerenchyma, epidermis and parenchyma (adjacent to sclerenchyma)	Phloem, parenchyma (adjacent to chlorenchyma) and chlorenchyma
Lemma	Xylem vessels, bundle sheath, sclerenchyma and outer epidermis	Phloem, inner epidermis and chlorenchyma
Palea	Xylem vessels, inner bundle sheath, sclerenchyma and outer epidermis	Phloem, outer bundle sheath, inner epidermis, parenchyma and chlorenchyma
Root	Xylem vessels, stele fibres, endodermis and pericycle	Phloem, epidermis, cortical parenchyma, root hairs and exodermis
Mature grain	Outer thick walled cells of pericarp	Inner thin walled cells of pericarp, nucellus, aleurone layer and starch cells of endosperm
Coleoptile	Xylem vessels	Phloem, bundle sheath, inner and outer epidermis and parenchyma
Ovary (squash preparation)	No cell types	All cell types
Stamen (squash preparation)	No cell types	All cell types
Pollen (mechanically isolated walls)	Walls of grains	No cell types

test with phloroglucinol-HCl, whereas those that fluoresced green did not. Pollen cell walls, however, although negative to phloroglucinol-HCl, fluoresced blue after treatment with ammonia, probably because of the presence of sporopollenin<sup>13</sup>.

Ferulic acid bound to unligified cell walls seems to be widespread in the Gramineae. This was indicated by a fluorescence behaviour similar to that of *L. temulentum* when transverse sections of the following grasses (leaf laminae) and cereals (immature internodes) were used: *Dactylis glomerata* L. cv. S37, *Festuca arundinacea* Schreb. cv. S170, *Festuca pratensis* Huds. cv. Comtesa, *Lolium multiflorum* Lam. cv. S22, *Lolium perenne* L. cv. S24 and *Phleum pratense* L. cv. S48, *Avena sativa* L., *Hordeum vulgare* L., *Triticum aestivum* L. and *Zea mays* L. cv. Caldera 535.

In contrast to the situation with the Gramineae, ferulic and *p*-coumaric acids or their carbohydrate esters were not released in detectable amounts after treatment of cell walls isolated from young petioles of *Brassica oleracea* L. var. acephala DC. cv. Maris Kestrel (Cruciferae) with sodium hydroxide<sup>4</sup> or cellulase<sup>8</sup>. The fluorescence behaviour of the cell walls of a young petiole of this plant was consistent with the absence of ferulic acid. Only the cuticle and cell walls of the xylem fluoresced in ultraviolet radiation and

**Fig. 2** As Fig. 1, but section treated with a solution of crude commercial cellulase (*Oxytropis* sp., Merck, 2.5 mg ml<sup>-1</sup> 0.2 M NaOH-AcOH buffer, pH 4.8 containing 0.02% Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub>) for 16 h at 37 °C and washed with water. ( $\times 168$ .)

Fig. 3 Transverse section (70  $\mu\text{m}$  thick) of young petiole of field-grown kale. Cut, mounted and photographed as described in Fig. 1 ( $\times 168$ .)

the fluorescence remained blue after treatment with ammonia (Fig. 3). Cell walls of *Trifolium pratense* L. cv. Hungaropoly and *Onobrychis viciifolia* Scop. cv. Cotswold Common (Leguminosae) showed similar fluorescence behaviour, indicating the absence of ferulic acid.

The synthesis and secretion of polysaccharides in the slime of the root cap is analogous to the synthesis and deposition of the matrix polysaccharides in cell walls. The Golgi apparatus and its associated vesicles are considered to be the site of synthesis and transport of the polysaccharides of the root-cap slime, and are believed to have a similar role in the case of the cell-wall matrix polysaccharides<sup>14</sup>. The root-cap slime of *Z. mays* showed blue fluorescence which changed to green after treatment with ammonia, suggesting the presence of ferulic acid esterified to the polysaccharides. It is possible that the site of bonding between ferulic acid and the polysaccharides of slime or of the cell-wall matrix is the Golgi cisternae, the resulting esters being transported within the associated vesicles.

Lignin could be synthesised in the Gramineae by oxidative coupling reactions involving ferulic acid units which are esterified to wall polysaccharides. This is consistent with the finding that the walls of the sub-epidermal sclerenchyma cells and the adjacent parenchyma cells of the fully elongated internode of *L. temulentum* fluoresced blue after treatment with ammonia, in contrast to the green fluorescence of the walls of similar cells of the immature internode (Table 1). Although lignified walls may contain some unpolymerised ferulic acid esterified to polysaccharides, we have shown that as stems of *L. multiflorum* mature, less water-soluble esters are released from their walls by treatment with cellulase.

The work reported here leads us to question conclusions drawn when radioactive lignin precursors were fed to

graminaceous species and the radioactivity detected in the cell walls was attributed to lignin<sup>1</sup>. We suggest that at least some radioactivity is associated with phenolic acids esterified to non-lignified walls. This suggestion is supported by a report that after feeding <sup>14</sup>C-cinnamic acid to wheat coleoptiles, radioactive ferulic acid was released from the walls by sodium hydroxide<sup>15</sup>. The production of vanillin or *p*-hydroxybenzaldehyde by nitrobenzene oxidation of cell walls has been used as a test for lignin<sup>1</sup> but these compounds could be obtained from ferulic acid and *p*-coumaric acids respectively.

We thank Drs L. H. P. Jones and E. L. Leafe for their interest in this work.

## Corrigenda

In the article "Mechanism of catalysis of hydrocarbon reactions by platinum surfaces" by G. A. Somorjai and D. W. Blakely (*Nature*, **258**, 580; 1975), the sentence which begins in line 26 of the second column on p. 580 should read . . . The rate of *n*-hexane production per kink site is determined by the slope of the line in Fig. 3b, which gives  $4 \times 10^{-28}$  mol s<sup>-1</sup> per kink atom. This is almost an order of magnitude higher than the slope in Fig. 3a which corresponds to  $5 \times 10^{-29}$  mol s<sup>-1</sup> per step atom.

The sentence which begins in line 10 of the caption to Fig. 3 should read . . . The rates of hydrogenolysis per surface site at the slope of the lines representing hydrogenolysis are  $4 \times 10^{-28}$  mol s<sup>-1</sup> per kink atom and  $5 \times 10^{-29}$  mol s<sup>-1</sup> per step atom.

In the article "Mechanism of reactions at square-planar metal centres" by F. R. Hartley and J. J. Périé (*Nature*, **256**, 636; 1975) Fig. 1a and b are incorrect. The correct forms are reprinted below.

## Worthy of sponsored pilgrimage

Ronan Picture Library

Johannes Kepler (1571–1630), an engraving from *Great Astronomers* by Robert Ball (London, 1895).

CENTENARY celebrations of the births and deaths of illustrious men are usually prompted more by an urge to conviviality than by a feeling that history ought to repeat itself at 100-year intervals. Just as it seems to be a law of economics that the rich grow richer as the poor grow poorer, so the great tend to grow greater at the expense of those who are not judged worthy of sponsored pilgrimage and fanfare. The resulting distortion of history will be kept to a minimum only if we stick to a high enough 'fame threshold'—and if Kepler is to fall below our threshold, who will be above it? A volume like that\* now edited by Arthur and Peter Beer, with more than 1,000 pages and encompassing more than 130 contributions, must inevitably include its share of empty eulogy, but the bibliographical advantages of having so much Kepler material in one place are very great—almost as great, in fact, as the difficulty in reviewing it adequately.

The volume takes in the full texts (in English translation where necessary) of the symposia held 400 years after Kepler's birth, in 1971, at Philadelphia, Leningrad, Graz, Linz,

London, Paris, Berlin and Evanston. There are also summaries of other papers, as well as a number of specially written articles published for the first time. The book is richly illustrated—and only Plate 6.4 needs to be read in a mirror. The translations, mostly by Judith Field and Richard Rodman, cast doubt on the editors' plea that translations, like women, are unfaithful when beautiful and not beautiful when faithful. There are 20 sections to the volume, but they fall into four broad groups: Kepler's intellectual influence on contemporaries; studies of his religious, philosophical, alchemical and mystical beliefs; mathematical and physical theories; and other matters which occupied Kepler's thoughts. At the end of the book there are extremely useful bibliographical and iconographic supplements and indices. Altogether, the volume is a monument to the industry and editorial logic of the Beers, father and son.

The short note by D. T. Whiteside, on Kepler's ovals, is an *apéritif* for the invaluable enlarged version of his paper which has since appeared in *Journal for the History of Astronomy*. Another note by Otto Neugebauer, shows that it is hardly surprising to find contemporaries of Kepler failing to understand the import of his work, faced as they were with "rather trivial obstacles . . . on practically every page". The obstacles in question are the trivial computing errors, unexplained changes in parameters, references to (Tycho Brahe's) observations accessible to scarcely anyone else, and so forth. To prove the point in an utterly convincing way, Neugebauer takes the penultimate chapter of *Astronomia Nova*, wherein Kepler shows the need for an elliptical orbit and an equal-area rule.

The *Astronomia Nova* was written in the form of a self-critical intellectual autobiography, and has generally been regarded as an honest one. But as instances of papers showing the circuitous, not to say devious, nature of the path travelled by Kepler's thoughts, one may cite those by Owen Gingerich and E. J. Aiton (three each), as well as that by C. A. Wilson Gingerich, who has written on the same material extensively elsewhere, makes some use of Kepler's unpublished notebooks (now in Leningrad) on Mars. He em-

phasises the importance to Kepler of a three-dimensional approach, and aptly suggests that the idea that the lines of planetary apsides (and hence the planetary planes) should pass through the Sun is important enough to be called Kepler's zeroth law. (The zeroth law is of course logically, if not historically, derivable from the first.) A problem often touched on but rarely tackled with much fervour is that of the interplay of observations (potential and original) and conjecture in Kepler's work. Could the ellipse be observationally distinguished from the alternatives, for example? Curtis Wilson's contribution begins with Newton's assessment: "Kepler knew the orb to be not circular but oval and guessed it to be elliptical". Wilson's all too brief paper explains very clearly in what sense Kepler was indeed guessing. One of the most thorough of recent studies of Kepler's accuracy—in connection with the solar theory—is that reported here in a shortened version of an admirable paper by Y. Maeyama.

Needless to say, Newton was not primarily concerned with Kepler's path to his discoveries. With his "Kepler's Century: Prelude to Newton's", I. B. Cohen starts the volume with, as it were, a Newtonian justification for Kepler's existence, not to mention some entertaining material on later attitudes to the Kepler story.

Outside astronomy proper, the volume includes a number of invaluable sketches which will be of lasting interest to scholars. Jurgen Hübner's assessment of Kepler's theology, J. O. Fleckenstein's of the neoplatonic movement, and Gérard Simon's account of his attempted reform of astrology, for example, help to explain the Kepler who could write (to Mästlin in 1598): "I am a Lutheran astrologer, throwing out the chaff and keeping the grain". Karin Figala considers Kepler's alchemy in the light of a recently discovered funeral oration for the Emperor's personal physician (Martin

\**Kepler: Four Hundred Years*. (Proceedings of conferences held in honour of Johannes Kepler. *Vistas in Astronomy*, Volume 18). Pp. xix + 1,034. (Pergamon: Oxford and New York, 1975). Subscribers' price: \$120.00, £50.00. Non-subscribers: \$150.00, £63.00. Available with Volume 17 on Copernicus. Two-volume subscribers' price: \$140.00, £60.00. Non-subscribers: \$175.00, £75.00.

Ryland II), with a poem by Kepler. This contribution sets higher standards of scholarship than some of the astronomical items. The short papers on Kepler's wanderings from Württemberg to Graz, to Prague, and so on, would make on their own a most enjoyable Baedekker's guide to the manners no less than to the places of Kepler's time.

One of the most surprising things about the 1971 symposia is that so few historians took the opportunity of adding to our understanding of Kepler's optics. A précis of J. A. Lohne's study of Kepler, Harriot, and the sine law is worth noticing, and yet for the full text one must turn to the *Weil der Stadt* proceedings. That a similar remark must be made for many of the articles in this volume is not a weakness but a source of strength. This is

essentially a 'State of the Art' report. In a report within a report, Robert S. Westman considers two early historiographical traditions in Kepler scholarship. In one of these, the history of science was regarded as a useful repository of still valued scientific ideas. The second, hermeneutical, tradition entailed an investigation of the philosophical foundations of Kepler's discoveries. Westman, speaking in Philadelphia towards the end of 1971, placed those papers given to the European conferences against this double historiographical background. This impressive and important volume, in an almost uniformly important series, is therefore complete to a fault, containing as it does its own review. It will be consulted long after its weighty (3 kg) contents have parted company with its covers.

J. D. North

## Applying a technique

*Mössbauer Spectroscopy*. (Topics in Applied Physics, Vol. 5.) Edited by U. Gonser. Pp xviii+241 (Springer: Berlin and New York, 1975.) DM70; \$30.10.

THE increasing use of the Mössbauer technique during the past 15 years in fields as diverse as relativity and archaeology, resulted in the publication of about 1,200 research papers in 1974. Its use in conjunction with more standard techniques in, for instance, chemistry and metallurgy departments means that it is no longer practicable to produce a book giving a critical study of the whole range of applications. Several good introductions to the basic principles exist already but the purpose of the present volume is both to introduce the technique to non-specialists and also to present them with general information on the applications related to their own fields of interest. Thus the introductory chapter is followed by five chapters, written by different authors, concerned with applications in chemistry, magnetism, biology, lunar geology and mineralogy and physical metallurgy. The level seems to be aimed at that of the research worker although the treatment varies from chapter to chapter, with those concerned with chemistry and magnetism requiring familiarity with the methods of quantum mechanics.

In the introduction, the conditions required for the emission of Mössbauer  $\gamma$  rays are described together with the properties of the hyperfine interactions, between the nucleus and its electronic environment, which form the basis of a Mössbauer measurement. A short experimental section is marred by poor

quality spectra and a misleading comparison of  $\gamma$ -ray detectors. Two chapters are devoted to a discussion of the information obtained from the hyperfine interactions, concerning the electronic structure and bonding properties in chemical compounds in general, and in metal proteins. In the latter case the potentially valuable use of the technique to determine the state of the iron in clinical specimens of blood or tissue is mentioned, with the hope that this could lead to advances in medical diagnosis. In the chapter on magnetism there is no mention of work on metals and alloys, and the text is concerned largely with studies of spin orientations in mixed iron oxides. That chapter, particularly, suffers somewhat from being restricted to the isotope iron-57.

The use of the Mössbauer effect as an analytical tool to determine molecular composition is brought out in the chapter on lunar geology and mineralogy, though little discussion is given of the main findings of other measurements. The final chapter on physical metallurgy seems to be at about the right level for an introductory survey. Methods are given for the analysis of the spectra of alloys and intermetallic compounds, with many examples including the study of carbon atoms in steels, the invar problem and the structure of amorphous alloys.

Although the level of presentation varies, in general it is higher than that usually found in an introduction for the non-specialist. As such, the book is more likely to be read by the Mössbauer specialist looking for a presentation of applications outside his own field of study. More comprehensive surveys in each field exist already and the price of \$30.10 is rather high for the purchase of a personal copy.

G. Longworth

## Finite geometries and designs

*Graph Theory, Coding Theory and Block Designs*. (London Mathematical Society Lecture Note Series, No. 19.) By P. J. Cameron and J. H. van Lint. Pp. v+114. (Cambridge University, Cambridge, London and New York, September 1975.) £2.80.

THIS splicing of lecture notes from two courses of seminar lectures given at Westfield College in 1973 is intended for a specialised group of mathematicians, combinatorialists interested in finite geometries and designs, and serves to introduce them to those parts of graph theory and algebraic coding theory that have recently interacted fruitfully with design theory. The authors have, however, provided a brief introduction to design theory proving certain elementary results, stating certain deeper results, and describing many of those designs that arise geometrically. Thus, in principle, the book can be read by any mathematician.

Chapters 2-5 are concerned with the connections between design theory and strongly regular graphs. Chapter 6 is a brief survey of known results concerning so-called "two graphs", a combinatorial structure that arises naturally in the study of doubly-transitive permutation groups. The remaining nine chapters are devoted to those aspects of algebraic coding theory of interest to design theorists. Chapters 9-11 constitute an introduction to coding theory and chapter 15, the last, an introduction to association schemes (a generalisation of strongly regular graphs) and some of the recent work of Delsarte. Sandwiched between are five chapters concerned with those codes of greatest combinatorial interest: Reed-Muller codes, self-orthogonal codes, quadratic-residue codes, symmetry codes, nearly perfect and uniformly packed codes.

The expert will note that proposition 13.4 is incorrect without an added hypothesis and that the remark on page 69 is false since ovals are always seen in the dual. In spite of minor flaws and sometimes sketchy proofs this slender volume should prove useful to its intended audience.

E. F. Assmus, Jr

**Erratum.** The size of the Mayan bas relief shown on p349 of the reviews section (*Nature*, 259, January 29, 1976) was incorrectly stated as  $1.3 \times 1.3$  cm. The correct size is  $1.3 \times 1.3$  m.

## Atmospheres and other fluids

*Atmospheric Thermodynamics.* (Geophysics and Astrophysics Monographs: an International Series of Fundamental Textbooks, Vol. 6.) By J. V. Iribarne and W. L. Godson. Pp. x+222. (Reidel: Dordrecht and Boston, Massachusetts, 1973.) n.p. *Advanced Fluid Mechanics: An Introduction.* By A. J. Raudkivi and R. A. Callander. Pp. xii+325. (Edward Arnold: London, July 1975.) Boards £12.00, paper £5.00.

THE book by Iribarne and Godson, which is based upon undergraduate lecture courses given by the authors, will be welcomed by students of the atmospheric sciences. It is one of the few textbooks in meteorology to deal exclusively with atmospheric thermodynamics and doubtless it will soon become deservedly established as a standard recommended text. The authors assume some knowledge of basic thermodynamics but devote the first four chapters of the book to a review of the fundamental relationships and concepts in the subject. There is some reference to the applicability of these relationships to meteorological problems in the introductory chapters but that aspect is more strongly emphasised in the latter half of the book. Strictly thermodynamic atmospheric processes are discussed at length (fog formation, cloud physics, precipitation, and so on) but sections are also included in which the importance of atmospheric dynamics and radiative processes is emphasised.

Throughout the text one is impressed by the concise and systematic treatment of the subject. Problems are given at the end of each chapter, the diagrams are informative and the book as a whole is well written and well presented. It has a good balance between basic thermodynamics and meteorological applications and will be useful to students and research workers alike.

With students of engineering particularly in mind, Raudkivi and Callander in their book have attempted to produce a work filling a gap which they feel exists between 'elementary' and 'advanced' texts on fluid mechanics. Claiming that the latter have been written almost exclusively by applied mathematicians (Batchelor's "Introduction to Fluid Dynamics" is cited as one example) their primary requirement has been to make the mathematical background simpler and more accessible to students already familiar with elementary fluid mechanics. It will be difficult for the reader to discern any significant improvement upon Batchelor's book in this regard, if indeed such a comparison is appro-

priate. A lengthy section on turbulent flows is included, for example, as is an interesting survey of diffusion and dispersion. The remainder of the text is taken up with chapters on potential flow theory, boundary layers (surprisingly appearing after the section on turbulent flow) and fundamental relationships.

The latter contains much information (rheological models, tides) not usually included in such a section and, as with the rest of the book, it is well written and well presented. Particularly attractive features of the book are the inclusion of experimental data to complement theoretical ideas, and a generous supply of worked examples.

Of necessity, the authors have had to be selective in their choice of topics but they have produced a book which will be of interest to workers in several branches of fluid mechanics.

P. A. DAVIES

## Basic astronomy

*Astronomy Today.* By Fred Hoyle. Pp. 179. (Heinemann Educational: London, October 1975.) £4.50.

*Astronomy Today* is a straightforward basic astronomy text, of the kind which many astronomers could write but which inevitably will reach a larger audience than most through the magic of the author's name. The book is lavishly illustrated and the text is clear, informative and readable. But given its title this is a disappointing book, which describes the Solar System in five chapters, the stars and life in the Universe in one each, and devotes the last chapter to Galaxies and the Universe, presenting a lucid exposition of Hoyle's picture of the redshift as indicating a Universe in which the mass of atoms increases with time.

This presentation of unorthodox ideas in such a way at the end of what is otherwise an orthodox book published in an educational series is curious, to say the least, and it seems that the UK publishers must take the blame for this, since the US edition of the book bears the much more apposite title *Highlights in Astronomy* (Freeman, 1975). The implication that this theory is as well established and broadly accepted as such fundamentals as the causes of seasons and eclipses is most ill-judged in the context of an educational text for young people. And the publishers are further guilty of misjudgement in describing the book on the cover as "ranging from the geological history of the Earth to the latest discoveries about neutron stars and black holes". Black holes are mentioned (once), but only in passing, and there is no mention at all of the state of the art in X-ray astronomy today,

the field in which most of the latest discoveries about black holes and neutron stars have been made.

This is a fine description of "the Solar System today", but in no way is the book representative of the exciting recent advances in high energy astrophysics that the cover and the author's name lead us to expect. It is doubly ironic that not only is Hoyle ideally equipped to write the book we are led to expect, but also that his exposition of novel cosmological ideas would sit far more happily in such a volume.

John Gribbin

## Riboflavin

*Riboflavin.* Edited by Richard S. Rivlin. Pp. xiii+433. (Plenum: New York and London, 1975.) \$46.90.

THIS book comprises a collection of review articles by different workers on the chemistry, physiology and metabolism of riboflavin and the effects of riboflavin deficiency principally in man and rat. Hormonal regulation of riboflavin metabolism, studies on analogues and antagonists and a useful section on methods of assay are well described. Of special interest are the sections on the teratological consequences of riboflavin deficiency and the effect of deficiency on the growth of neoplastic tissue. Editorially the texts have been well cross-referenced and repetition has been minimised without adversely affecting content and readability.

Some abbreviations are used without a preceding definition—M:E ratio and PAH—and inconsistencies occur with others—for example, nicotinamide adenine dinucleotide, NAD (p162), DPN (p308). One section presents arguments for the further enrichment of bread as a means of improving riboflavin status in the US but alternative methods are hardly discussed.

The most serious omission is the lack of adequate detail and discussion on obtaining riboflavin-deficient rats. Chapter 10 mentions briefly (7 lines) the many factors that can influence the deficient state (p305) but without any explanation; and, for the diet used by the author, the reader is referred to a 'recent' reference—1951! This is presumably a mistake, as the diet to which one is referred in no way satisfies the 'severe criteria of deficiency' which the writer considers necessary.

In general, however, the book is well referenced and will provide a valuable and timely addition to the bookshelves of medical schools and institutions of nutrition and pharmacy.

David I. Thurnham

## High fashion in liquid dielectrics

*Simple Dielectric Liquids: Mobility, Conduction and Breakdown.* By T. J. Gallagher. Pp. vi+154. (Clarendon: Oxford; Oxford University: London, October 1975.) £6 00 net.

"BREAKDOWN in liquids could readily become a compendium of unrelated observations", wrote Whitehead in the introduction to his book on breakdown in solids. Although this pronouncement was made from the cosiness of one of those periods when that subject seemed to support an established orthodoxy, it has always held more than a grain of truth. It is the tendency to try to create an orthodoxy which has acted as an impediment to progress in all of liquids research. Arguably, such periods of stasis are little more than a state of mind among referees for scientific journals and other influential workers. The result in a notoriously difficult experimental field is a wild veering of fashion more reminiscent of *haute couture* than scientific progress. Everything in liquid dielectrics has been ascribed successively to ions, electrons, molecular bonds, bubbles or particles, according to vogue.

Technologically this is a very important field. In power distribution alone a small improvement in electric strength would produce enormous financial economies, and in electronics the liquid state has not begun to offer the possibilities provided by the other states of matter. It is an ideal field for PhD training, being generally rather too speculative for industry, yet sufficiently demanding. There has been a large volume of published work which does not seem to be matched by a corresponding degree of solid achievement. Without doubt much of this is due to the nature of the test object itself. The most critical aspect of the dielectric sample, the metal-liquid interface, is almost a completely unknown quantity, yet it determines the transfer of charge in conduction experiments and also the probability of breakdown. It must therefore be disheartening for the new researcher to find a turgid literature rife with ill-controlled experiments and glib theories.

What can one say of an author who has the temerity to attempt to survey such a field? Gallagher has done as good a job as could possibly be expected. This review should rapidly become the *vade-mecum* for all researchers in the field, new or old. It is particularly stimulating to be able to pick out the high points in which one result condemned great chunks of the preceding literature; for example the discovery of the oxygen effect in breakdown, the e.h.d. stability theory, fast carriers in

pure liquids, the statistical nature of breakdown, and so on.

If one has to find the conventional adverse criticism, it is that the author maintains his excellent disinterestedness to a fault. Having made a remark which invalidates a theory (for example, that simple equilibrium thermodynamics cannot be applied to a transient irreversible process such as breakdown) he proceeds to give it a full treatment at the expense of others which might deserve more of his limited space. A similar remark applies to some of the experimental results (for example, the use of strange techniques of statistical selection possibly inspired by vision of the Holy Grail of Intrinsic Strength). These are, however, quibbles in respect of a text which deserves to become mandatory for any serious worker in the field. The diagrams, tables, bibliography, author and subject indexes are all excellent. Readers should note that the treatment does not include the proceedings of the most recent (1975) conference, which is published by the Delft University Press. **J. E. Brignell**

## Coding for isoenzymes and haemoglobins

*Haemoglobin, Isoenzymes and Tissue Differentiation.* (North-Holland Research Monographs: Frontiers of Biology, Volume 42.) By C. J. Masters and R. S. Holmes. Pp. xiii+308. (North-Holland: Amsterdam and Oxford; Elsevier Scientific: New York, 1975) Dfl.79; \$32.95.

THE isozyme (isoenzyme) concept, initiated by Markert and Møller 16 years ago, and the accompanying techniques of zone electrophoresis and specific histochemical staining, have led to new insights in many areas of biology and biochemistry. Essentially all enzymes are capable of existing in multiple molecular forms—isozymes—whether they are encoded in different genetic loci (multiple locus isozymes) or encoded in different alleles at a locus (allelic isozymes=allozymes). This book reviews primarily those isozymes (and proteins with specific function, for example, haemoglobins) which are encoded in different but related genetic loci. Two approaches are successfully used in presenting the concepts. The first is a discussion of the molecular, genetic, and evolutionary bases of the more thoroughly documented isozyme systems. The second is the illustration of some of the ways that isozymes can be used as tools to analyse the mechanisms of genetics, physiology, development and evolution.

This is not an exhaustive com-

pendium of all isozyme systems but selectively focuses on those areas of biology (cellular, developmental, genetic and evolutionary) and those enzymes, which represent the authors' areas of expertise. The results of key papers have been summarised (at times critically evaluated) and integrated into a broad contemporary biological context. The condensations of the material, the selected areas reviewed, and the thorough coverage of the earlier literature make this book a useful adjunct to the recently published four-volume proceedings of the Third International Isozyme Conference (Academic, New York) which is a comprehensive collection of original research reports covering almost all areas of biology.

The biological and experimental utility of isozymes is effectively and persuasively presented. The title is somewhat misleading, however, in that it fails to convey the evolutionary emphasis in the first third of the book. This section deals with the evolution of these multilocus isozymes (and haemoglobins), mechanisms of gene duplication, and the utilisation of these isozyme systems to establish phylogenetic relationships. A physiological rationale is often brought forward to explain the divergence in kinetic, physical and other properties of the isozymes as well as the divergence in the developmental and cellular specificity of their syntheses. There is, throughout the book, an excellent blend of evolutionary and developmental concepts. The middle third of the book analyses the differential expression of related genetic loci during development and the physiological relevance of their temporally and spatially specific syntheses.

The last third of the book is devoted to some current problems in isozymology. An interesting analysis is provided of the mechanisms involved in the regulation of isozyme levels, particularly the balanced contributions of preferential synthesis and preferential catabolism; the latter point has often been overlooked when examining isozyme repertoires. In addition, a thorough analysis is made of the subcellular localisation of isozymes and the genetic and molecular basis for the specificity of the positioning of the isozymes within the cell—a topic of profound importance when considering the mechanisms of enzyme regulation. In this last section the authors indicate those areas of isozymology which will probably be the major research directions of the future. This clearly written and well organised overview of many facets of isozymes and haemoglobins should be of interest to biologists and biochemists representing a wide spectrum of research interests.

**Gregory S. Whitt**

*An Introduction to Medical Physics.* By Edwin G. A. Aird. Pp. viii+293. (Heinemann Medical: London, May 1975.) £4.95.

THIS book deals in a straight-forward way with those applications of physics in medicine that are most used. It is broadly divided into "Ionising Radiations and their Uses" and "Other Applications of Physical", roughly 2:1 giving a rather classical, 'measure the dose', hospital physics flavour. It reads easily, however, and in the radiation sections, the clarity and succinct presentation were appreciated. In the second part some of the information could have been made more up-to-date—although this is where the subject is expanding very rapidly, for example, chapter 8 on the use of ultrasonics.

The discussion of physiological measurement is most welcome for it is here that physics and physiology merge. The emphasis, however, is entirely on the technical—as it is throughout the book—with no attempt to show, even in a small way, the conceptual stimulus of physics.

The number of errors detected were small, an indication of the care in both writing and production, although the confusion between longitudinal and transverse orbits of the medium in the propagation of sound waves is too fundamental to go unremarked (p179) and p184) and should be corrected as soon as possible.

Overall, the book demonstrates clearly one facet of the applications of physics in the community. It can be warmly recommended to its author's intended audience—hospital technicians, radiographers and graduate or specialist nurses. For a graduate scientist entering the field it is well worth reading quickly as the introduction it purports to be.

**R. G. Gosling**

*Comprehensive Chemical Kinetics.* Volume 14: Degradation of Polymers. By C. H. Bamford and C. F. H. Tipper. Pp. xv+562. (Elsevier Scientific Amsterdam, Oxford and New York, 1975.) Dfl 200; \$83.50.

THIS series has been a brave and generally very successful attempt to review the whole field, which is loosely described as chemical kinetics. The present volume describes the very complex reactions which cause degradation in synthetic polymers and it is not surprising that the emphasis is on mechanisms rather than detailed kinetics. Indeed, few polymer degradation reactions are well enough understood to enable precise descrip-

tion of the kinetics of the elementary steps. The book has four chapters, classified according to the mode of initiation of the degradation reaction. The first, dealing with thermal degradations contains an excellent introduction to the kinetic models used in describing these reactions, followed by detailed discussions of the behaviour of a wide range of common polymer types. A similar pattern is followed in chapters two and three, which describe degradations induced by high energy radiation and by photochemical methods. The final chapter is concerned with the complex reactions which can occur when polymer degradation occurs in the presence of oxygen or ozone.

## Books brief

As a whole this book is clearly and concisely written and all the authors have done a good job in reviewing their fields. There is much material of interest both to the expert and the beginner. One serious criticism is that the literature coverage does not extend beyond 1971. A publication delay of four years is excessive by any standards and together with the price makes the value of this book rather doubtful, even for specialist libraries.

**N. C. Billingham**

*Films on Solid Surfaces: The Physics and Chemistry of Physical Adsorption.* By J. G. Dash. Pp. xi+273. (Academic: New York and London, September 1975.) \$26; £13.

THE powerful battery of techniques both experimental and theoretical, which have evolved over the past 20 years has enabled the field of surface studies to progress from a state consisting largely of guesswork to one of increasingly detailed understanding. Attempts on the experimental side in the early 1950s to verify the predictions of 'two-dimensional theory' were generally unsuccessful and the apparently confident prediction—that perfect two-dimensional states, for example, crystals, magnetic arrays, superconductors, could not exist—could hardly be questioned. Thanks to the impressive advances in methods such as electron spectroscopy, field-emission and field-ion microscopy, molecular scattering and to the ease with which ultra-high vacuum conditions can be established,

an increasing amount of reliable information on adsorbed films is accumulating. There is an increasing interest in the study of the statistical thermodynamics of physisorption and on the thermodynamics of non-interacting monolayers, which latter relates to the important question of mobility of adsorbed atoms in the formation of surface films. Much of the progress on the experimental side has come from physicists for whom a volume such as the present one will form an invaluable introduction to some of the more chemical aspects of the subject. The introduction to theoretical studies is clearly written and a useful selection of experimental results—limited presumably to keep the overall length in check—gives an excellent view of the present state of the field.

**O.S. Heavens**

*The Heavy Transition Elements.* (A Macmillan Chemistry Text.) By S. A. Cotton and F. A. Hart. Pp. x+272. (Macmillan: London and Basingstoke, September 1975.) Hard cover £8.95; paper cover £4.95.

THIS book is a logical sequel to a cognate volume from the same publishers, which dealt with the 3d transition elements. A first impression is that of the wealth of descriptive inorganic chemistry contained within its covers. Here is a truly up-to-date account of the significant chemistry of these elements, without the loss of older well-established facts.

The choice of structural figures to illustrate chemical points is excellent; and chapters, sections and subsections of the text are well organised and, helpfully, are consistent from chapter to chapter wherever possible. At the start of each chapter there is a table of coordination number against oxidation state for the corresponding 3d element of the group, which gives a useful summary for comparison purposes.

The book, in addition to covering the 4d and 5d elements from zirconium and hafnium through to silver and gold, has excellent chapters on the lanthanides and actinides, and another chapter devoted to metal complexes containing  $\pi$ -bonding ligands.

Although not intended as a work of reference, the bibliography is adequate, and each chapter is referenced with a range of appropriate review articles.

This book is a must for libraries, and very desirable for the bookshelves of individual inorganic chemists.

**Edward Abel**

# obituary

**Detlev Wulf Bronk** died at New York Hospital on November 17, 1975 from complications following a stroke. He was 78 years old. Bronk was one of the outstanding leaders of science in the United States, and his influence also reached out far into the international scene. In the course of his career, he was active and well-known in scientific organisations in Europe, Asia, and Latin America as well as North America.

His initial scientific interest was in electrical engineering and physics, but he soon became committed to biological problems. As a National Research Council (NRC) fellow in the late 1920s, he worked with A. V. Hill at the University of London on studies of the production of heat in muscles and with Edgar Douglas Adrian, now Baron Adrian of Cambridge, on the development of techniques of recording the electrical activity of single nerve fibres.

Because of these interests, he was appointed director of the newly established **Eldridge Reeves Johnson Foundation for Medical Physics** at the University of Pennsylvania in 1929. This remained his base until he left to become president of The Johns Hopkins University in 1949.

During World War II, he became involved in aviation medicine based on a combination of prior interests, which included a period as a naval air cadet in 1917-18. This activity not only carried him to a number of theatres of combat

but involved him in a variety of applied scientific enterprises which made it natural for him to assume the chairmanship of the National Research Council of the National Academy of Sciences (NAS) at the end of the war. At that time the Council was the major working arm of the Academy.

In 1950, he was elected president of the NAS, where he spent a substantial fraction of his time participating as a leader in the very rapid development of science in the United States that accompanied the great growth of government investment in science following World War II. In this connection he served as a member of the National Science Board of the National Science Foundation for fourteen years and was its chairman between 1956 and 1964.

In 1953, he was asked to become head of the Rockefeller Institute for Medical Research, on whose board he had served since 1946. He accepted this post with the understanding that he would be in a position to develop a graduate program in parallel to the postdoctorate educational program which the Institute had supported since its creation early in the century. The Institute eventually changed its name to The Rockefeller University—the first purely graduate university in the United States. He retired as president of Rockefeller University in 1968, but remained exceedingly active in national and international scientific affairs up to the time of his death. In fact, his illness, which came

upon him quite suddenly, took place just a few weeks after his return from the Soviet Union, where he had participated, as a foreign member, in the 250th anniversary celebration of the Soviet Academy of Sciences.

Detlev Bronk was one of the most honoured scientists of our time, having participated and received almost all of the awards in almost all of the activities that lay within his sphere of professional concern. Those who knew him well and worked with him, however, admired him most for his intense interest in individuals as such. He had an enormous circle of close friends and the gift of bringing them together into effective working partnership on countless occasions. This ability served the interests of the NAS exceedingly well, since he employed it, in a most remarkable way, to make that organisation a highly effective advisor both at home and abroad.

Closely related to his interest in people was a profound conviction that the pursuit of science has its own intrinsic rewards which are reflected in its influence on human enlightenment. He understood quite clearly that, while science could serve as handmaiden to the applied arts, it must not become a slave to them. He believed deeply that the freedom of science is one of the essential freedoms which must be sustained if mankind is to become a more perfect reflection of the Creator.

**Frederick Seitz**

## Better treaty is worth waiting for

JULES VERNE in *Sens dessus dessous* (1889) reported that the government in Washington was very interested in the possibility of firing a projectile of 180,000 tons which would displace the North Pole by 23°, thus eliminating the obliquity of the ecliptic and thereby seasonal variations in the Sun's elevation. During 1956, Senator Estes Kefauver, the US Vice-Presidential candidate declared that hydrogen bomb tests could tilt the axis by 10°. Neither Verne's nor Kefauver's calculation took into account the Earth's spheroidal shape. When this is accounted for, the displacements in both cases assume more modest dimensions—being reduced by a factor of about 10<sup>11</sup>. "After seventy years", wrote Walter Munk and Gordon Macdonald, in telling this story in *The Rotation of the Earth* (Cambridge University Press), "the government in Washington still refuses to recognise the existence of the equatorial bulge".

This week the United Nations Conference of the Committee on Disarmament reconvenes in Geneva, and environmental warfare will be high on the list of topics to be studied. If denying Moscow (and London) a decent summer every year is less high on the list these days, there still remain plenty of possibilities, however unfeasible they may be at present. They include

- stimulation or suppression of rain, hail, fog, snow and lightning
- generation and guidance of tornadoes and hurricanes
- modification of climate
- diversion or pollution of rivers and ocean currents
- changes in physical, chemical or electrical properties of the atmosphere or oceans
- stimulation of earthquakes and/or oceanic tidal waves
- disruption of natural vegetative cover

Excellent surveys are given by Jozef Goldblat and Bhupendra Jasani in a recent issue of *Ambio* (Vol. IV, No. 5-6).

In the past two years the United States and Soviet Union have been holding bilateral talks on environmental modification, and will be proposing a draft convention. Its crucial sentence runs: "Each State Party to this Convention undertakes not to engage in military or any other hostile use of environmental modification techniques having widespread, long-lasting or severe effects as the means of destruction, damage or injury to another State Party". Environmental modification techniques are later defined to comprise techniques which change the environment "through the deliberate modification of natural processes".

A veritable industry has grown up around the analysis of what is omitted from arms control and disarmament measures, and this convention offers particularly rich pickings. The exercise is helped by the existence of two earlier drafts—one proposed by liberals in the United States Senate in 1973 and given overwhelming support there, the other submitted to the United Nations General Assembly in 1974 by the Soviet Union. The table shows the most significant variations.

The omissions show rather clearly US military thinking on the subject. Environmental modification techniques that

	Military R & D forbidden?	All states protected?	All operations forbidden?	Review Conference after 5 years?
US Senate Resolution (1973)	Yes	Yes	Yes	Yes
USSR Proposal (1974)	'Prepara- tions for use' for- bidden	Yes	Yes	Yes
US/USSR Proposal (1975/6)	No	No, only 'States Party'	No, only those lead- ing to 'widespread, long-lasting or severe effects'	No

are limited in extent, short in duration or not too severe are permitted. Bickering about where the line is drawn is, by the convention, transferred to the Security Council, where the veto can be used. Research and development are permitted, so techniques can be brought to the point of readiness; if any country decides to turn its hostility on another and has a new and remarkable weapon it is unlikely to be too squeamish about ignoring a treaty. It is difficult to know whether to attach any significance to the limitation of beneficiaries to 'States Party'. China has not been in the habit of signing treaties; the two superpowers seem to be keeping their options open in her direction. Finally, the lack of a review conference seems to be the easiest way to allow the subject to go underground once the ink is dry on the treaty.

The definition of environmental modification as change "through the deliberate modification of natural processes" was not in the earlier drafts. Was it added simply for neatness or does it exclude anything significant? It does resolve an ambiguity, namely, whether bombing a dam to flood the countryside or illuminating enemy territory at night time is to be regarded as environmental modification. Unfortunately, as with so much else in the convention, the almost feasible is declared beyond its scope.

There are many reasons why the proposed convention is weak, and since widespread, long-lasting and severe modifications are by no means yet upon us (indeed many ideas are by common consent, fairly ridiculous) there is still scope for action. The superpowers should be told to go away and work out something more meaningful in which research and development for peaceful purposes is given a firm international grounding, since the environment does not recognise frontiers. That done, there need be no excuse that military research and development is needed because it might have peaceful applications. And a much more realistic treaty could be written. □

## Australian aftermath

Political changes have affected Australian science. In the first of two articles. **Peter Pockley** paints a picture of the period up to Labour's downfall.

The old, the new and the ever-present: Gough Whitlam (top), Malcolm Fraser (centre) and Sir John Kerr (bottom). (Photos: AIS)

WHILE it may be rash to write historical perspectives close to the events under examination, a claim that Australian science politics have never had a more turbulent twelve months would be hard to beat. The dismissal of Mr Gough Whitlam's Labour government by the Governor General, Sir John Kerr, on 11 November and its replacement, first by vice-regal fiat and ultimately by election of 13 December, by the conservative coalition led by Mr Malcolm Fraser has brought about an atmosphere of tight security and public silence on most areas of government policies and practices. Yet, science politics have boiled merrily along in the public gaze.

All government departments with a substantial science component have suffered change, not because of their scientific responsibilities but largely as a by-product of Mr Fraser's determination to dismantle many of Labour's bureaucratic monuments. However, while the new Prime Minister is working hard to do this, or simply to neglect Labour's social initiatives, like medical and legal aid, he will be hard put to affect one over-riding legacy of the three Whitlam years. This is the evident politicisation of many sectors of Australian society which had previously never noticed, let alone used, their political feet. Under the previous 23 years of Liberal-Country Party rule, the most successful influences on government were the established forces of commerce who operated largely in a private, sometimes covert, fashion. Under Labour, the opportunities for overt political action were expanded, partly by design, partly by default.

The environmentalists and scientists, for example, were encouraged into political action by the deliberate design of direct channels to Cabinet through the establishment of ministers and departments devoted to their interests. It should be noted, though, that these two particular groups and ministries were vastly different. The Environment Department, begun from scratch, had an activist and intellectual in Dr Moss Cass as its first Minister. The staffing of the department had a strong scientific basis from the Secretary, Dr Don McMichael, down. The environmental movement was among the strongest supporters of Labour in their 1972 and 1974 election victories.

In contrast, the Science Department

was formed by splitting the former Department of Education and Science, whose head, Sir Hugh Ennor, went to the Science part. Despite the new organisational design, Australian scientists were slow to forge a stronger platform for their own interests. Some blame was directed at the department which, apart from Sir Hugh Ennor, a former biochemistry professor at the Australian National University, was not strong in scientific experience. The new Minister for Science, Mr Bill Morrison, was less encouraging to the scientists and bureaucrats under his control than he might have been, both through his critical approach to their work and a certain lack of energy in publicly promoting their interests. In an interview for *Nature* in 1973, Mr Morrison remarked that "there are absolutely no votes in science": if true then his time as Science Minister was politically useless to him, but he only needed 30 of the votes which went to his Liberal opponent to have saved his seat at the recent election, and there just might have been 30 disinherited scientists in his electorate.

### Two confrontations

When the government defaulted seriously on science matters, though, the general political climate had prepared scientists for exerting effective public pressure. After a constructive start to 1975 with the announcement in January of the formation of the Australian Science and Technology Council (ASTEC), the government had to ride out two major confrontations with the scientific community in which the scientists displayed considerable nous and had significant effect. The first boilover was the raid on CSIRO's statutory responsibilities by the then Minerals and Energy Minister, Mr Rex Connor (who was returned at the recent poll), following the extraordinary scene of Mr Clyde Cameron's fit of pique in refusing for a time to serve in the Science portfolio. In the face of heavy odds, CSIRO held its ground in the fight.

The second occasion concerned a first-class foul-up of the financing of research grants. There are two principal government schemes for supporting individual and small group research; these are run by the Australian Research Grants Committee (ARGC) and the National Health and Medical

Research Council (NH&MRC). The funds available to these schemes were ruthlessly slashed in the August budget; ARGC's funds for 1976 were cut by 66% to about \$3 million, and NH&MRC's by 43% to about \$4 million. The exact amounts were hard to ascertain from the budget papers which referred to the financial year 1975/76 (July to June) while the research grants schemes, like universities, conformed to the calendar year. The reality of the potential disaster to research in universities and non-government institutions only sank slowly into the collective consciousness of Australian scientists.

The disparate and dispersed nature of Australia's scientific community normally militates against unified and forceful action on a national basis. But, although slow in ignition, the scientists

---

**'The disparate and dispersed nature of Australia's scientific community normally militates against unified and forceful action on a national basis. But, although slow in ignition, the scientists were long in burning'**

---

were long in burning. In the face of an inflation-conscious government, resolute at last to hold the line on overall expenditure, the scientists mobilised themselves with nationwide protest meetings and lobbying through the press and private channels; one remarkable occasion in Melbourne drew 800 odd researchers—the atmosphere was described as “euphorically united” against the philistine forces of government. By late September, they had forced both Ministers responsible (Science and Consumer Affairs—Mr Cameron — and Health — Dr Doug Everingham, who was later defeated at the poll) to admit to bungling through a failure to appreciate the difference between financial and calendar years during the final budget negotiations. Face-saving formulae were found to restore the 1976 grants to roughly the 1975 levels in paper money terms; for 1976, ARGC finally allocated \$7.2 million and NH&MRC \$7.15 million. Even these levels, though, constituted about 12–15% less in real terms than the previous year due to the effects of inflation.

#### **Prelude to the fall**

By the time the research grants controversy had died down, the Labour Government was beginning to look decidedly shaky. Following the mid-year Cabinet reshuffle, there was firmer and more competent leadership among the senior ministers, but their economic decisions, although basically sound, were biting hard on many important groups. The budget was severe on the

19 universities and 85 advanced colleges by deferring triennial financing for one year. A “pause year” was introduced for 1976, before resumption of the progression of triennia in 1977. The recommendations of the Universities Commission and the Commission on Advanced Education, for expenditure of \$1,780 million and \$1,681 million for the 1976–78 triennium, were set aside, and higher education was thrown into great uncertainty. The effects, though, were mainly felt by the senior administrators of universities and colleges and even their public protests did not cut much ice among their staffs.

The consequences of the economic situation and of Labour's administration of it did not strike home to the great bulk of academics until their own personal interests in research were threatened. In comparison with the cutbacks in growth of expenditure on salaries and capital, the initial research cuts were very small beer (for universities the cutback is of the order of \$200 million for 1976, an exact figure being hard to calculate on a comparative, annual basis because of triennial financing). Yet those initial research cuts, totalling about \$7 million, did more to lose the confidence of the academic community in the government than any other factor, and the government could ill afford to lose the support of any articulate group. Ironically, when the constitutional issue reached crisis point, many of the previously disenchanted academics flocked back to active support of the Labour cause.

It is doubtful if the scientists of Australia ever saw themselves as the precipitants of crisis in government, but their associations with key political events of 1975 were close and, at times, uncomfortably so. By being forced into political defence of their own territory, many scientists appeared to become more informed and articulate on basic political matters than previously.

Mr Fraser chose to use his majority in the Senate to defer Labour's Budget after Mr Whitlam had sacked Mr Connor from the Ministry for allegedly misleading Parliament on an aspect of the long-running “overseas loans affair”. Mr Fraser also took one or two other useful precautions before embarking on this unprecedented course—like squaring off the proprietors of the three national chains of newspapers, whose unquestioning support he enjoyed throughout the campaign.

With the fall of Mr Connor, his adviser Professor Harry Messel disappeared from immediate view in Canberra. The other member of Mr Connor's tightly knit team in the raid on CSIRO, Sir Lennox Hewitt, then Secretary of Mr Connor's Department,

*Top: Sir Hugh Ennor, Secretary, Department of Science. Below: Rex Connor, former Minerals and Energy minister. (Photos: AIS)*

had already departed the Canberra scene, having been strongly encouraged to move sideways into the security of the chairmanship of Qantas, Australia's overseas airline. Nonetheless, the awkward division of responsibility for CSIRO between the Minister for Science and Consumer Affairs and the Minister for Minerals and Energy was translated into a division of CSIRO's funds (\$143 million from all sources for 1975/76) along similar lines in the August budget. Since, however, the budget did not get passed by the Senate until the election had been forced on Labour by the Governor General, the personality of CSIRO was never effectively split by these arrangements.

**(to be concluded)**

## USSR

# Plyushch says protest

*The Soviet Union recently released Leonid Plyushch, the Ukrainian mathematician held for over three years in Dnepropetrovsk penal mental hospital. Vera Rich reports*

"I consider that the scientists of the west should protest in an organised manner and publicly against the campaign in the Soviet Union against dissidents, and against prisons, camps and penal psychiatric institutions". This statement has come from Leonid Plyushch, who warmly acknowledges the help of the western academic community in effecting his release from the hospital following the granting of an exit visa in January. He told *Nature* that he thought pressure from Western scientists was "one of the active factors which assisted my release".

In Plyushch's case, a two-pronged attack on the Soviet authorities was mounted on his behalf—on the one hand by mathematicians and cyberneticists (his professional colleagues), and on the other by psychiatrists, who saw his continued incarceration and the massive doses of drugs to which he was subjected as a blot upon their profession. The mathematicians' campaign followed what has by now become a standard pattern—appeals to the Soviet authorities, proposals to elect Plyushch as a member of eminent mathematical bodies and a concerted effort to keep his case before world opinion. The psychiatrists' campaign was a more complex matter. They were not only concerned with effecting Plyushch's release; they also felt that his committal impugned the honour of their profession. While working to secure his release, they therefore sought a reversal of the diagnosis. This diagnosis stated, apparently on the basis of his criticism of Soviet "state capitalism" (Plyushch's term), his defence of his native Ukrainian culture, and his signature on a petition to the United Nations, that he was suffering from "sluggish schizophrenia" and "reformism"—diseases which, as yet, the psychiatric profession elsewhere does not acknowledge.

Plyushch himself has offered two possible reasons for his committal to the *psikhushka* rather than to an ordinary prison or camp: firstly, he refused to answer the interrogators' questions, "because I considered, and I told them so, that the KGB is an anti-Soviet, anti-Communist, anti-constitutional organisation"; secondly, "because they knew that in court I

would speak from a Communist position and that nothing would happen in court to show that I was an anti-Soviet person". Since it appears to be current Soviet policy to present all separatism in the Union Republics as inspired by fascism and international capitalism, this would have been extremely embarrassing.

Plyushch's ideal for his native Ukraine is an independent socialist state on the Dubcek model—or, at the very least, a reversal of the policy of Russification of higher education and learning, which since the decree on education of November 1958 has gradually introduced Russian as the universal language of the learned professions throughout the Soviet Union. This has in some cases reduced formerly important learned journals into little more than overflow outlets for Moscow publications, and has undermined the very promising lead which, fifteen years ago, the Ukrainian SSR was making in Plyushch's own field of cybernetics.

## Soviet response

In belated response to the campaign by bodies like the Royal College of Psychiatrists, the Soviet authorities, in the person of Dr Snezhnevskii of the Serbskii Institute of Psychiatric Medicine in Moscow, countered finally with accusations of non-professional conduct against the Royal College, which had mentioned "patients" by name. This particular correspondence between the Royal College and Snezhnevskii has not yet been concluded, but it is worth noting that the College only voiced its protests after appeals to world opinion from Plyushch's family and the families of other "psychiatric" prisoners; moreover, an official at the Soviet embassy in Paris had himself divulged names of internees (including that of Plyushch) when he claimed (in a communication to the French mathematician Henri Cartan) that Western psychiatrists who were shown the relevant documents at the Serbskii Institute had all agreed that the persons in question were ill at the time of detention (each of the psychiatrists concerned, who included Dr Denis Leigh, the Secretary General of the World Psychiatric Association, and an ex-President of the American Psychiatric Association, publicly denied this later).

With Plyushch's release, the Soviet Embassy in London has made a determined stand to prove that, even if Plyushch were now sane (as three

Photo: AP

Leonid Plyushch: released

Western psychiatrists—Drs Low-Beer, Sluga and Ferdieri—have declared), he was at the time of his committal mentally ill. *Soviet News*, the official embassy "hand-out", presents his case as a cure; his mental health is said to have "improved lately", "as a result of treatment". His release is thus presented as a triumph for Soviet psychiatry. To reinforce this impression *Soviet News* also carries an interview with Denis Leigh. General in its content, in its present context it could be misconstrued as supporting the Soviet viewpoint on Plyushch.

Although the Plyushch case could now be considered closed, the evidence he has brought with him does reopen certain issues for Western scientists. They have long known of the Soviet use of drugs such as haloperidol, sulfazin and triflazine (stelazin) as a means of repression, and what now emerges from Plyushch's evidence is the number of "patients" involved. Plyushch says that he has "almost no information" about other psychiatric hospitals, and he understands that "things are a bit better" in them. But Dnepropetrovsk, he says, is the worst, and he reports that some 60 dissidents, and not the few originally thought, are at present confined there. He stresses the problem that "in a psychiatric prison, a person degenerates intellectually".

Since it is among the intellectuals that the dissident movement in all its varieties has taken the strongest hold, Plyushch's evidence seems certain to provoke considerable concern and disquiet among the world scientific and academic community as a whole. □

## USA

# The public's case is put

*The tortuous process of setting controls on the use of a revolutionary, but potentially hazardous, technique for manipulating genes from living organisms has entered a new and politically important stage in Washington. Colin Norman reports*

For the first time, the question of controls over genetic manipulation experiments was last week opened up to allow members of various public groups to express their opinions on the risks and benefits of the research, and to influence the development of the proposed controls. The forum was provided by an open meeting of a top-level advisory committee of the National Institutes of Health (NIH), the institution which funds the bulk of biomedical research in the United States. The meeting was called by NIH Director Dr Donald Fredrickson to discuss whether or not the proposed guidelines, drafted by another NIH committee last December after months of argument and confusion, should be adopted. Fredrickson will decide that question before the drafting committee next meets in April. Hanging on his decision are several exciting experiments which are currently under embargo.

The technique involves the use of a newly-discovered class of enzymes to transplant genes from one organism into another. The utility of the technique is that it enables genes from any organism, including man, to be inserted into a virus or bacterium so that they are copied by the reproductive machinery of their new host. That possibility could open up revolutionary advances in understanding how genes work and more distantly, it could lead to such applications as improving yields of crop plants and repairing genetic diseases.

But, in 1973, scientists involved in the research began to express concern about the fact that the technique allows genes to be shuffled between species and joined in combinations which are unlikely to have occurred by evolution. It is conceivable, for example, that a virus or bacterium bearing transplanted genes could be endowed with unpredictable biological properties so that, in the worst imaginable case, a novel epidemic could be let loose if they escape from the laboratory. Such concerns led a committee of the National Academy of Sciences, chaired by Paul Berg of Stanford University, to urge in July 1974 that a

moratorium be placed on some uses of the techniques until the hazards are assessed. That call was followed early last year by an international meeting of geneticists to discuss the hazards; since then, the NIH committee has been attempting to draft regulations to control the technique.

Last week's meeting provided a confused discussion which resulted in conflicting advice being given to Fredrickson about the acceptability of the proposed regulations. The committee, which consisted of scientists, lawyers and lay members, listened to statements from those who drafted the regulations and from a variety of groups and individuals, on the basis of which each member will provide Fredrickson with views on whether or not the proposed controls are acceptable. The fundamental issue is whether, and under what conditions, some of the research which was placed under a voluntary moratorium by the Berg committee's appeal should be allowed to go ahead.

The proposed controls would allow some of the research to be resumed, but under very strict conditions. Essentially, the controls specify that most experiments should be performed in laboratories especially equipped with safety devices—in much the same way that research involving hazardous pathogens is now performed—and, in addition, genes should only be transplanted into organisms which have been crippled in such a way that they would be incapable of surviving outside the laboratory.

Berg himself said last week that he believes that the proposed controls are "stricter than necessary to protect public health", but added that he believes that it is better to err on the side of caution. Similarly, Dr Roy Curtiss, a microbiologist from the University of Alabama, told the committee that he believes the proposed controls are sufficiently strict to guard against the possible hazards. He also announced that he has constructed in his laboratory a strain of the common intestinal bacterium *E. coli*, which appears to have been mutated so as to be incapable of surviving outside an artificial laboratory environment. *E. coli*, the geneticists' workhorse, is the most likely host for transplanted genes.

But a few scientists expressed the opinion that the proposed guidelines are too strict, and will greatly restrict an exciting and potentially beneficial area of research. Dr David Hogness, a member of the committee which drafted the proposed controls, for

example, suggested that there is little evidence that the speculated hazards are real, and argued that "in the present climate of opinion, the benefits of increasing knowledge have been underemphasised". And Dr Donald Brown, a geneticist who has been using the technique to grow and purify frog genes in *E. coli*, suggested that the controls are so strict as to be totally irrational.

On the other hand, several other witnesses, most prominently members of a group of radical scientists called the Boston Area Recombinant DNA group, argued that many planned experiments should be delayed, at least until the hazards have been evaluated. In particular, they urged that *E. coli* should not be used as the host for transplanted genes because that bacterium is a common inhabitant of the human gut.

Dr Allen Silverstone, a spokesman for the Boston group said, for example, that "unless we can be assured that the possibility of danger is reduced to insignificance, we would suggest that the NIH withhold funding such research, until the questions of safety and procedure are settled, especially to the satisfaction of honest critics within the scientific community and the public. We do not propose this lightly. We recognise that many scientists wish to do these experiments, and thus far their restraint has been admirable."

Faced with those conflicting views, Fredrickson must soon decide whether or not to accept the proposed controls or suggest that they should be modified. If he does suggest modifications, it is likely that he will require that the drafting committee should pay more attention to devising ways in which the proposed controls should be implemented.

The proposed guidelines, which would apply only to research funded by NIH, suggest that implementation of the controls should largely be left to institutional committees, which would ensure that the safety precautions at institutions where experiments will be undertaken, meet conditions set out in the regulations.

It should be noted that, by providing public input into his decision, Fredrickson has drawn the sting from a common criticism that the process has lacked participation from people outside the scientific community. Senator Edward Kennedy, for example, has suggested that such matters are too important to be left solely to scientists, and he would presumably be ready to provide such input by legislation if necessary. Last week's public meeting should at least guard against the research being regulated by legislation. □

## SWEDEN

## Probing the ionosphere

*Representatives from six European countries met in Kiruna, North Sweden, last month to inaugurate the EISCAT project for research into the Earth's higher atmosphere. Wendy Barnaby reports*

THE aim of the \$21 million EISCAT (European Incoherent Scatter Facility) project, which scientific organizations in Britain, Finland, France, Norway, Sweden and West Germany are sponsoring, is to learn more about the chemical, physical and dynamic processes which the solar wind induces in the Earth's ionosphere. The dual frequency high power radar system which will be used is expected to be built in three years' time, and the project will run for at least ten years after that Britain, France and West Germany will each contribute about a quarter of the initial financing, and the rest will come from the Scandinavians.

As a method of exploring the ionosphere, incoherent scatter involves beaming radar waves there to cause the free electrons of the ionosphere's plasma to operate as antennae and

'scatter' radio signals, which are then monitored by receivers on earth. These signals are rich in information about the properties of the ionosphere and the processes going on within it. The EISCAT facility will operate from VHF (224 MHz) and UHF (933.5 MHz) transmitters at Tromsø, Norway. The signals will be picked up from electrons at heights between about 80 and 2000 km in the ionosphere by a VHF receiver at Tromsø and UHF receivers at Tromsø, Kiruna (Sweden) and Sodankylä (Finland). They will then be passed to the Geophysical Institute at Kiruna, the project's headquarters, for analysis.

Solar-terrestrial physics will undoubtedly be extended by what the analyses will reveal. One member of the EISCAT Council, Dr F. Horner (UK), has explained that the movement of ionization, the density of electrons, the temperature of ions and electrons, structural changes in the ionosphere and neutral atmosphere, and the ionospheric source of the solar wind will all be further clarified. One of the main topics for investigation will be aurora, and the way in which they

are formed by ionization. The facility is being built in high latitudes specifically to make such studies possible. There will be no immediate practical applications of the research, Dr Horner said, although in the long term it will increase understanding of radio communications. It will also throw light on the ways in which the earth's climate is affected by ionospheric conditions.

Although EISCAT is not the first incoherent scatter project, it is by far the most sophisticated. Teams in Peru and Alaska, for example, have already probed the lower ionosphere with radar waves of 1–10 MHz. The British Science Research Council made the last observations in its project MISCAT (multi-static incoherent scatter) as late as last August; this involved the transmission of waves of 400.5 MHz to obtain electron and ion temperatures in a region 100–400 km within the ionosphere. The data obtained is still being processed at the Appleton Laboratory, Slough, and the University College of Wales, Aberystwyth, and is also expected to yield information about the drift velocities of the ions. For the British scientists, therefore, EISCAT is a logical extension of the SRC's work. □

## BRITAIN

## Engineering a royal society

THE Council of Engineering Institutions (CEI) wheeled on its biggest gun at its tenth anniversary celebration—Prince Philip the retiring president—in the hope of generating badly-needed momentum towards unity in the engineering community.

The Prince, having eloquently exhorted engineers to stick together, launched a new concept—a Fellowship of Engineering, to recognise eminence in the profession; but the idea of a sort of Royal Society for engineers was not without a sizeable band of sceptics.

CEI's problems have multiplied in recent months as engineers, worried about their professional status, their salary, and their public relations, have begun to doubt that CEI was doing enough for them. Meanwhile CEI is suffering from internal strife: its largest members, the Mechanicals, Electricals and Civils, are trying to reform its voting structure, which at present gives equal weight to every one of the fifteen constituent institutions. For lack of progress, the Electricals last December served notice that they would pull out of CEI in a year's time. Unsurprisingly,

the press has now latched on to the woes of CEI in a big way.

Many engineers have looked to CEI to produce some sort of national academy of engineering whose members would be widely recognised as outstanding and whose opinion might be sought by the government. The notion that the government might seek technical advice from professionals not in the Civil Service is a bit outmoded these days, and the need for yet more marks of distinction in engineering doesn't seem entirely obvious when an engineer of distinction can already trail a string of initials like MSc, CEng, FICE, FIMechE, FIGasE, FInstE, MIEE, MICheE after his name. But FEng is now to be the prize to cap all prizes. Excepting FRS, of course. The Royal Society has been a bit of a problem, because it already has seventy or so on its books with at least nominal engineering qualifications. Proponents of the Fellowship of Engineering want very much the FEng to have equal "status" with FRS; and some would even like the Royal Society to stop electing engineering fellows so as to

prevent FEng from being a sort of failed FRS.

There are others, notably the Mechanicals and Electricals, who also worry about the "failed FRS" image through the association of the Fellowship with CEI, "or any body which may replace it". They argue that CEI or its successor will necessarily be of lower technical status, being "mainly concerned with the mundane day-to-day activities of the average member". They would have preferred the Royal Society to have been more extensively involved, preferably as a co-founder and thus as a guarantor of high standards and continuity. This has not happened; invitations have gone out to the 70 FRS's and to 70 other distinguished engineers to become Fellows of the CEI, and the Royal Society simply says that it has learnt of the initiative with satisfaction.

This new mark of distinction thus suffers at the very beginning from dissent about its parent body. This will take a much more serious turn if the Electricals really do pull out of CEI. There will be anxious searching through CEI's mail these next few days in the hopes that a large fraction of the first 140 (the ultimate number is to be 1000) accept their invitations. □

## IN BRIEF

**Reactor action**

Research and technology ministers from France and Germany discussed plans for the joint development of fast breeder and high temperature reactors at last week's intergovernmental meeting in Nice. Both countries are concerned about rising costs, but their research programmes also complement one another well; moreover plans broke down recently for German cooperation with Britain, whose apparent isolation is beginning to show in the face of co-operation on fast breeders between Germany, Belgium, Luxembourg and the Netherlands.

**BNFL setback?**

British Nuclear Fuels Ltd (BNFL), still waiting to close the controversial deal to reprocess spent Japanese nuclear fuel at Windscale, is investigating a potentially embarrassing incident there. Last week, radioactive liquid containing tritium, an element capable of diffusing through apparently impermeable materials, seeped into a stainless steel

pipe carrying cooling water through a storage tank that contains reprocessed material. BNFL claim that no radioactivity escaped from the tank.

**Safeguards draft**

A draft resolution from Britain to fellow members of the International Atomic Energy Agency (IAEA) in Vienna calls for an extension of nuclear safeguards agreements and will, if accepted, come before the IAEA board of governors when it meets next week. Existing safeguards, administered by the IAEA primarily to prevent the clandestine diversion of nuclear materials to military use, apply only to signatories of the Non-Proliferation Treaty; opposition can be expected from non-signatories India and Brazil.

**NASA study**

A major study released by the National Aeronautics and Space Administration (NASA) says that during the next 25 years space research and development

should be directed more toward Earth-oriented programmes, such as environmental monitoring and weather prediction. The study, conducted by a committee of top NASA officials and outside consultants, may form the basis for much of NASA's planning in the next few years, it recommends that space research should focus more on fundamental problems, such as the evolution of the universe and the nature of black holes, that there should be a major increase in emphasis on data management, and that the USA should develop a permanent space station.

**Privacy**

The Data Protection Committee, envisaged in the recent UK White Paper on Computers and Privacy as a first step towards a Data Protection Authority, is to be presided over by Sir Kenneth Younger. It was the Younger Committee's report on privacy in 1972 which first recommended an independent review body to oversee the gathering of personal information.

To obtain support for any piece of research today, it is almost essential to claim that one objective is to produce a model. This use of the word in scientific circles is relatively new. Until recently the Shorter Oxford Dictionary restricted its definition to cover such conceptions as small replicas (like Dinky toys) and to describe those persons who posed for artists and photographers, or who displayed *haute couture* garments to society ladies. The date 1971 is given when it included "a simplified or idealised description of a system, situation or process often in mathematical terms, devised to facilitate calculations and predictions" to the Addenda printed at the end of the second volume.

Provided they are correctly used, some models are clearly useful. One of the earliest was Professor Jay Forrester's world model devised for the long-term study of global problems. Provided it was fed with the correct material, it performed admirably. Unfortunately it could easily be misused, as is often indicated in that egregious publication "Limits to Growth". For instance, it is assumed that there is always an increase in environmental pollution if industrial production increases, and so a growth economy must always lead to intolerable pollution and disaster. There are many arguments against uncontrolled economic growth, but this is probably the least valid. Then it is assumed that DDT levels in fish and fish-eating

birds will rise for many years even after the use of DDT ceases. Fortunately it has been found, in several regions, that almost as soon as the

**Mistaken models****KENNETH MELLANBY**

use of the insecticide is curtailed, levels in fish-eating birds start to fall. These, however, are misuses of what is clearly a true model, and one that can frequently be useful.

My real complaint is that the word model is so often abused. Many so-called models are no more than descriptions—some could best be described as "maps". We even find a written or spoken description called a "verbal model", though not by me,

nor in any publication for which I have any editorial responsibility. Then there is the mathematical model. I read that "in order that it (a hypothesis) can be tested numerically it has to be stated in mathematical terms: this is what is called a 'model' ". Again, not by me. This so-called model is surely nothing but a mathematical description, with all its faults and advantages. I resent the assumption that this is the only way in which to test a hypothesis. Some of us find a mathematical description, no matter how crude (and such a description can only be an approximation to the truth) illuminates the subject, and gives intellectual satisfaction. Others, and I believe they may be just as good scientists, find such treatment merely confusing. The danger today is that the mathematicians, and even the pseudo-mathematicians, may be gaining in influence, and trying to make others adopt methods which may not be the only ones needed to solve all our problems. All descriptions, mathematical, verbal or conceptual, are inaccurate simplifications of the truth, and can never be a substitute for accurate observation.

Recently model has taken on another meaning. Doorbells in the sleazier parts of London are often labelled simply "Model". Some are more descriptive, as "Second Floor, Lulu, Parisian Model, Very Athletic". This does seem a fruitful field for scientific research.

## Egypt's needs

SIR,—Egypt's population, as Salah Galal writes (December 18, page 564), may be expected to reach 220 million by the year 2100, and to satisfy the country's water and power needs in the future would call for two Aswan High Dams a year and the equivalent of two extra Nile Rivers. Sea water desalination is looked to as offering the obvious means of supplying the country's water needs.

This presentation of the situation leads me to ask the following questions:

● Does not the projected vast demand for power and water indicate an unreasonable population growth? Perhaps the problem is not so much how to supply the rapidly increasing population as how to keep the population within suppliable limits.

● The product value of 1 m<sup>3</sup> of irrigation water in Egypt is about 3 cents (US). The cost of producing 1 m<sup>3</sup> of desalinated water by nuclear energy is at least 25 cents. Thus the Egyptian economy will lose 22 cents on every cubic metre of water desalted for use in irrigation, which means a total annual cost of some \$4,000 million for the projected water consumption in the year 2000. Rather than dismaying Egypt's agricultural economists, does this prospect not indicate that a solution to the country's water problem should be sought through other avenues?

As I see it, the most practical answer lies in the more efficient use of the waters of the Nile. It is a fact that a few hundred kilometres east of the Nile Delta, in Israel's northern Negev, the productivity of irrigation water is six times more than in Egypt; the product value per cubic metre of water in that area is 18 cents. Based on this, it may be concluded that the unused potential of the Nile River is itself worth several Niles; and although in order to fully exploit this potential a considerable capital investment might be required, this investment would still be far less than that required for water desalination.

Should it be decided to approach the problem of future resources first and foremost by stepping up the productivity of present resources, I would like to suggest one practical way of contributing towards a solution which would not involve Egypt in inordinate expense: that some of the water draining

from irrigated lands into the sea in the Delta area be sold to Israel.

Every year approximately 10,000 million cubic metres of Egypt's used irrigation water flows through drainage canals out to sea. This water is by Israeli standards still suitable for irrigation. About a tenth of the estimated discharge—equal to the output of dozens of desalting plants—could be absorbed economically in the Israeli Negev and transported there inexpensively by a canal built along the coastal strip of the Sinai Desert. The conveyance of this water to Israel for sale means Egypt's recovery of water that would otherwise be lost.

Egypt's benefits from the transaction would, among other things, be:

● payment for water which at present brings in no economic returns, and  
● a guaranteed amount of food production (in the area in question, with modern irrigation methods, one cubic metre of water produces 10 kilograms of potatoes).

The political climate in the region at present might not appear conducive to the implementation of a project of this nature and, for the time being, the idea put forward here may seem fanciful (although perhaps less fanciful than the projected annual 18,000 million cubic metres of desalinated water by the end of the century). However, even at this stage it might be worth examining the economic advantages of such an undertaking for both participants, since perhaps the very consideration of such a scheme could contribute towards the improvement of the political conditions and help to bring closer a time when such a project might become practicable.

Yours faithfully,

B. KALLY

## Photochemical smog

SIR,—I wish to call attention to a potential hazard in controlling photochemical smog by reducing hydrocarbon (HC) emissions without a corresponding reduction in the emissions of the oxides of nitrogen (NO<sub>x</sub>). If HC concentrations are reduced to keep hourly oxidant levels below the EPA ambient air quality standard of 80 p.p.b., and if NO<sub>x</sub> concentrations are not correspondingly reduced, then on many days all the NO will not be oxidized. In the presence of NO, ozone levels are

always considerably below the normal background level of 25 p.p.b., because of the rapid reaction between NO and O<sub>3</sub>. Thus on the days that NO is not completely oxidised, ozone levels will be considerably below background levels. If many such days should occur in succession, the bacteria count might increase, and this might enhance the incidence of disease (for example, streptococcus salivarius shows 90% mortality when exposed to 0.025 p.p.m. O<sub>3</sub> at 60–80% relative humidity for 30 minutes).

In many communities automobiles account for a greater percentage of the photochemically active HC than of the NO<sub>x</sub>. (In Los Angeles it is about 90% for photochemically active HC, as against 70% for NO<sub>x</sub>.) However the control devices presently being installed on cars are designed to control 80% of the HC and 40% of the NO<sub>x</sub>. As a result the percentage reduction in photochemically active HC should be about 2–3 times as great as the percentage reduction in NO<sub>x</sub>. This may not be a policy of wisdom.

Yours faithfully,

JULIAN HEICKLEN

Pennsylvania State University,

## Turkish poppy industry

SIR,—A footnote to Peter Collin's article (January 15, page 73): when the Government of Turkey forbade farmers to grow poppies, it became essential to collect substantial seed samples of populations of the many types of poppies grown in the country, both to conserve genetic diversity for future use and to ensure that sufficient seed would be available if it were once again to be required. This was successfully organised by the Crop Research and Introduction Centre at Menemen, Izmir, which was established in 1964 by the Government of Turkey with the cooperation of UNDP and FAO, and whose purposes have always included the conservation and study of the vast resources of genetic diversity in the economic plants of Turkey and their wild relatives (see *Nature*, 258, 278–279, 1975).

Yours faithfully,

A. H. BUNTING

## Immunity to parasites

from K. N. Brown

IN a world where a majority of the human population suffer serious morbidity and mortality from eukaryotic parasites, control of these infections must be one of the most pressing of current biomedical problems. Fortunately, there are few more intriguing biological challenges than the capacity of protozoan and metazoan parasites to maintain an integrated existence with their hosts long after being recognised and responded to by the host's immune system. Since they combine this characteristic with an ability to move, as a normal part of their life cycle, between a number of quite different environments, for example, from human blood to mosquito gut, and from fresh water to vertebrate tissue, eukaryotic parasites display an unusual level of phenotypic adaptability.

In the relationship with their vertebrate hosts, parasitic protozoa have the important advantage that every cell (except individual gametes) has the potential to carry the life cycle through to completion. Thus a population can sustain considerable cell death and yet survive as a 'strain'. Because transmission is often intermittent and seasonal however, it is simply not enough for a few individuals to survive host immune reactions, the survivors must themselves multiply in that same immunocompetent environment. In at least three genera, trypanosomes, plasmodia and babesia, this feat is achieved by repeated changes of exposed antigens.

Cross (Parasitology, **71**, 393; 1975) in a careful study of trypanosome variable glycoprotein antigens, has shown very extensive differences in amino acid composition from one variant to another, indicating that, as has long been suspected, variation is a phenotypic event, probably antibody-induced. That differences in the exposed part of the molecule would need to be sufficiently profound to exclude antibody cross-reactivity, could be surmised from the nature of the infection and earlier serological studies, but that they should involve a major part of the molecule came as a surprise.

Whether or not antigenic variation in *Plasmodia* and *Babesia* occurs by changes in analogous surface glyco-

proteins important for extracellular survival, is conjectural, but seems very likely from recent observations by Miller *et al.* (*J. Immun.*, **114**, 1237; 1975).

In any event it is by antigenic variation that these parasites evade some of the worst consequences of the host immune response, and render artificial immunisation extremely difficult. Immunisation by controlled infections still remains the only realistic method of inducing protection, although frequently unsatisfactory and impractical. Thus the recent report of the protective effect of intravenous BCG against murine *Babesia* and *Plasmodia* by Clark *et al.* (*Nature*, **259**, 309; 1976) is important, although the authors' suggestions concerning the role of non-antibody T cell products in destroying intra-erythrocytic parasites, will require much more critical examination before it is generally accepted. The effects, immunological and otherwise, of BCG on host responses to these infections, need investigation.

Many observations have shown that T cells are crucial for protective immunity to malaria. Brown (*Nature*, **230**, 163; 1971) has suggested one interpretation of their role in relation to clinical immunity and antibody responses to successive antigenic variants, and protection has been transferred to non-immunes by T cells from immune animals (Brown, *Ciba Symp.*, **25**, 36; 1974). Elegant experiments by Jayawardena *et al.* (*Nature*, **258**, 149; 1975) using the T<sub>H</sub>T<sub>8</sub> chromosome marker have correlated capacity to produce a protective response to malaria with T cell reactivity.

Parasite survival may be helped by their ability to induce immunodepression, and immune responses to other pathogens may be inhibited (for example see Cox, *Nature* **258**, 149; 1975). This effect seems to be localised to the lymphoid tissue directly exposed to the parasite (Golenser *et al.*, *Protozoology*, **22**, 71A, 1975), and is most readily detected during acute high parasitaemias, although in some particularly virulent trypanosome infections immunodepression may be more generalised. Parasites may produce

nonspecific lymphocyte mitogens (Greenwood and Vick, *Nature*, **257**, 592; 1975). Although responses to unrelated antigens may be depressed, however, specific responses to the primary parasitic infection are extremely active, and the antigenic lability of parasites, rather than shortcomings in host immune responses, seem to account for their survival.

Unlike protozoan populations, individual metazoan parasites cannot sustain any great degree of cell death, but they can maintain intimate contact with host tissues without producing any of the localised cellular reactions which normally characterise the presence of foreign tissues. In schistosomes, profound changes occur in the structure of the parasite surface in the first few hours after skin penetration by the aquatic infective larva. Electron microscopy (Hockley and McLaren, *Int. J. Parasit.*, **3**, 13; 1972) suggests that the absence of host cell reaction depends on continuous membrane activity at the schistosome tegument, especially evident in the first few hours after penetration. Other experiments have shown that antibodies which will kill schistosomules immediately on penetration will not destroy older worms (Clegg and Smithers, *Int. J. Parasit.*, **2**, 79; 1972). The parasite surface is immunogenic, since by injecting TNP-treated schistosomules into infected mice, Ramalho-Pinto *et al.* (*Nature*, **259**, 603; 1976) have shown T cell recognition of surface antigens. Since this response falls later in the infection and cannot be recalled readily by cercarial challenge, it may be significant for survival of adult worms. Immunity to reinfection develops normally in these animals, which is rather puzzling.

Curiously, although adult worms usually avoid immune destruction, many are killed in heavy infections. Schistosomes have host-like antigens, probably glycolipids, associated with their surface, which may mask antigenicity (Clegg, *Ciba Symp.*, **25**, 162; 1974; Smithers and Terry, *Adv. Parasit.*, **14**, 399, 1976). Can the specific T cells demonstrated by Ramalho-Pinto *et al.*, under strong antigenic

stimulus, help B cell responses to these host-antigen-worm membrane associations, to produce antibody-mediated death of adult worms? The semi-auto-immune nature of such a response could require for its initiation a heavy infection with its massive antigenic stimulus.

Clearly in infections with protozoan

and metazoan parasites, the problems of parasite-host integration and host immune responses are complex. A full understanding of interactions and reactions at the interface between parasite and host is essential if we are to be able to interpret and modify host-parasite relationships to man's advantage. □

## Colliding beam fusion

from John G. Cordey

THE controlled fusion of the light elements deuterium and tritium has been the main goal of plasma physicists for the past 20 years. The basic problem is one of containing a mixture of deuterium and tritium at a temperature of  $10^8$  °C for a sufficient length of time so that a significant number of fusion reactions take place. At these temperatures the gaseous mixture is a fully ionised plasma which has to be isolated from metallic walls. The main approach to the containment problem has been to use a strong magnetic field to separate the plasma from the walls. Considerable progress has been made using this technique, and toroidal containment devices of the tokamak type are now being designed, which will have parameters similar to those of future fusion reactors (Rebut, *Phys. Bull.*, **26**, 264; 1975).

The precise conditions for a reactor to break-even on energetic grounds were first given by Lawson (*Proc. Phys. Soc. B70*, 6; 1967). For a plasma in thermal equilibrium (that is with Maxwellian distributions of deuterons and tritons) the Lawson criterion requires that the temperature be greater than 5 keV, and the product of density and the containment time (the ' $n\tau$ ' product) be greater than  $10^{14}$  s cm<sup>-3</sup> for break-even.

The colliding beam torus, discussed by Kulsrud and Jassby on page 541 of this issue of *Nature*, and also by Cordey *et al.* (*Nucl. Fusion*, **15**, 710; 1975) is a toroidal containment device in which the deuterons and tritons, instead of being Maxwellian, are oppositely directed beam-like distributions. These counterstreaming distributions are built up by injecting 60 keV beams of deuterons and tritons into, say, a tokamak device. (This technique of beam stacking has been used for many years in accelerators, at a much lower density of course.)

The mean relative velocity of the two counterstreaming distributions is chosen to be close to the peak of the D.T. fusion cross section at around 120 keV. The resulting fusion power output per

unit volume of the CBT (colliding beam torus), is thereby much larger than that of a conventional fusion reactor with Maxwellian distributions at say a temperature of 10 keV. The conditions for a break-even reactor using the CBT approach are as a consequence far less restrictive. In particular, the ' $n\tau$ ' product has only to be greater than  $3 \times 10^{12}$  s cm<sup>-3</sup> for break-even, rather than the  $10^{14}$  s cm<sup>-3</sup> demanded by the Lawson criteria for the conventional reactor. Since the energy containment time is thought to scale with the radial dimensions of the device, a small scale experiment demonstrating the efficacy of the CBT approach could be built, whereas a demonstration experiment of the conventional reactor will have to be very large indeed. In fact, the next generation of conventional fusion experiments (such as JET, TFTR) are becoming so large and expensive that in Europe they are having to be built collaboratively.

There are however, it seems to me, several possible difficulties associated with this alternative CBT approach. First, the setting up of the colliding beam configuration requires that the containment time of the thermal plasma is less than the fast ion slowing down time, and that there is no recirculation of the thermal plasma. Although as the authors point out, this first condition is satisfied in present-day tokamaks, the parameters in these machines are very different from those of the CBT. In particular, the mean ion energy is much greater than the electron energy whereas the reverse is the case in tokamaks. In view of the fact that the ion distribution in the CBT is anisotropic, there is a strong possibility that the plasma may suffer from microinstabilities which would reduce the slowing down time of the fast ions. The prevention of recirculation of thermal particles relies on the design of an effective diverter; so far there has been little experimental work on diverters and so this part of the proposal remains somewhat speculative.

Also I have some doubts as to

whether the CBT can be developed into an economic reactor in its present form. The quoted values of  $Q$ , the energy amplification factor, of 4-8 are somewhat smaller than the value of 15 which is said to be necessary for an economic fusion reactor system (Conn *et al.*, *Nucl. Fusion*, **15**, 775; 1975). Even if a pure fusion reactor is not possible however, the high power output per unit volume of the CBT means that it would be eminently suitable as a neutron test facility or with a fissionable blanket as a fission-fusion hybrid reactor.

One further problem that is not mentioned in this particular article, but discussed elsewhere by Jassby (*MATT*-1145; 1975), is concerned with the penetration of the injected fast neutrals into the plasma. So that the ions leaving the ion sources can move freely across the containing magnetic field, they are neutralised by a gas cell; on entering the plasma they are then re-ionised by the trapped ions. The mean free path of 60 keV deuterium atoms in a plasma of density  $n$  is  $(2 \times 10^{15})/n$  cm, this places a restriction upon the density or the radius of the device, either of which may affect its reactor potential.

I think to assess whether this novel idea can be developed into a reactor first requires an experimental demonstration of the setting up of the colliding beam configuration. This could probably be done on an existing tokamak with the injection of a few megawatts of, say, 40 keV ions, which is well within the reach of existing neutral beam technology. The scaling of these experiments would then give a clearer indication of the future potential of the CBT as a reactor. □

## Biological safeguards in genetic engineering

from David Sherratt

As well as discussing the types of safeguard needed to eliminate any hazards resulting from genetic manipulation experiments in which genes from potentially any organism can be introduced into and replicated in bacteria, a number of biologists are now attempting to assess experimentally the possible hazards and to develop ways in which they can be minimised (see *Nature*, **258**, 861; 1975). Safeguards fall into two categories—physical containment, which prevents the escape of any possibly hazardous material, and biological containment, which ensures

that any possibly hazardous material can only function in precisely defined conditions unlikely to be found outside a designated laboratory. Suitable physical containment facilities are already available in a few laboratories that handle dangerous pathogens.

Since genetic engineering experiments involve the insertion of the DNA to be cloned into a 'vector' which can then be introduced into a bacterium where it is capable of replication and expression, biological containment can be aimed at both the vector and bacterium. At present the favoured vectors are either derivatives of bacteriophage lambda or one of a number of small plasmids, which consist of duplex circles of DNA able to replicate autonomously within bacteria. The favoured host bacterium is *Escherichia coli*, largely because it has been extensively studied by molecular biologists over the past 20 years.

Unfortunately *E. coli* is a normal inhabitant of the gut, and even though most laboratory strains seem to fare badly when competing with the normal intestinal flora, it has been felt advisable to construct even more 'crippled' strains which not only are unable to grow, or transfer any of their genes in the gut, but are killed by the gut environment. To this end, strains are being constructed that have some or all of the following features:

(1) Nutritional requirements which cannot be met in the intestine, such as requirements for the cell wall constituent diaminopimelic acid and nucleic acid precursors; (2) inability to survive at gut temperature and possession of DNA which is degraded at this temperature; (3) sensitivity to certain gut contents such as bile salts

The introduction of other 'weakening' genetic mutations to the host bacteria (such as nonsense suppressor mutations which upset normal translation and can markedly inhibit cell growth, and temperature-sensitive mutations) may depend on the particular vector used. Since plasmid vectors and their inserted DNA need to be maintained within the host bacterium (naked DNA soon loses its biological activity outside the cell), it is particularly important that the host/plasmid combination is effectively 'crippled' and the presence on the bacterial chromosome or on the plasmid of additional mutations that render the vector unable to replicate or transfer at 37 °C is desirable.

On the other hand, with lambda as a vector, the DNA can be maintained either within the free virus or within a lysogenic cell, integrated into the bacterial chromosome or in some cases in the plasmid state. If a lambda vector contains potentially hazardous genes it is clearly advantageous for it to be un-

able to lysogenise bacteria; then only the virus (and the free DNA) needs to be 'contained'. A number of lambda mutations are known which reduce the frequency of lysogeny greater than 10<sup>6</sup>-fold. Luckily lambda has quite a narrow host range, probably being unable to infect most intestinal strains of *E. coli*. In addition, a number of mutations can be introduced to minimise its spread through sensitive bacterial populations. For example, Enquist *et al.* (page 596 of this issue of *Nature*) have introduced three nonsense mutations into a lambda vector to ensure that viable phage can only be produced in certain suppressor<sup>+</sup> bacteria, which it is hoped are not likely to be encountered by chance. Another approach is to propagate the vector on a non-modifying strain of bacteria so that the vector DNA will be restricted and degraded in any bacteria having a restriction system. Lambda derivatives containing these types of safety features are also being developed in Edinburgh, Paris, Stanford and Wisconsin.

Another possible hazard results from the fact that free vector DNA can be taken up and replicated by bacteria. Although this process is rather inefficient, the large-scale experiments necessary to obtain sufficient amounts of cloned DNA for some purposes pose a potential hazard. Consequently it is desirable to maximise the yield of vector per bacterial cell. Several thousand copies per cell of some plasmid vectors can be obtained under particular conditions, whilst lambda mutations that make the host lysis-defective are very useful since they increase the phage yield per cell up to 10 times and moreover the phage remain in the bacterial cell until artificially lysed making collection easier and safer. It is also an advantage for the vector to carry conditional-lethal mutations that prevent it replicating in an accidentally infected host under physiological conditions.

An alternative approach to safe genetic engineering is to develop vectors and host organisms that are neither pathogenic to animals and plants nor comprise part of their normal bacterial flora. The favoured organisms emerging from these studies are *Bacillus subtilis* and certain strains of *Pseudomonas*. These are normal soil inhabitants and grow well in defined media, but although a fair amount is known about the genetics and physiology of *B. subtilis*, little is known about the genetics of its potential vectors. By contrast, some *Pseudomonas* plasmids are quite well characterised, although they suffer from the disadvantage (for safety) of being transferable to and expressed in other strains and species. Also, some species of *Bacillus* and *Pseudomonas* are extremely patho-

genic and so again there is the necessity to construct 'safe' vectors whose accidental transfer throughout populations is eliminated. □

## Thyroglobulin mystery solved?

from J. R. Tata

FOR many, thyroglobulin is simply a convenient "marker" for analytical electrophoresis and gel filtration for calibration of molecular weights of proteins. For a few, thyroglobulin is a unique giant iodoglycoprotein (molecular weight of 660,000 for the native protein) made exclusively in the thyroid gland of all vertebrates. Its hydrolysis in the gland causes the release of the two thyroid hormones, thyroxine and tri-iodothyronine, which are themselves quite unusual iodoamino acids, known as iodothyronines. Although numerous proteins can be enzymically or chemically iodinated, it is only in the confines of the thyroglobulin molecule that a few privileged mono- and di-iodotyrosyl residues can couple to form the hormonally active iodothyronines covalently retained within the large polypeptide (Edelhoch, *Rec Progr. Horm. Res.*, **21**, 1; 1965). Because of the uniqueness of its composition and structure, and the clinical and physiological importance of thyroid hormones, the thyroglobulin molecule has been intensively investigated in the past 40 years. A consequence of this activity has been the controversy that has been generated in the past decade over its subunit structure and heterogeneity. The number of subunits proposed has varied from 2 to 10 with molecular weights ranging from 25,000 to 200,000. Two recent reports now seem to put an end to this controversy.

The first report is based on some elegant work by Gilbert Vassart and his colleagues in Brussels (Vassart *et al.* *Proc. natn. Acad. Sci. U.S.A.*, **72**, 3839; 1975). It exploits the technique of translating heterologous messenger RNAs in *Xenopus* oocytes, first developed in Gurdon's laboratory (Lane *et al.*, *J. molec. Biol.*, **61**, 73; 1971). The Belgian group had earlier immunologically characterised a 33S RNA extracted from membrane-bound polysomes from ox thyroids as mRNA coding for thyroglobulin (Vassart *et al.*, *Eur. J. Biochem.*, **55**, 5; 1975). What they have now done is to demonstrate by sucrose density gradient centrifugation and gel filtration under denaturing conditions that a "19S" non-iodinated thyroglobulin (corresponding to a protein of 600,000 molecular weight) was

the major immunoreactive product of translation of 33S mRNA in *Xenopus* oocytes. The identity of this peptide with thyroglobulin was confirmed by tryptic peptide analysis which led Vassart's group to propose that thyroglobulin is a dimer of two equal subunits of 300,000 daltons. Evidence obtained from more conventional techniques for a similar large subunit of thyroglobulin also comes from a recent report from Edelhoch's laboratory at the National Institutes of Health (Haerberli *et al.*, *J. biol. Chem.*, **250**, 7294; 1975). Ten years ago Harold Edelhoch proposed that thyroglobulin was composed of four smaller subunits. But the new work from the NIH laboratory, on the basis of equilibrium density centrifugation and gel filtration in 6M guanidinium HCl of guinea pig thyroglobulin, definitely establishes the presence of a subunit of about 300,000 daltons. Two smaller subunits of molecular weights of about 210,000 and 110,000 were also detected, but all three had the same amino acid composition as whole thyroglobulin, the only major difference between them being their different iodine contents. A major reason for the earlier observations of a variety of small subunits, and the failure to detect the large one of 300,000 daltons, may lie in the extreme susceptibility of thyroglobulin to both substrate-specific and nonspecific proteases, with which the thyroid gland is particularly well endowed.

There are some interesting points emerging from the Belgian work on microinjection of *Xenopus* oocytes. Earlier experience with the translation of several foreign RNAs in frog oocytes had shown that oocytes are capable of carrying a variety of post-translational modifications of the newly synthesised polypeptide (Lane and Knowland, *The Biochemistry of Animal Development*, **3**, 145; 1975). The recovery of non-iodinated thyroglobulin is the first evidence of a failure of the oocyte to carry out a post-translational modification of a polypeptide synthesised on a vertebrate mRNA. The recovery from the oocyte of such a large sized subunit of thyroglobulin reveals a striking protection against proteolysis of the polypeptide synthesised on the injected mRNA template, especially as the *Xenopus* oocyte is known to degrade certain proteins injected into it (Dehn and Wallace, *J. Cell Biol.*, **58**, 721; 1973). What is not yet known is whether or not the primary translational product in the oocyte is a "pro-thyroglobulin", or even a "pre-pro-thyroglobulin", in line with the increasing evidence that most, if not all, secretory proteins may be synthesised as larger precursors and then specifically cleaved in the membrane of endoplasmic reticulum. In this context,

it would be interesting to find out if thyroglobulin mRNA is translated on membrane-bound ribosomes of the oocytes as it is in the thyroid cell. It would also be interesting to determine whether the oocyte carries out the post-translational glycosylation of thyroglobulin, especially as this protein is unusual in its carbohydrate composition. Whatever mysteries post-transla-

tional modifications may hold, the work from the Belgian and American laboratories seems to have solved that of the subunit structure of thyroglobulin. The work by the Belgian group is also the first in which the technique of microinjection of RNA into frog oocytes or eggs has been successfully applied to answering questions concerning protein structure. □

## The Great Barrier Reef

### Geomorphology . . .

from George E. Farrow

At a meeting in London on January 28-29, David Stoddart (University of Cambridge) and Sir Maurice Yonge added the results of the 1973 Great Barrier Reef Expedition to the illustrious series of southern zone expeditions with which the Royal Society has long been associated.

COMPARED with other recent Royal Society expeditions such as the much longer Aldabra Expedition of 1967/8 with its vital 'natural history' emphasis, or with the Solomon Islands Expedition of 1965, there was a singular dearth of faunistic papers—in fact only one out of the 19 presented. The meeting was very much a discussion on the recent geological history of the reefs, particularly in relation to possible Holocene sea-level changes.

The 1973 Expedition was financed jointly by the Royal Society and the Universities of Queensland. It worked deliberately north of Cairns, in view of previous concentration on central and southern sectors of the Great Barrier, notably by the famous 1928/29 Expedition. Seventy islands were mapped, and a flora of 200 species collected from forty—a demonstrably Australian flora with many common pan-tropical plants missing.

The most striking achievement of the expedition must surely have been G. R. Orme's (University of Queensland) use of high resolution seismic profiles to demonstrate clearly the remnant nature of the present-day reefs. This lends strong support to Purdy's recent study of central American reefs which similarly showed that modern reefs inherit their structure from earlier, eroded reef limestones. Many submerged terraces were identified on the Barrier, those at -45 m and -109 m being strongly developed. The latter was associated with a buried valley system, overlying which a thick fluvial regressive sequence seems

likely.

More than 80 radiocarbon dates have so far been obtained from material collected during the expedition, dating being carried out at the Australian National University, Canberra. Rationalisation of the dates in terms of a 'Fairbridge-type' sea-level curve proved impossible, however, because of difficulties in establishing datum levels for both the present and the past. Uncertainty about the eustatic *versus* cyclonic significance of reef island terraces and ramparts made it clear that a critical reassessment is needed of many existing dates used for sea-level reconstructions in the literature.

Though it is premature to attach significance to the dates, several interesting clusters appeared. Microatolls, some with elevations greater than the highest modern 'ponded' examples, commonly date at around 5,500 BP, the bigger cays around 3,500 BP, with two groups of beach rock at 3,000 BP and 2,000 to 1,500 BP. Even the most mobile sand cays give dates which indicate that the sediment is at least 2,000 yr old. Indeed, one came away from the discussion feeling decidedly palimpsest.

A disappointing aspect of the age dating was that suspected pre-Holocene material recovered from a 30-m hole drilled on Bewick Island proved too recrystallised for Uranium Series age determination.

D. R. Stoddart presented clear evidence, by the remapping of Low Isles (so elegantly mapped by Spender in 1928/9), of the major changes that can overtake islands in a very few years. Consternation overtook several members of the 1928/29 Expedition on hearing that the eroded foundations of their headquarters were mapped in 1973 as part of the intertidal zone! An evolution is to be recognised in the sequence of environments (and therefore in the sediments) that results from the diachronous leeward progres-

sion of belts of mangrove, themselves initially dependent on a degree of stability imparted by storm ramparts. But there is little to suggest that such an evolutionary sequence would be synchronous on neighbouring islands.

With the recent establishment of the Australian Institute of Marine Science at Townsville, a new phase of intensive long term study of ecological and sedimentary processes has become possible. This should go a long way towards rectifying our present ignorance of scale and rate factors operating in the overall barrier system.

In order to capitalise on the geophysical work of the expedition a series of boreholes at intervals across the shelf is needed to demonstrate the nature and sequence of the suspected major Holocene fluvial development overlying the -109-m terrace: until this is done the interpretation of seismic evidence must remain conjectural. Such a study would be well complemented by detailed examination of the aggradational sequences along the Queensland coast.

On a more local scale the expedition has demonstrated that the time is ripe for 'taking an island apart' by systematically drilling a series of holes through a single island like Bewick, with a view to reconstructing in three, rather than in two, dimensions the evolution of the modern reef geometry. Again, the seismic survey has suggested the potential rewards that such a drilling programme might bring in revealing exactly how the morphology of the earlier dissected reef limestone surface influences the subsequent growth and development of the modern reef system.

Over the next few years, therefore, we should see a new understanding emerge of the internal structure of the Great Barrier Reef, even perhaps including an appreciation of its foundation structure in relation to the plate-tectonic history of the western Pacific.

But there is surely another side to all this. Plate tectonics is all very well, but have we not forgotten the organisms—the very substance and most singular feature of the reefs? Have we yet begun to appreciate, for example, the immense potentiality that the 1,600 km length of reef offers for latitudinal studies of organic diversity? As it is, the basic fieldwork still remains to be done, to enable the spectrum of reef communities of the northern Barrier to be compared with those at Low Isles, let alone with other Indo-Pacific reefs. So we can confidently look forward to a resurgence of interest in the natural history of the Great Barrier, and the despatch of a further, faunistically orientated expedition. □

... and ecology

## Reef biogenesis

from Jean H. Weber

A symposium on coral reef biogenesis was organised by the Australian Institute of Marine Science (AIMS) on December 15–16, 1975 in Townsville, Queensland, Australia. The long term objective of the AIMS work on coral reef biogenesis is to develop a unifying model of the growth, development, and maintenance of the Great Barrier Reef, and the symposium was held to identify critical areas of research. Further details may be obtained from the Director, AIMS, Townsville, Queensland 4810.

M. LITTLER (University of California, Irvine) reviewed and evaluated the literature pertinent to the calcium-depositing habit in macroalgae, noting the current debate on the relative ecological importance of various kinds of calcifying organisms. Suggested research areas included partitioning pH changes into those due to calcification and those due to photosynthesis, by following changes in total alkalinity of the system by chemical methods. Studies of periodicity and stress effects on deposition rates were also recommended, as well as of grazing pressure on reef-building algae, inter and intra-specific competition, recruitment, and bioenergetics.

One vital group of reef algae are the symbiotic zooxanthellae, which make possible the survival of reef corals in a nutrient-poor environment. L. Muscatine (University of California, Los Angeles) evaluated the state of knowledge of the coral/zooxanthellar symbiosis. Some fundamental questions still remain unresolved (what, for example, is the quantitative contribution of zooxanthellae to maintenance respiration of a coral? what is the mechanism of nutrient retention and recycling? how does photosynthesis accelerate calcium deposition?).

Marine productivity begins with photosynthesis and the production of metabolic intermediates. A. Benson (Scripps Institution, San Diego) noted that the importance of lipids in the energy budget of a wide variety of reef organisms was first suggested by the recognition of wax esters, triglycerides, and phospholipids as components of mucus secreted by corals and other reef organisms. This mucus is consumed by various animals, including fishes and many commensals. Reef corals derive their stores of lipid by a yet undefined transfer process from their symbiotic zooxanthellae.

M. Doty (University of Hawaii) reviewed the essential functions of the serially appearing algal components of coral reefs: the planktonic (micro-), fleshy (meso-), and crustose (macro-morphic) constituents.

Coral reefs are unique among marine ecosystems in their ability to produce biogenic sedimentary materials and to retain these materials in the form of a wave-resistant structure. This ability to alter the environment is a function both of the rate of production and the nature of the material produced. The growth of reefs is mediated initially by an environmental "coarse-tuning", imposed by geological, meteorological and oceanographic variables. The reef system itself then acts as a "fine-tuning" device. S. Smith (Hawaii Institute of Marine Biology) examined the nature of CaCO<sub>3</sub> materials produced, rates of production, and the external factors which influence and are in turn influenced by the growth of coral reefs.

D. Stoddart (University of Cam-

## A hundred years ago

MOST of the natives who come into intimate contact with the Russians at the present time, we are informed, profess Christianity. That many heathen customs still, however, cleave to them is shown by the following incident. At a "simovie" where we landed for some hours on Sept. 16, we as usual came upon a burying-place in the wood near the dwelling-houses. The corpses were laid in large coffins above ground, with a cross in nearly every case raised over them. At one of the graves there was a consecrated picture fixed to the cross, which must be considered an additional proof that a Christian reposed in the coffin. Notwithstanding this, several garments, which had belonged to the deceased, were found hanging on a bush near the grave, together with a bundle containing food, principally dried fish. At the graves of the richer natives we are informed that the survivors place, together with food, some rouble notes, in order that the departed may not be altogether destitute of ready money on his entrance into the other world. But that fine clothes are not considered any special recommendation with St. Peter was evidenced by the exceedingly shabby, tattered, and patched condition of the garments hung up at the grave in question.

from *Nature*, 13, February 17, 313; 1876.

bridge) outlined the geological aspects of reef biogenesis. External form has been used to infer both history and internal structure, without itself being precisely defined. To understand variation in time and space, reefs must be considered as volumes or three-dimensional shapes, as opposed to the commonly-used profile diagram, which is well-adapted to describe zonation but unable to demonstrate spatial variability. New advances in describing reef form have included the use of nearest-neighbour techniques for studying patch-reef distribution, the use of spectral analysis of bottom roughness to describe groove-and-spur formations, the application of the hypsometric integral to describe lagoon basins, and the development of various indices of topographic diversity to describe reef communities. Such quantitative morphometric techniques can be applied on different scales, from entire reef complexes to individual coralla. Until three-dimensional reef forms have been described more precisely in this way, the heavy theoretical loading given to highly simplified reef descriptions must be misleading. □

## Spatial contrast vision

from a Correspondent

A Workshop on Spatial Contrast Vision was held in Amsterdam on 9–14 January 1975. It was sponsored by the Commission for Biophysics and Biochemistry of the Netherlands Royal Society of Arts and Sciences.

VISUAL scientists tend to be divided into two camps on the question of how patterns are perceived. One view is that visual information is processed by one or more frequency-selective channels; a strong statement of this theory is that the visual system performs a two-dimensional Fourier analysis. The opposing camp holds that the fundamental building-blocks are the responses of single neurones, the receptive fields of which are sensitive only to specific features of the stimulus; the strong statement is that more central neurones are increasingly selective, and that an individual percept depends ultimately on activity in a single high-order neurone.

This dichotomy could be found in much of the discussion at the Amsterdam meeting. L. H. Van der Tweel (University of Amsterdam) criticised misapplications of Fourier theory: in particular, the tendency to

ignore the question of how phase information is preserved in vision. It was later shown by Ü. Tulunay-Keesey (University of Wisconsin) that phase information can be lost by frequency-selective channels, because equal adaptive effects are found when adapting and test gratings are present in phase or out of phase. This finding raises the question of how spatial channels can ever specify the position of an object.

J. Nachmias (University of Pennsylvania) considered whether vision could be mediated by a single channel, the sensitivity of which varied with the spatial frequency of the stimulus. He concluded that such a model cannot account for known data; a multiple-channel theory is needed. This problem was discussed further by J. G. Robson (University of Cambridge), who described problems in the interpretation of human psychophysical data in terms of the properties of neural receptive fields. The classic concept of a receptive field is of a centre, within which all like stimuli elicit similar responses, and a surround, within which the same stimuli have an opposing effect. New evidence that this is an oversimplification was presented by P. O. Bishop (Australian National University), who described local differences of function within receptive fields. Sensitivity to the direction of stimulus movement can be found in small areas of the receptive field, and cells that exhibit directional sensitivity within the centres of their fields often have non-selective surrounds.

The convention of classifying retinal ganglion cells as X and Y cells was proposed by Enroth-Cugell and Robson in 1966, on the basis that X cells perform a linear summation of light within their receptive fields. The distinction has proved to be useful: neurones with X and Y characteristics have now been found in other parts of the visual system, and they differ in several characteristics. C. Enroth-Cugell (Northwestern University) reported that X and Y cells have different profiles of spatial sensitivity, and may have different neurochemical transmitters. R. M. Shapley (Rockefeller University) showed that only X cells respond linearly to temporal modulation of light. The central projections of X and Y cells differ, as shown by K.-P. Hoffman (Gutenberg University, Mainz). The X cells project only to area 17 of the visual cortex, whereas Y cells project to areas 17 and 18. Hoffman also described a third major category of visual neurones, the W cells, whose only unifying characteristic is their slow conduction velocity.

The ability of many neurones to respond to a limited range of spatial

frequencies was examined by R. L. DeValois (University of California) and L. Maffei (Laboratorio di Neurofisiologia, Pisa). In general, tuning curves become more sharply peaked as one ascends in the visual system. Considerable interest (and perhaps some scepticism) greeted Maffei's conclusion that all neurones that are located in the same column of visual cortex (that is, in a line perpendicular to the surface) tend to respond most vigorously to gratings that have the same orientation, but their preferred spatial frequency changes in a regular pattern as the recording electrode is advanced. Conversely, cells in hypercolumns (tangential to the surface) have different preferred orientations, but all respond to the same spatial frequencies.

Most of these findings emphasise spatial interactions of an inhibitory nature. A. Fiorentini (Laboratorio di Neurofisiologia, Pisa), however presented compelling data that both facilitatory and inhibitory interactions can be found in human vision.

During a 'critical period' in early life, the visual system of many animals is labile and its function can be modified substantially by depriving or distorting the visual input. This phenomenon has been studied extensively because of its implications in the treatment of human amblyopia. C. B. Blakemore (University of Cambridge) described recent experiments in which occlusion of one eye resulted in a selective loss of afferent fibres to the visual cortex from those parts of the lateral geniculate nucleus to which the occluded eye projects. J. Atkinson and O. J. Braddick (University of Cambridge) reported that the contrast vision of human infants can be tested as early as 1 month, and that a rapid improvement in sensitivity occurs during the second month of life. This raised the question of the age at which the critical period begins in man. Bishop stated that the literature suggests 5 months, but Atkinson and R. A. Crone (University of Amsterdam) argued for an earlier onset.

A wide gap still exists between experimental data and an understanding of visual perception. This was emphasised by E. H. Land (Polaroid Corporation), who gave a dramatic demonstration that knowledge of the properties of a discrete physical stimulus is not sufficient to predict its appearance, and by N. S. Sutherland (University of Sussex), who attacked the notion that the central nervous system analyses visual information in a passive manner. In so doing, Sutherland seems to have questioned the meaningfulness of the two popular models of contrast vision that are stated at the beginning of this report.

## Hazards of plutonium with special reference to the skeleton

F. W. Spiers

Bone Dosimetry Research, Medical Physics Unit, Cookridge Hospital, Leeds LS16 6QB, UK

Janet Vaughan

Bone Research Laboratory, Nuffield Orthopaedic Centre, Oxford, UK

*In the past attempts have been made to deduce plutonium toxicity in man from studies based on animal experimentation. An alternative method is to use the comparative dosimetry of plutonium and radium in man, with results broadly in agreement with maximum permissible levels set by the International Commission on Radiological Protection.*

SEABORG recognised as early as 1944 that "the physiological hazards of working with plutonium and its compounds may be very great"<sup>1</sup>. Subsequent experimental work on the biological behaviour of plutonium has confirmed Seaborg's fear about his new element and has shown that it is more carcinogenic than radium. As increasing quantities of plutonium will be produced in connection with nuclear energy programmes, it is important to have some estimate of the risks involved, namely the possible incidence of malignant cancers in individuals who have acquired a plutonium burden in the course of their work.

We present here some estimates of the risk of development of malignancies associated with the skeleton, based on a dosimetric comparison with the incidence of radium-induced cancer in man, about which considerable evidence exists<sup>2,3</sup>. Both <sup>226</sup>Ra and <sup>239</sup>Pu emit  $\alpha$  particles with not very different energies and both are deposited in bone; <sup>226</sup>Ra is deposited throughout the volume of mineral bone whereas <sup>239</sup>Pu is deposited on bone surfaces, with some distributed in bone marrow. Our calculations, however, take these differences into account since they are based, as UNSCEAR<sup>4</sup> recommends, on the known cells at risk and the determination of the physical dose these cells receive. Similar dose calculations cannot yet be made for the other major sites of plutonium retention, the lung and the liver, because the cells at risk are not known with the same certainty.

### Cells at risk in the skeleton

The cells at risk in the case of the skeleton are the progenitor osteogenic cells on bone surfaces, all the progenitor cell types found in the marrow and cells in the epithelium closely applied to bone in the sinuses of the skull<sup>5,6</sup>. The following brief review illustrates the evidence available that malignancies have been found in all these tissues, in animals and man, when irradiated by  $\alpha$  particles. Of the tumours listed, osteosarcomas are by far the most numerous

The data on <sup>239</sup>Pu refer to experimental animals with known

plutonium burdens. In 75 dogs injected with <sup>239</sup>Pu (ref. 7), 55 osteogenic sarcomas were recorded, compared with one case of leukaemia. There were no osteosarcomas in the controls but one leukaemia occurred.

In rats studied by Benstead *et al.*<sup>8</sup> 45 osteosarcoma were recorded against four cases of myeloid leukaemia. Russian workers<sup>9</sup> comment on a high incidence of tumours of the blood-forming organs in rats but data on osteosarcoma are not given. In extremely careful studies in mice, Loutit (personal communication) has recorded generalised lymphomas and local lymphomas as well as osteosarcomas and angiosarcomas. The mouse studies of Finkel and Biskis<sup>10</sup> show a high incidence of both osteosarcomas and reticular tumours, but are difficult to assess because of the large number of reticular tumours in the controls. One carcinoma of the sinuses is recorded by Jee<sup>7</sup> in a beagle dog whereas none were seen in controls.

No malignancies attributable to plutonium have been recorded in man, although in some cases the body burdens have been as high as 0.42  $\mu$ Ci (ref. 11). Tumours have occurred however, in a large group of persons (1,346 in all) exposed to radium, as either <sup>226</sup>Ra or <sup>228</sup>Ra or a mixture of the two. For this population information is available on radium body burden, calculated radiation dose received and subsequent pathology<sup>2,3,12,13</sup>. The total number of osteosarcomas in the radium study when last reported was 51; there were 22 cancers of the sinuses<sup>3,13</sup>.

Some patients had both types of tumour. Finkel and his colleagues<sup>2</sup> include in their record two cases of myeloid leukaemia and three other less well defined blood dyscrasias. When these figures were taken from the recent analysis of the radium cases, some of the early patients described by Martland<sup>14</sup> were not included by Rowland *et al.*<sup>3</sup>. In addition to osteogenic sarcoma, these early cases had atypical dysplasia of the marrow associated with severe anaemia. Their body burdens of radium were extremely high. Loutit<sup>15</sup> has suggested that they should be regarded as samples of malignant transformation of marrow cells. The risk of leukaemia from a plutonium burden is possibly greater than that from a radium burden as plutonium is retained in marrow as well as in the bone itself<sup>16-21</sup>. An ICRP publication<sup>22</sup> therefore suggested in 1972 that the skeleton probably should be considered as two distinct organs, one comprising the cortical and trabecular bone and the other the bone marrow. It may be noted that the time taken for leukaemia to develop is likely to be longer than in the case of external radiation since plutonium, entering the body by inhalation or tissue wounding, will translocate slowly and continuously from lungs, lymph nodes, wound site, or initial liver deposits. The marrow dose will build up slowly with time<sup>21</sup>.

## Animal work and toxicity estimates

Attempts have been made to relate the toxicity of a known body burden in dogs injected with different radionuclides to known body burdens of radium in man using the formula

$$\frac{\text{dose from X in animal}}{\text{dose from } ^{226}\text{Ra in animal}} = \frac{\text{dose from X in man}}{\text{dose from } ^{226}\text{Ra in man}}$$

where the doses refer to some given level of toxicity.

The doses for dogs and humans are based on an average distribution of both radionuclides in bone, that is on the average dose to mineral bone. The UNSCEAR report<sup>23</sup> makes a general comment on such types of comparison between radium data for man and animal data: "this question carries the assumption that the ratio of the absorbed doses which produce different effects for different radionuclides will be the same in man and the experimental animal, independent of promoting host factors which might act differentially, an assumption that at present remains unproved". The ratio of the doses to the cells at risk for <sup>239</sup>Pu and <sup>226</sup>Ra are not necessarily the same as the ratio of the absorbed doses to bone. Apart from the fact, pointed out by UNSCEAR<sup>23</sup>, that it is unsatisfactory to base toxicity estimates on average dose to mineral bone when it is dose to sensitive tissues that is important, there are other difficulties involved in this comparison of data for dogs and humans. First, Spiers<sup>24</sup> has shown by direct measurement of both dog and human bone that considerable structural differences in the two species affect the dose to the sensitive tissues in marrow and on bone surface and are not taken into account by the average dose to mineral bone.

Table 1 Calculated dose rates

Radionuclide	Mean dose rates (rad yr <sup>-1</sup> ) for 1 µCi skeletal content*			
	Trabecular marrow	Trabecular endosteum	Cortical endosteum	Air-sinus epithelium
<sup>226</sup> Ra + retained daughter elements	1.6 (1.5)†	19 (18)†	35	275‡
<sup>239</sup> Pu	16.9	129	193	193‡

\* Bone data assumed: skeletal mass = 5 kg, total endosteal area = 16 m<sup>2</sup>.

† Deduced from data (plane slab calculation) by Charlton and Cormack<sup>31</sup>.

‡ Estimate only.

Second, since plutonium is a surface seeker, the rate at which resorption and apposition occurs will affect the dose received by sensitive tissues. There is no reason to suppose that 'turnover rate' is the same in man and dog and it will certainly not be the same in young dogs and adult man as is accepted in the above formula. Marshall and Lloyd<sup>25</sup> have indeed drawn attention to the fact that it is unwise to compare toxicity in young dogs with that in adult man since the rate of bone turnover, that is both removal of plutonium-containing bone and its burial by new bone formation, may be different. As a result of their calculations of different remodelling times in young dogs and adult man, Marshall and Lloyd conclude that in the case of monomeric plutonium the relative biological effectiveness of plutonium compared with radium (RBE) in man is about three times that in dogs.

The differences between the skeletons of young dogs and adult humans are again emphasised by a study<sup>26</sup> of the relative carcinogenicity of <sup>226</sup>Ra and <sup>228</sup>Ra in man and a comparison with the results for the Utah dogs<sup>7</sup>. In the case of the Utah dogs, <sup>228</sup>Ra was more carcinogenic than <sup>226</sup>Ra with an RBE of 2.5. Rowland *et al.*<sup>26</sup> concluded, however, that in man there was no difference in the toxicity of the two isotopes. As they say, these observations make it difficult to accept that toxicity ratios observed in beagles can be used directly to predict toxicity ratios

in man. Although examination of the data they give for cumulative dose levels above 1,000 rad does not altogether substantiate their claim that there is no statistical difference between the toxicity of <sup>228</sup>Ra and <sup>226</sup>Ra in man, it seems probable that the comparison of the data for dogs and humans gives too high an RBE for <sup>228</sup>Ra relative to <sup>226</sup>Ra in humans. On theoretical grounds ICRP<sup>27</sup> has put the maximum permissible body burden (MPBB) for <sup>228</sup>Ra lower than that for <sup>226</sup>Ra.

Since considerable reservations must be made in interpreting simple translation to man of toxicity data obtained with dogs, it is worthwhile attempting to estimate the toxicity of <sup>239</sup>Pu by a method that uses the data for <sup>226</sup>Ra in man coupled with new calculation of dose to the relevant tissues.

## Dose rates calculated from skeletally deposited radionuclides

A method of calculating the radiation dose to tissues in bone from skeletally deposited radionuclides has been devised that takes into account the physical dimensions of the trabeculae and marrow spaces in trabecular bone<sup>24, 28, 29</sup>. It is based on the principle that particles cross the small marrow cavities in approximately straight lines with varying lengths of path. A complete description of all possible path lengths through the marrow spaces and through the trabeculae makes it possible to calculate the fraction of energy deposited, and hence the dose, in the marrow spaces by particles arising in the trabeculae. This is done by a Monte Carlo method operating in probability distributions of random path lengths measured by a specially-designed bone-scanning microscope<sup>30</sup>. The dose is averaged over the whole distribution of path lengths to give a mean value for a given bone, and sufficient bone specimens are analysed for a mean dose for the whole skeleton to be obtained. Mean dose rates have been calculated for a skeletal content of 1 µCi of a given radionuclide for the following tissues: (1) bone marrow in trabecular bone (*D<sub>M</sub>*); (2) endosteal tissue, 10 µm thick, on trabecular bone surfaces (*D<sub>S</sub>*); (3) endosteal tissue on the surfaces of cavities in cortical bone (*D'<sub>S</sub>*), and (4) epithelial tissue adjacent to bone in the air sinuses (*D<sub>AS</sub>*).

Table 2 Calculated risks

Tissue	Late effect	Risk coefficient: cases per 10 <sup>3</sup> per yr for 1 rad yr <sup>-1</sup>
Trabecular marrow	Leukaemia	<i>r<sub>M</sub></i> = 0.101
Trabecular endosteal surfaces	Osteosarcoma	<i>r<sub>OS</sub></i> = 0.079
Cortical endosteal surfaces	Osteosarcoma	<i>r'<sub>OS</sub></i> = 0.016
Air-sinus epithelium	Carcinoma	<i>r<sub>AS</sub></i> = 0.003

The method of calculation, developed initially for β emitters, assumes that the radionuclide is deposited uniformly throughout the volume of the mineral bone. It can be applied equally to a "volume-seeking" α emitter such as <sup>226</sup>Ra and results for this radionuclide are given in Table 1. Where comparisons can be made, the dose rates agree well with those derived from data by Charlton and Cormack<sup>31</sup> for the dose near a plane slab of bone containing <sup>226</sup>Ra (Table 1).

In the case of those radionuclides, such as <sup>239</sup>Pu, that are deposited on bone surfaces the Monte Carlo program must be modified to consider particles as originating only at the endosteal points of any given trabecular path. A further factor must be introduced to allow for the contribution to the dose from the trabecular surface immediately adjacent to the cavity concerned. The details of the calculation for "surface-seekers" will be published later, but approximate dose rates for a skeletal content of 1 µCi <sup>239</sup>Pu are given in Table 1. For the purpose of this article it has been assumed that 10% of the skeletal content could be deposited in bone marrow<sup>21</sup>, with the remainder distributed uniformly over the endosteal surfaces of the

skeleton. The dose rates calculated for  $^{239}\text{Pu}$  agree reasonably well with those based on a thin plane source. Thus the dose rate for the trabecular endosteum is about 10% less than that calculated for a thin plane<sup>32</sup>. It is about 25% less than the value deduced from the data of Marshall *et al.*<sup>33</sup> but in this case uniform energy deposition along the particle track was assumed. Dose rates near trabecular surfaces may be expected to be somewhat lower than for a thin plane source because the trabecular surfaces are not flat and the marrow spaces are generally too large for appreciable cross contributions to the dose from other trabecular surfaces. No allowance has been made for possible burial of the Pu by bone growth because insufficient evidence is available; the dose rates in Table 1 are therefore likely to be maximum estimates. In the case of  $^{238}\text{Pu}$ , the  $\alpha$ -particle energy and the consequent dosimetry are almost the same as for  $^{239}\text{Pu}$ , though it must be remembered that because of its high specific activity  $^{238}\text{Pu}$  does not necessarily behave biologically like  $^{239}\text{Pu}$ .

### Calculation of total risk to bone

The principle of the calculation<sup>34</sup> depends on a knowledge of the risk coefficients for the relevant late effects (leukaemia, bone sarcoma and air-sinus carcinoma) when bone tissues are irradiated by  $\alpha$  particles. The coefficients are expressed as the equilibrium risk rates, namely, the number of cases per 1,000 persons per year when a dose rate of 1 rad yr<sup>-1</sup> is maintained for a sufficiently long time. The 'equilibration' time depends on the latency period of tumour appearance, and for irradiated bone this is likely to be long—bone tumours have occurred from 10 to 30 yr after irradiation.

The total risk rate,  $R_1$ , for a skeletal content of 1  $\mu\text{Ci}$  of a given radionuclide can be stated as

$$R_1 = r_M D_M + r_{OS} D_S + r'_{OS} D'_S + r_{AS} D_{AS} \quad (1)$$

where  $r_M$  is the risk coefficient for leukaemia per unit dose rate and  $D_M$  is the dose rate to bone marrow per  $\mu\text{Ci}$  skeletal content;  $r_{OS} D_S$  refers similarly to bone sarcoma in endosteal tissues in trabecular bone,  $r'_{OS} D'_S$  to bone sarcoma in cortical bone and  $r_{AS} D_{AS}$  to air-sinus carcinoma. Clearly other risks, if any, could be added but these particular ones will be considered in respect of the  $\alpha$  irradiation of bone.

and the total risk rates to bone are as given in Table 3 for  $^{226}\text{Ra}$  and  $^{239}\text{Pu}$ . The risk estimates for plutonium are made on the almost axiomatic assumption that the effect of unit  $\alpha$ -particle dose, delivered under the same conditions to the target cells concerned, does not depend on the radionuclide from which the  $\alpha$  particles originate (apart from possible minor changes in RBE with  $\alpha$ -particle energy).

The data in Table 3 can be used to derive a quantity,  $q$  ( $\mu\text{Ci}$ ), which we can define as the skeletal content which results in some stated maximum risk rate  $R_{MPL}$ ; the value of  $q$  is then obtained from the relationship

$$q R_1 = R_{MPL} \quad (2)$$

If bone only is irradiated by the bone-seeking radionuclide, the value of  $R_{MPL}$  could be taken, for example, as the risk rate associated with the limit 5 rad yr<sup>-1</sup>, the maximum permissible dose rate set by ICRP for radiation workers. This value can be deduced from the conclusions of the UNSCEAR report<sup>36</sup> as about 0.5 cases per 1,000 per yr, and  $q$  is then given by

$$q = 0.5/R_1 \quad (3)$$

Values of  $q$  are listed in the penultimate column of Table 3 and the present ICRP values of the MPBB<sup>27</sup> in the last column. It may be noted that, in deriving  $q$ , linear dose-response relationships have been assumed on both sides of equation (2), also that the occurrence of air-sinus carcinoma in the radium series is almost certainly due to heavy  $\alpha$  irradiation resulting from trapped radon in the poorly ventilated sinus cavities, which does not happen with plutonium.

The ICRP figures are based on the MPBB of 0.1  $\mu\text{Ci}$  assigned to  $^{226}\text{Ra}$ , a value that has remained unchanged for some 30 yr. The limit 0.1  $\mu\text{Ci}$  was set by the clinical evidence of bone cancer that had occurred by the early 1940s in the comparatively large group of persons who had acquired a body content of radium. The values of the MPBB for other  $\alpha$  emitters are set by the effective energy deposited in the skeleton compared with that deposited by 0.1  $\mu\text{Ci}$   $^{226}\text{Ra}$  and the daughter elements in the  $^{226}\text{Ra}$  decay chain<sup>27</sup>. The ICRP values in Table 3 are based on a deposition of 99% of the body content of  $^{226}\text{Ra}$  and 90% of  $^{239}\text{Pu}$  in the skeleton<sup>27</sup>. Some comparison can therefore be

Table 3 Risk rates

Radionuclide	Risk rate: equilibrium no. cases per 10 <sup>3</sup> per yr for maintained skeletal content of 1 $\mu\text{Ci}$					$q$ ( $\mu\text{Ci}$ )	MPBB (ICRP) ( $\mu\text{Ci}$ )
	Leukaemia	Bone sarcoma		Carcinoma	Total		
		Trabecular	Cortical				
$^{226}\text{Ra}$	0.2	1.5	0.6	0.8	3.1	0.16	0.1
$^{239}\text{Pu}$	1.7	10.2	3.1	0.6	15.6	0.032	0.04

The values of the risk coefficients can be deduced from the data for the radium cases. In 777 cases reported by Rowland *et al.*<sup>3</sup> the mean dose to bone was 1,860 rad and the malignancies observed over 40 yr were: 51 cases of osteosarcoma and 20 cases of air-sinus carcinoma. In another analysis by Finkel *et al.*<sup>2</sup> covering many of the same cases there were several blood dyscrasias of which at least three were acceptable as myeloid leukaemias (case histories and histology seen by J. V.). For our purpose of risk calculation we have taken the perhaps arbitrary figures of four cases of leukaemia. Details of the derivation of the risk estimates for  $\alpha$  particles will be given elsewhere. The calculations are on a linear dose-response basis and allow for the power-law reduction of dose rate with time after acquisition of the radium<sup>36</sup>. The results are given in Table 2, as the equilibrium numbers of cases per 1,000 per yr for a maintained dose rate of 1 rad yr<sup>-1</sup>.

If the dose rates in Table 1 are multiplied by the corresponding risk coefficients, the risk rates to the various tissues in bone

made between the skeletal contents,  $q$ , and the MPBB values. The comparison can only be approximate because the ICRP recommendations<sup>27</sup> require that the MPBB for long-lived radionuclides, such as  $^{226}\text{Ra}$  and  $^{239}\text{Pu}$ , shall only be reached after 50 yr occupational exposure. In our calculations the values of  $q$  are the skeletal contents which, if maintained, will result in the stated risk rate by the end of an equilibration time of some 30 yr or more. Nevertheless, the general concordance between two very different approaches to determining a maximum permissible skeletal content is such that the MPBB for  $^{226}\text{Ra}$  still seems valid and that for  $^{239}\text{Pu}$  is not in need of major revision in respect of bone. If, however, more recent ICRP data<sup>22</sup> on the distribution of  $^{239}\text{Pu}$  in the body are considered (45% in bone and 45% in liver), and the liver risk can be assessed adequately, some revision of the MPBB for  $^{239}\text{Pu}$  may be necessary.

The data in Table 3 can also be used to calculate the expected number of cases if a skeletal burden of 0.04  $\mu\text{Ci}$   $^{239}\text{Pu}$  were

maintained for about 50 yr; the expectation would be about two cases of leukaemia and 13 cases of bone sarcoma per 1,000 persons so exposed. Such estimates are necessarily tentative in view of the assumptions involved; they may be too high because the dose-response relationship so far reported for  $^{226}\text{Ra}$  is non-linear and a more detailed analysis (as that by Rowland *et al.*<sup>3</sup>), might lead to much lower estimates.

## Implications and conclusions

Because, as we have shown, it is difficult to translate animal toxicity data directly to man, there is an advantage in estimating plutonium toxicity on  $\alpha$ -particle dosimetry in human bone and data on cancer induction in man by  $^{226}\text{Ra}$ . This has involved some simplifications of the very complex radiobiological problems involved. For example, we have followed the ICRP and UNSCEAR in assuming a linear dose-response relationship. Other relationships are possible and a detailed theoretical study of the consequences of adopting different dose-response formulae has been made by Mayneord and Clarke<sup>37</sup>. Any formula adopted would have to be applied to both sides of equation (2). Further, we have assumed uniform volume deposition of  $^{226}\text{Ra}$  and uniform surface deposition of  $^{239}\text{Pu}$  in the skeleton. If a linear dose-response relationship holds then non-uniformity does not affect the expectation of cancer induction; there is indeed some evidence<sup>38</sup> from the induction of bone sarcoma in mice by  $^{45}\text{Ca}$ ,  $^{90}\text{Sr}$  and  $^{226}\text{Ra}$  that tumour numbers follow the average bone dose rather than the dose in the "hot spots". It should also be noted that in the case of inhaled plutonium, and with wound contamination, the plutonium at the local site will change with time and generally the bone content and the bone dose rate will increase with time. Also the risk to cells in the marrow will arise in part from plutonium that has translocated from elsewhere and this, as in the case of Thorotrast, takes time to reach an effective level<sup>39,40</sup>.

In making our analysis we have not considered the 'hot particle' problem which is as yet incompletely resolved and which is especially important in relation to cancer risk in the lung<sup>41-44</sup>. We have some comments to make, however, which seem to be relevant in respect of the risk when only a few cells in any one organ are irradiated. Recently, Mayneord and Clarke have extended their studies of point sources of  $\beta$  particles<sup>36</sup> to the case of point sources of  $^{239}\text{Pu}$  (ref. 45), and found that a peak probability of malignant change,  $1.5 \times 10^{-10}$  per hot particle, occurs at an integrated particle activity of  $0.3 \mu\text{Ci s}$ . We find we can deduce a risk of the same order of magnitude from data on the occurrence of osteosarcoma in the long bones of the radium cases. Measurements of trabecular surface areas by Spiers *et al.* (to be published later) have shown that the incidence of osteosarcoma in segments of the long bones is proportional to trabecular surface area with an incidence over a period of some 40-50 yr, of  $2.4 \times 10^{-6}$  per  $\text{cm}^2$  of trabecular surface. Because the osteosarcoma cases represent various radium burdens, this correlation suggests a worst-case situation in which, over long periods of exposure, the endosteal surface doses approach a carcinogenic level and the outcome is proportional to the area, that is, to the number of endosteal cells put at risk. If we were to make the admittedly large extrapolation to a shell of cells surrounding a  $^{239}\text{Pu}$  hot particle of radius equal to the  $\alpha$ -particle range (35  $\mu\text{m}$  in tissue) we would get a risk of malignant change for the area concerned ( $1.6 \times 10^{-4} \text{ cm}^2$ ) of about  $4 \times 10^{-10}$  per particle.

If we accept the risk estimate of Mayneord and Clarke of  $1.5 \times 10^{-10}$  per particle and take an average lung residence time of 2 yr for insoluble particles, the particle activity for peak probability is  $0.5 \times 10^{-2} \text{ pCi}$  and the number of hot particles for one maximum permissible lung burden (MPLB) of 16,000 pCi is  $3.2 \times 10^6$ . The expectation of malignant change for one MPLB would then be  $5 \times 10^{-4}$  spread over a long period of years. If one MPLB were received annually over 50 yr the total expectation of lung cancer would be about 12 cases per 1,000, not very different from the total risk to bone and bone marrow given earlier in this article. Reservations must be made in regard

to all such calculations because no account can be taken at present of the effects of particle movement.

## Summary

Since our calculations of "maximum risk" skeletal contents for the radionuclides  $^{226}\text{Ra}$  and  $^{239}\text{Pu}$  accord well with values of the MPBBs arrived at by the ICRP in 1959 on other grounds, we conclude that the MPBB of  $0.04 \mu\text{Ci}$  for  $^{239}\text{Pu}$ , then agreed, is not in need of major revision in respect of bone. A maintained skeletal burden of  $^{239}\text{Pu}$  of  $0.04 \mu\text{Ci}$  would lead, on our calculations, to possibly two cases of leukaemia and 13 cases of bone sarcoma per 1,000 persons over about 50 yr.

Carcinoma of the air sinuses would present a very much smaller risk than bone cancer. The risk to the lung cannot be so readily evaluated because, among other uncertainties, the cells at risk and the possible movement of the sources of radiation are little understood.

The fact, however, that recent studies by Mayneord and Clarke lead to risk estimates for the lung that are of the same order as those we find for bone suggests to us that, as far as we know, the maximum permissible lung burden set by the ICRP can also reasonably be accepted.

# Quantitative assessment of carcinogenic risks associated with 'hot particles'

W. V. Mayneord

Institute of Cancer Research, University of London, UK\*

R. H. Clarke

Berkeley Nuclear Laboratories, Berkeley, Gloucestershire GL13 9PB, UK

*We have examined the hot particle problem in terms of the number of irradiated cells and the doses to which they are subjected, assuming both linear and nonlinear dose-response functions typical of those reported in the radiobiological literature. We assess the risk associated with point sources of  $\alpha$ ,  $\beta$  and  $\gamma$  activity compared with uniform irradiation, as well as the effects of fractionation of a single particle, and the change in risk if the particle moves. Finally, although the biological data are insufficient for firm estimates, we have tentatively attributed absolute carcinogenic risks in these various situations.*

THE recommendations of the International Commission on Radiological Protection assume that there is no threshold in the biological response to radiation, and that effects increase linearly with dose<sup>1</sup>. As a consequence, the average dose to an organ is a measure of carcinogenic risk, and concentration of the same energy into smaller volumes, which thereby locally sustain higher doses, leads theoretically to an identical probability of overall biological effect. The assumption of any form of dose-response relationship other than linear implies that spatial distribution of energy deposition may be important.

A special case of great theoretical and practical importance is the point source of  $\alpha$  or  $\beta$  activity, which subjects only a small fraction of the cells of an organ to very large doses. This 'hot particle' problem has become the subject of considerable controversy since Tamplin and Cochran<sup>2</sup> concluded that the associated tumorigenic risk is many orders of magnitude greater than that estimated from mean organ dose on the hypothesis of linearity. More recently, Lovins and Patterson<sup>3</sup> have questioned whether the present protection levels for  $\alpha$  emitters are adequate. The biological evidence concerning this alleged increased risk has been reviewed by Bair, Richmond and Wachholz<sup>4</sup> and also by the UK Medical Research Council<sup>5</sup>, both reports concluding that "there is at present no evidence to suggest that irradiation of the lung by particles of plutonium is likely to be markedly more carcinogenic than when the same activity is uniformly distributed".

## Theoretical model

Our fundamental assumption<sup>6</sup> is that the biological response of a single cell (that is, the probability of a relevant biological effect) is some function  $\phi(p_c D)$  of dose  $D$ , where  $p_c$  is the probability of malignant disease per cell per unit dose. The value of  $p_c$  has often been assumed constant, but is, in reality a

function of position, since the probability of effective emergence of a cell after 'transformation' may depend on local physiological and histological conditions, oxygen tension, cell contacts and the like. Indeed  $p_c$  is a function of many biological and physical variables, and for a given system may be periodic, varying during the cell cycle. Assuming, however, an overall mean value of  $p_c$ , and that the dose is spatially represented by  $D = f(x, y, z)$ , the overall expectation ( $\epsilon$ ) of malignancy in an organ or tissue may be written

$$\epsilon = \int n \phi(p_c f(x, y, z)) dV \quad (1)$$

where  $n$  is the number of cells per unit mass of tissue liable to undergo the effect.  $n$  will also probably be a complicated function of position and may also be a function of time.

The response,  $\phi(p_c D)$ , may take a variety of forms, but those of particular interest to us are the experimentally observed carcinogenic dose-response relationships. These often behave as power laws of dose at low doses, rise to a maximum in the region of a few hundred to a few thousand rads, the response then decreasing at higher doses. Many examples of this type of behaviour have been cited by UNSCEAR<sup>7</sup>, Mole<sup>8</sup> and ourselves<sup>9</sup>. The decrease in biological effect at high doses may arise for a variety of reasons ranging from loss of reproductive capacity<sup>8</sup> or 'cell death' to simple Poisson probabilities of events<sup>9</sup>. We have often used one form of response of particular importance, namely

$$\phi(p_c D) = p_c^2 D^2 \exp(-\lambda D) \quad (2)$$

as representative of a range of biological observations.

Only for uniform irradiation of an organ or tissue can we expect the observed macroscopic dose-response relationship to have the same form as the cellular dose-response function<sup>6</sup>.

## Point source $\beta$ and $\gamma$ emitters

We have integrated equation (1) using the cellular response function (2) for  $\beta$ -emitting single point sources of high and low energy<sup>6</sup>. The high energy source chosen was <sup>86</sup>Rb (91.2%, 1.78 MeV  $\beta$ ; 8.8%, 0.71 MeV  $\beta$ ), the small  $\gamma$  contribution being ignored. The low energy source was <sup>35</sup>S (100%, 0.167 MeV  $\beta$ ). For both sources, the dose-distance data tabulated by Cross<sup>9</sup> were used. The values of  $\lambda$  chosen ( $5 \times 10^{-4}$  and  $5 \times 10^{-3}$  rad<sup>-1</sup>) correspond to peaks in the dose-response function (2) at 4,000 and 400 rad respectively. The results of integration, performed numerically by computer, are shown in Fig. 1 as a function of the integrated source activity (Ci s).

When the same amount of energy is uniformly distributed throughout mass  $M$ , the corresponding expectation  $\epsilon_u$  for the same dose-response function (2) is

$$\epsilon_u = M n p_c^2 \bar{D}^2 \exp(-\lambda \bar{D}) \quad (3)$$

where  $\bar{D}$  is the mean organ dose.

\*Present address: 7 Downs Way Close, Tadworth, Surrey KT20 5DR, UK.

Fig. 1 Expectation of a malignancy from point sources of high ( $^{86}\text{Rb}$ ) and low ( $^{35}\text{S}$ ) energy  $\beta$  emitters, as a function of source activity compared with a uniform distribution of the same amount of energy through different masses  $M(\text{g})$ . The cellular response function was  $\phi(p_e D) = p_e^2 D^2 \exp(-\lambda D)$  for  $\lambda = 5 \times 10^{-4}$  and  $5 \times 10^{-3} \text{ rad}^{-1}$

The results of equation (3) are also plotted in Fig. 1, where the ordinate is not the expectation,  $\epsilon$ , but the related quantity  $\epsilon/np_c^2$ . We will return later to the evaluation of  $np_c^2$  required to transform the expectations from equations (1) and (3) to absolute values.

From Fig. 1 we see that for tissue masses of more than  $\sim 1 \text{ g}$  and for low source strengths, the point-source expectation exceeds that from uniform irradiation. At high source strengths, the opposite may be true. The mean organ dose at which the crossover occurs increases with the  $\beta$  energy of decay and decreases with increasing organ mass.

The effect of reducing the dose at which the peak in the response function occurs, that is, increasing  $\lambda$ , is to reduce greatly the single point-source expectation. During the rest of this paper, we have concentrated on the dose-response function peaking at 4,000 rad ( $\lambda = 5 \times 10^{-4} \text{ rad}^{-1}$ ) since it predicts the higher expectations.

We note that the ratio of point-source expectation to that for uniform distribution of the same amount of energy is greatest at very low source strengths, that is, for small values of absolute expectation. We see too that the point source expectation rises roughly linearly with source strength. This rather surprising result suggests that the total energy absorbed is still an important parameter.

We have next applied the theory to a mixed  $\beta$ - $\gamma$  emitter,  $^{60}\text{Co}$ , with  $\gamma$  rays of 1.17 and 1.33 MeV per disintegration and  $\beta$ -rays of 0.318 MeV. The resulting expectations are shown in Fig. 2 for a 1-kg sphere of tissue. We see that above  $10^{-1} \text{ Ci s}$  (0.12 rad), the  $\gamma$  contribution adds significantly to the single point-source expectation, so that uniform irradiation becomes more 'carcinogenic' only beyond  $10^2 \text{ Ci s}$  (120 rad to 1 kg). We note that both the absolute energy and the ratio of  $\gamma$  to  $\beta$  decay affects the mean dose at which uniform irradiation becomes more carcinogenic.

### Point source $\alpha$ emitters

The range of  $\alpha$  particles is much smaller than that for most  $\beta$ -radiation, and the resulting doses are, correspondingly,

confined to very localised volumes. The dose-distance function assumed for  $^{239}\text{Pu}$  was

$$D = 1.83 \times 10^{-6} \left( \frac{0.69}{r^2} + 7.22 \times 10^4 \right) \text{ rad per disintegration} \quad (4)$$

(J. R. Harvey, personal communication) where  $r$  is the distance from a point source, if less than the assumed mean range of the three  $^{239}\text{Pu}$   $\alpha$ -particles ( $r \leq 35.5 \mu\text{m}$ ). The results of integrating equation (1) for a single point source of varying strength, using the response function (2) peaking at 400 and 4,000 rad respectively, are shown in Fig. 3, together with the results for uniform distribution of the same amount of energy throughout 1 g of tissue.

Again we see that at very low source strengths there is an increased relative risk from a single point source of  $^{239}\text{Pu}$  compared with uniform irradiation. At higher source strengths the expectation falls more steeply than with a  $\beta$ -particle source because of the assumed form of the  $\alpha$  dose-distance function. Uniform irradiation becomes more carcinogenic beyond about  $3 \times 10^{-6} \text{ Ci s}$  for response functions peaking at 4,000 rad and beyond  $3 \times 10^{-7} \text{ Ci s}$  for those peaking at 400 rad. The effect of changes of value of  $\lambda$  in equation (2) are thus even more marked for  $\alpha$  sources than  $\beta$  emitters.

From Fig. 3 we see that, for a point source, at  $\geq 10^{-6} \text{ Ci s}$  'cell killing' predominates even for the smaller value of  $\lambda$ . One may question the use of our homogeneous dose function, when individual cells have highly ionising tracks passing through a small fraction of their volume. The detailed pattern of distribution of energy loss from an  $\alpha$  particle passing through a single cell may be important<sup>6</sup>, and the stochastic methods of microdosimetry developed by Rossi and Kellerer<sup>10</sup> may be more appropriate. We note, however, that our model suggests a peak expectation at about the same integrated source strength as predicted recently by Bair *et al.*<sup>11</sup> on a stochastic basis assuming one  $\alpha$ -particle traversal per cell.

We also note that our absolute estimates (below) of risk are of the same order as that deduced by Spiers and Vaughan<sup>12</sup> for the case of small numbers of cells subject to the risk of osteogenic sarcoma.

Fig. 2 Expectation in 1 kg of tissue from a point source of  $^{60}\text{Co}$  compared with a uniform distribution of the same amount of energy for a cellular response  $\phi(p_e D) = p_e^2 D^2 \exp(-0.5 \times 10^{-3} D)$

Fig. 3 Expectation from a point source of  $^{239}\text{Pu}$   $\alpha$  particles as a function of source activity compared with that from uniform irradiation of 1 g of tissue by the same amount of energy using a cellular dose-response function  $\phi(p_c D) = p_c^2 D^2 \exp(-\lambda D)$  for  $\lambda = 5 \times 10^{-4}$  and  $5 \times 10^{-3} \text{ rad}^{-1}$ .

### Fractionation of single point sources

Figure 4 shows the results of breaking up a single  $^{239}\text{Pu}$   $\alpha$ -emitting 'hot particle' into as many as  $10^8$  smaller particles, keeping the mean organ dose constant. We see that there is a maximum expectation when each particle activity approaches that corresponding to the peak of the single point source results of Fig. 3. Further fractionation decreases the expectation, since the differential coefficient of the single point source expectation, with respect to source strength  $< 10^{-7} \text{ Ci s}$ ,

Fig. 4 Expectation in a large mass of tissue for a given organ burden of  $^{239}\text{Pu}$  fractionated to varying numbers of independent sources. The cellular response function peaked at 4,000 rad.

is  $> 1$ . The maximum expectation increases roughly linearly with increasing mean organ dose.

Figure 5 shows the results of fractionation of the single  $\beta$ -emitting point source using the response function peaking at 4,000 rad. For the  $^{86}\text{Rb}$  point source, at low mean organ doses, the effect of increasing the number of sources while keeping the organ burden constant, is to reduce the risk. Above  $\sim 10 \text{ Ci s}$  (4 rad to 1 kg) there is a 'pessimism' number of particles. At higher doses significant dose overlapping occurs between sources. When the  $^{35}\text{S}$  single point source is fractionated, the expectation is increased for mean doses of more than  $3 \times 10^{-4} \text{ rad to 1 kg}$  ( $10^{-2} \text{ Ci s}$ ). We note the four orders of magnitude lower mean organ dose at which fractionation becomes important for the low, as compared with the high-energy  $\beta$  emitter.

### Moving point sources of $^{239}\text{Pu}$

As our model is assumed to be independent of dose rate, the problem of a moving point source is essentially that of a line source. We have previously presented a theoretical model for such  $\beta$  sources<sup>6</sup> and have now performed similar integrations for a  $^{239}\text{Pu}$   $\alpha$ -point source moving various distances through tissue. Neglecting end effects, the expectation for a source strength  $S_L$  per unit length (that is the integrated source strength/velocity of travel) is shown in Fig. 6. We see that a high source strength moving with high velocity can be equivalent in expectation to a low source strength at low velocity.

Fig. 5 Expectation in a large mass of tissue as a function of the number of discrete sources for a given organ burden of a high ( $^{86}\text{Rb}$ ) and low ( $^{35}\text{S}$ ) energy  $\beta$  emitter, assuming  $\phi(p_c D) = p_c^2 D^2 \exp(-0.5 \times 10^{-3} D)$ .

These results again merely reflect the fact that the significant contributions to expectation originate largely from a narrow dose band around the maximum of the dose-response curve.

### Absolute values of expectation

The basic problem<sup>8</sup> lies in attempting to quantify  $p_c$ , the probability of transformation per cell per rad. We know that for a range of human body organs the risk of carcinogenesis is between  $\sim 0.1\%$  and  $1\%$  per 100 rad, for doses in the region of a few hundred rad (ref. 13). If a typical value of  $0.5\%$  per 100 rad be assumed, on the basis of a linear hypothesis the pro-

Fig. 6 Expectation from a moving point source of  $^{239}\text{Pu}$  using a cellular response function,  $\phi(p_c D) = p_c^2 D^2 \exp(-0.5 \times 10^{-3} D)$ .

bability per tissue ( $p_t$  | linear) is

$$(p_t | \text{linear}) = 5 \times 10^{-5} \text{ rad}^{-1}$$

On a dose-squared hypothesis, using equation (2) and ignoring the exponential term at the normalisation dose of 100 rad

$$(p_t | \text{square}) = 7.1 \times 10^{-4} \text{ rad}^{-1}$$

Assuming an organ of mass  $M$  with  $n$  cells per unit mass it is easy to show that

$$(p_c | \text{linear}) = (p_t | \text{linear}) / Mn$$

$$(p_c | \text{square}) = (p_t | \text{square}) / (Mn)^{1/2}$$

For a 1-kg organ containing  $\sim 10^9$  cells per unit mass, we find

$$n(p_c | \text{square})^2 = 5 \times 10^{-10} \text{ g}^{-1} \text{ rad}^{-1}$$

On the linear hypothesis the value is

$$n(p_c | \text{linear}) = 5 \times 10^{-8} \text{ g}^{-1} \text{ rad}^{-1}$$

We note that normalisation at a higher dose would reduce the estimate of  $n(p_c | \text{square})^2$ .

Respirable 'hot particles' often have activities in the range 10 pCi–100 nCi. Let us assume a mean residence time in the lung of  $10^8$  s ( $> 3$  yr). The results then obtained for a single point source of  $^{86}\text{Rb}$  and  $^{35}\text{S}$  are shown in Table 1, where it is seen that the absolute expectation for a high energy  $\beta$  emitter ( $^{86}\text{Rb}$ ) from a point source using the square-law response function is essentially the same as that predicted by the linear hypothesis using mean organ dose. For a low energy  $\beta$  emitter (here  $^{35}\text{S}$ ), at higher source strengths, assumed linearity leads to higher values of the absolute predicted risks.

If the results were evaluated for 1 g of tissue, we should raise both  $n(p_c | \text{linear})$  and  $n(p_c | \text{square})^2$  by a factor of  $10^3$ . In Table 1 the mean organ doses and absolute expectations would also increase by a factor of  $10^3$ .

When fractionation is considered, at organ burdens  $< 10$  Ci s the  $^{86}\text{Rb}$  effects are reduced, so the use of mean organ doses and linearity overestimates risks. For  $^{35}\text{S}$ , however, fractionation increases expectation: at 10 Ci s an increase of  $10^3$  in expectation is seen on the square-law response. The effect of this on the  $^{35}\text{S}$  expectations in Table 1 is to bring the linear hypothesis and power-law estimates into close agreement.

The results for absolute expectations associated with stationary sources of  $^{239}\text{Pu}$   $\alpha$  particles are shown in Table 2. Since the single point-source results apply only at very low mean organ dose ( $< 10^{-6}$  Ci s  $= 3 \times 10^{-6}$  rad  $\text{kg}^{-1}$ ), expectations have been quoted for the distribution of activity leading to peak expectation following fractionation (Fig. 4). We see that

Table 2 Comparison of absolute expectation from  $^{239}\text{Pu}$   $\alpha$ -point sources fractionated to give peak expectation with the cellular response function  $\phi(p_c D) = p_c^2 D^2 \exp(-0.5 \times 10^{-3} D)$ , and that predicted by linearity for a 1-kg organ and a given incidence of 0.5% at 100 rad

Integrated activity (Ci s)	$D$ to 1 kg (rad)	Absolute expectation	
		Peak value, nonlinear response	Linear response
$10^{-7}$	$3 \times 10^{-7}$	$7.5 \times 10^{-11}$	$1.5 \times 10^{-11}$
$10^{-3}$	$3 \times 10^{-3}$	$7.5 \times 10^{-7}$	$1.5 \times 10^{-7}$
$10^{-2}$	$3 \times 10^{-2}$	$7.5 \times 10^{-6}$	$1.5 \times 10^{-6}$
$10^{-1}$	$3 \times 10^{-1}$	$7.5 \times 10^{-5}$	$1.5 \times 10^{-5}$
$10^0$	$3 \times 10^0$	$7.5 \times 10^{-4}$	$1.5 \times 10^{-4}$
$10^1$	$3 \times 10^1$	$7.5 \times 10^{-3}$	$1.5 \times 10^{-3}$

for virtually all source strengths of interest in radiological protection, the peak of absolute expectation predicted by the power-law response is a factor of  $\sim 5$  above the value estimated by using mean organ doses and linearity. To obtain such expectations it has been necessary to choose circumstances when the  $^{239}\text{Pu}$   $\alpha$  energy is distributed in such a way that the largest number of cells are exposed to doses in the region of the peak of the dose-response curve.

The moving  $\alpha$ -particle source results from Fig. 6 have been transformed into absolute expectations in Table 3. Once again the use of linearity and mean organ doses predicts expectations

Table 1 Comparison of absolute expectation from a single point source of  $^{35}\text{S}$  or  $^{86}\text{Rb}$  in a 1-kg organ, as predicted using cellular responses  $\phi(p_c D) = p_c^2 D^2 \exp(-0.5 \times 10^{-3} D)$  and  $p_c D$  (linearity) using different values of  $p_c$  derived for each response function assuming a given incidence of 0.5% per 100 rad

Nuclide	Integrated activity (Ci s)	$\epsilon / np_c^2$ (Fig. 1)	$D$ to 1 kg (rad)	Absolute expectation

in excess of those for the power-law response except when the source strength per unit length (or source strength/velocity) is at the peak of the curve in Fig. 6 (at  $\sim 10^{-4}$  Ci s cm $^{-1}$ ), when the power law predicts slightly higher expectations than the linear hypothesis. This is true for any combination of source strengths, velocities and distances, which again reflects the fact that peak expectations arise from the power-law response when the greatest number of cells are exposed to doses near the peak of the dose-response curve.

## Conclusions

We have estimated carcinogenic expectations by integrating nonlinear peaked cellular dose-response functions over spatially varying dose distributions and contrasted them with the expectations predicted by the linear hypothesis. If the dose-response function is peaked, then it is noticeable that the relative expectation is largely controlled by cells receiving doses in the vicinity of the peak. Thus, whether the relative maximum expectation arises from uniform irradiation, from a single point source, from a 'pessimum' number of 'hot particles', or during relative motion of the source, depends on the energy absorbed being distributed so as to subject the largest number of cells to doses near the peak of the response curve.

When we estimate absolute values of expectation, however, the use of the mean organ dose and the assumption of a linear non-threshold dose-response function seems to give a good guide to the upper limit of absolute expectation predicted

even for a peaked nonlinear function. Linearity can be very conservative for small numbers of  $\alpha$ - or low energy  $\beta$ -emitting sources, while at worst it seems unlikely to underestimate risks by more than a factor of  $\sim 5$  for those exceptional distributions of activity which lead to maximum expectations. The circumstances in which the 'hot particles' are relatively more dangerous are those in which the absolute risks are low.

An underestimation of the risk on assuming linearity would be most likely to occur if there was a high power-law response (say,  $D^4 \exp(-\lambda D)$ ) fitting the linear response at low doses ( $< 100$  rad) and the response peaking in the region of 10,000 rad rather than between 100 and 1,000 rad.

# Aspects of the dosimetry of plutonium in bone

M. C. Thorne

Medical Research Council, Radiobiology Unit, Harwell, Didcot, Oxfordshire OX11 0RD, UK.

*After animals have been exposed to plutonium it eventually becomes distributed unevenly throughout the bone tissue. There is therefore a need to study the dosimetry of plutonium, particularly  $^{239}\text{Pu}$ , as a function of its depth of burial in bone. This article discusses a simple approach to the problem, and the magnitude of some of the possible errors involved.*

PLUTONIUM is deposited primarily on the endosteal surfaces of cortical and trabecular bone<sup>1</sup> although a certain amount is also found on periosteal surfaces. After deposition the plutonium gradually moves into the volume of bone mainly by

becoming buried under newly deposited bone mineral<sup>1</sup>. Thus, at times long after a single intravenous injection, the distribution of plutonium in bone will typically consist of a thin layer of the element some distance below the endosteal surface together with a diffuse distribution between that layer and the endosteal surface.

Endosteal surfaces are defined here as the mineral bone surface of all marrow cavities and haversian canals; that is, the interface between mineralised bone and non-mineralised osteoid. Thus, if the skeleton contains  $1 \mu\text{Ci}$  of  $^{239}\text{Pu}$  and if  $A \text{ m}^2$  is the total area of endosteal surface, then  $1/A \mu\text{Ci}$  of the radionuclide will be associated with each  $\text{m}^2$  of the surface, if deposition on periosteal surfaces is neglected. If the plutonium is buried a distance,  $d \mu\text{m}$ , below the endosteal

Errors are 1 s.d. statistical errors arising from the limited number of Monte Carlo iterations used.

surface then the dose rate,  $D_s(q, d)$  to an endosteal tissue layer of thickness  $q$   $\mu\text{m}$  will be given by

$$D_s(q, d) = I \times E_\alpha \times 51.2 \times k(q, d) / Aq \rho \text{ rad d}^{-1} \quad (1)$$

where  $E_\alpha$  is the energy of the  $^{239}\text{Pu}$   $\alpha$  emission in MeV,  $\rho$  is the density of soft tissue, which may be taken as  $1 \text{ g cm}^{-3}$ , and  $k(q, d)$  is the average fraction of that energy absorbed in an endosteal tissue layer of  $q$   $\mu\text{m}$  thickness if the decay occurs  $d$   $\mu\text{m}$  below the endosteal surface.

It is usual to define  $D_{\text{BONE}}$  as the average dose rate to an infinite extent of mineral bone contaminated at a level of  $I/M \text{ } \mu\text{Ci g}^{-1}$ ,  $M$  being the mass of mineral bone in grams. Thus

$$D_{\text{BONE}} = 51.2 \times I \times E_\alpha / M \text{ rad d}^{-1} \quad (2)$$

From equations (1) and (2) it can be seen that

$$D_s(q, d) / D_{\text{BONE}} = Mk(q, d) / Aq \rho \quad (3)$$

For man,  $M$  may be taken as 5,000 g, since the evidence suggests that bone mineral comprises about 7% of the total adult body weight<sup>2</sup>. The value of  $A$  has been variously estimated at 14.0 (ref. 2), 12.5 (J. M. Marshall *et al.*, unpublished) and 16 m<sup>2</sup> (F. W. Spiers, personal communication). I shall take  $A$  at 12.5 m<sup>2</sup> in accordance with the results presented by Marshall (unpublished), but it should be emphasised that this is an estimate, and that the true mean for a particular occupationally exposed population could easily differ from this by as much as 25%.

Inserting these values into equation (3) gives

$$D_s(q, d) / D_{\text{BONE}} = 400k(q, d) / q \quad (4)$$

The value of  $k(q, d)$  has been calculated using Monte Carlo techniques under two simplifying assumptions: first, that bone

surfaces are essentially flat over distances comparable with the range of an  $\alpha$  particle in tissue; second, that the surfaces are sufficiently far apart for cross-fire to be neglected. Decays were originated at a distance  $d$   $\mu\text{m}$  below the endosteal surface, and emission directions were chosen at random to yield an isotropic decay distribution. Using a modified form of the Bragg equation the rate of energy loss along each of the randomly chosen tracks was evaluated and the fraction of energy deposited in the first  $q$   $\mu\text{m}$  above the endosteal surface was thus determined.

Fig. 1 Relationship between the dose rate to the endosteal layer and the depth of burial of plutonium in bone mineral.

A considerable amount of approximation was involved in determining the rate of energy loss along each track. For soft tissue the form of the Bragg equation was taken from Harley and Pasternak<sup>3</sup> except that an  $\alpha$ -particle shielding correction was used at energies less than 2 MeV, in order that the calculated values of stopping power in this energy range were in agreement with those tabulated by Walsh<sup>4</sup>. That gave a  $^{239}\text{Pu}$   $\alpha$ -particle range in soft tissue of 37  $\mu\text{m}$ . The same Bragg equation was used for mineralised bone, except that, at all  $\alpha$ -particle energies, the stopping power was multiplied by a constant,  $C$ , given by

$$C = (\rho_{\text{BONE}} / \rho_{\text{SOFT TISSUE}}) (SP_{\text{BONE}} / SP_{\text{SOFT TISSUE}}) \quad (5)$$

The value for  $\rho_{\text{BONE}}$ , the density of mineral bone, was taken to be  $1.95 \text{ g cm}^{-3}$  (ref. 2) and that of  $\rho_{\text{SOFT TISSUE}}$  was taken as unity. The ratio of the mass stopping power of soft tissue,  $SP_{\text{SOFT TISSUE}}$  to the mass stopping power of bone,  $SP_{\text{BONE}}$ , is not well known. It has been estimated at 1.225

Table 2 Values of  $D_A(d) / D_{\text{BONE}}^*$ 

$d(\mu\text{m})$	0	1	2	3	4	5	6	7	10	15	20	25

\*Errors are statistical errors from the number of Monte-Carlo iterations used.

(ref. 5) and 1.41 (J. M. Marshall, unpublished), depending on the degree of calcification assumed. The ratio is taken here as 1.3, but that value could easily be in error by as much as 10%. It is for this reason that the same Bragg curve has been used for both mineral bone and tissue, since any difference depending upon the different elemental composition of mineral bone and soft tissue would be small compared with the estimated systematic error of 10%.

Using the Monte Carlo calculations  $k(q, d)/q$  was calculated for various values of  $q$  and  $d$  (Table 1).

If  $q$  is taken as 10  $\mu\text{m}$ , a value suggested<sup>6</sup> for evaluating the dose to cells on endosteal surfaces, it can be seen from Fig. 1 that the relationship between the dose rate to the endosteal layer and the depth of burial of the plutonium is slightly curvilinear. Over a range of depths of burial from 2  $\mu\text{m}$  to 20  $\mu\text{m}$  this curvilinear relationship may, however, be closely approximated by a straight line. Thus, for plutonium distributions in which the bulk of the plutonium lies within this range, the average depth of burial may be used to calculate the average endosteal dose.

The methods described here have also been used to calculate the average dose rate to active red bone marrow from plutonium buried at different depths in mineral bone. In the adult human, active red bone marrow is primarily associated with the trabecular marrow spaces, and is estimated to have a mass of 1,500 g (ref. 2). If  $I_T \mu\text{Ci}$  of  $^{239}\text{Pu}$  are associated with trabecular bone and  $I_C \mu\text{Ci}$  are associated with cortical bone, then the average dose rate to active red bone marrow,  $D_A(d)$ , from  $^{239}\text{Pu}$  buried a distance  $d \mu\text{m}$  below the endosteal surface is given by

$$D_A(d) = 51.2 I_T E_a k(q_A, d) / 1,500 \text{ rad d}^{-1} \quad (6)$$

where  $q_A$  is a value of  $q$  greater than the range of  $^{239}\text{Pu}$   $\alpha$  particles in soft tissue. Since

$$D_{\text{BONE}} = 51.2(I_C + I_T)E_a/5,000 \text{ rad d}^{-1} \quad (7)$$

It follows that

$$D_A(d)/D_{\text{BONE}} = (10/3)(I_T/(I_C + I_T))k(q_A, d) \quad (8)$$

If  $^{239}\text{Pu}$  is uniformly distributed over all endosteal surfaces, then  $I_C$  will be approximately equal to  $I_T$ , since the endosteal areas of cortical and trabecular bone are approximately equal<sup>3</sup>. Under this assumption

$$D_A(d)/D_{\text{BONE}} = (5/3)k(q_A, d) \quad (9)$$

Values of  $D_A(d)/D_{\text{BONE}}$  calculated according to this formula are given in Table 2 for various depths of burial. It should be noted that if the plutonium forms a thin layer exactly on endosteal surfaces then, by simple geometric arguments,  $k(q_A, 0) = 0.5$  and  $D_A(0)/D_{\text{BONE}} = 0.83$ .

# Neutralised colliding beam torus

R. M. Kulsrud & D. L. Jassby

Plasma Physics Laboratory, Princeton University, Princeton, New Jersey 08540

*We describe a new type of deuterium-tritium fusion reactor, consisting of two dense oppositely-directed D and T plasma components confined in a torus. These components can be formed by neutral-beam injection at moderate energies. The reactor could have significant power gain with relatively lenient plasma confinement requirements.*

EXPERIMENTS over the past few years have demonstrated that a deuterium plasma at temperatures of  $\sim 1$  keV can be stably produced and confined in a torus. These experiments, which are directed toward producing a self-sustained controlled thermonuclear reactor, involve temperatures within one order of magnitude of practical reactor values. It is now reasonable to take seriously other proposals for toroidal devices, not necessarily self-sustained, which could conceivably be constructed sooner and which could produce net power.

## Two-component torus

One such possibility, which has been generally accepted as feasible, is the two-component torus (TCT)<sup>1-4</sup>. One component of the TCT is a cold tritium plasma (T), which serves as the target for the other component, an energetic confined beam of deuterons (D). The optimal deuteron injection energy is 150-200

keV (somewhat above the peak of the nuclear cross section) to increase the total probability of fusion, integrated over the deceleration of the deuterons by Coulomb interactions with the tritons and the neutralising plasma electrons. If the electron temperature is  $\gtrsim 5$  keV, it can easily be shown that the fusion power output exceeds the beam power injected into the plasma<sup>1-4</sup> (although the electrical power output is still less than the beam power). The electron temperature is maintained against transport and radiation losses by energy transfer from the energetic deuterons. The critical confinement of the electron energy and of the fast deuterons in such a device can be an order of magnitude poorer than confinement times required for a conventional self-sustaining reactor<sup>1-4</sup>, and plans are well advanced to build a prototype TCT.

## Colliding beam torus

Here we discuss another type of beam-driven toroidal reactor. We envisage a toroidal plasma in which the D and T ion components both have substantial energies,  $\sim 40$  keV, but move in opposite directions. The ion distributions are maintained by oppositely directed neutral beams of D and T which are injected into the torus and trapped by ion impact, charge exchange, and electron ionisation in the already-existing plasma of energetic D and T components (in steady state). Because of the opposite velocities of the D and T, the relative collision energy is nearly 4 times the energy of each beam, so that it is above the peak of

the D-T cross section ( $\sim 120$  keV). This is analogous to using colliding beams in high energy particle accelerators, but with plasmas the densities can be made much larger by continual trapping of the beams in the torus, and collisions occur throughout the entire volume of the torus. We estimate that densities  $\sim 5 \times 10^{13} \text{ cm}^{-3}$  may be achieved for realistic toroidal parameters with a few neutral-beam sources of already available types.

We denote the concept of two energetic colliding components as the 'colliding beam torus' or CBT. Its primary advantage over the TCT is the lower beam voltage required. Highly efficient generation of 40-keV neutral beams is already possible, while efficient generation of 150-keV beams is still in an embryonic state. Another advantage of the CBT is that the number of electrons per energetic ion is lower, so that the same electron temperature may be achieved with even poorer confinement of the electron energy than required by the TCT. The lower temperature and injection energy result in smaller plasma size.

### Model of the CBT

Let us consider how the CBT plasma may be set up. To trap the injected neutral beams, one must initially have a conventionally formed target plasma in the torus. Injection of the neutral D and T beams into the plasma must gradually replace the cooler plasma with the two energetic components, and finally, as the energetic components themselves slow down on the neutralising background of electrons, the lower energy parts of the beams must be removed much faster than the more energetic parts of the beams. We require that there be very few impurity ions in the torus, since impurities enhance angular scattering of the energetic ions, thereby destroying their directedness. More precisely, we hypothesise that first, the initial target plasma leaves and does not return, second, the plasma remains very pure, and third, the low energy ions leave much faster than the high energy ions. In our calculations on the CBT, we neglect entirely the loss of ions with energies  $W > 2T_e$ , and assume that the loss rate for  $W < 2T_e$  is constant, with a half life  $\tau$ . Under these hypotheses, we show by detailed calculations that the CBT situation can actually be maintained in steady state by beam injection at moderate energies. Further, we show that the resulting fusion power is quite favourable, relative to the injected-beam power, and that the energy confinement requirements are quite moderate. We indicate that the colliding plasma components can be formed by neutral injection without undue losses. Finally, calculations show that the CBT is stable to velocity-space instabilities.

There is some experimental evidence that our hypotheses can be realised. Experiments in the ATC tokamak show that, by gettering the walls, plasma leaving the torus can be captured<sup>5</sup>. The remaining plasma is very pure, and its density will decay nearly to zero, as required for the initial background plasma of the CBT. Similar results have been obtained in Alcator by special discharge cleaning<sup>6</sup>. We hope that similar effects could be produced in larger devices by efficient divertors. Further, beam injection into several tokamaks has been carried out, and the loss time of beam ions is found to be much larger than that of the thermal plasma<sup>7-9</sup>. Presumably, the losses are produced by micro-instabilities, and small-scale irregularities affect slow ions more than fast ions.

### Calculations

Consider an homogeneous plasma of D and T ions and an equal density of electrons in a uniform magnetic field,  $\mathbf{B}$ . Let the electrons have a Maxwellian distribution with temperature  $T_e$  determined by energy balance. Let there be equal monochromatic sources  $S/2$  of D and T at  $+v_{20}\mathbf{B}/|\mathbf{B}|$  and  $-v_{30}\mathbf{B}/|\mathbf{B}|$  respectively, and let both ion species be uniformly lost for energies  $< 2T_e$  at a rate  $\tau^{-1}$ . Then, for any  $T_e$ , a uniform steady state will be reached under the influence of D-T, D-e, and T-e

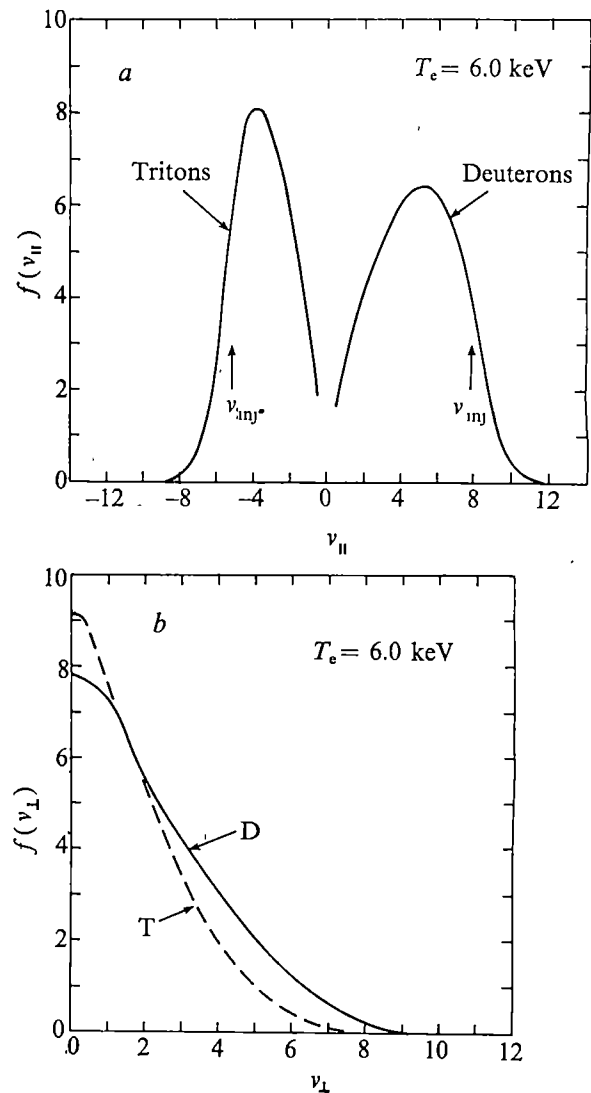

Fig. 1 Steady-state ion velocity distribution functions (a) parallel and (b) in a direction,  $\mathbf{x}$ , perpendicular to  $\mathbf{B}$ . The velocity scale is in  $(\text{keV})^{1/2}$  for the deuterons only. Injection velocities are indicated by  $v_{inj}$ ,  $n_T/n_D = 0.92$ .

Coulomb collisions. To determine the resulting three-dimensional distribution functions in velocity space for D and T,  $f_2(v_2)$ ,  $f_3(v_3)$ , we solve two simultaneous Fokker-Planck equations numerically, using one of the standard codes suitably modified to include two species of ions<sup>10</sup>. The finite size of the torus is simulated by an energy loss rate  $\tau_E^{-1}$  produced by thermal conductivity, radiation, and so on. The electron temperature  $T_e$  is determined by a power balance between the rate of energy gain by D-e and T-e collisions and the loss rate  $\tau_E^{-1}$ . In steady-state conditions

$$\frac{dT_e}{dt} = C_2(W_2 - 3/2T_e) + C_3(W_3 - 3/2T_e) - T_e/\tau_E = 0 \quad (1)$$

where  $W_2$  and  $W_3$  are the mean D and T energies, and  $C_2$  and  $C_3$  are constants. We use equation (1) to determine the  $\tau_E$  required to achieve a given  $T_e$ . Since  $\tau$ , the time constant for cool-ion loss, is somewhat arbitrary, we can make  $\tau_E$  and  $\tau$  equal. (The results are, however, relatively insensitive to  $\tau/\tau_E$  in the range 0.5–2.0.)

The resulting distribution functions for  $T_e = 6.0$  keV are shown in Figs 1 and 2 for injection energies  $W_{20} = 60$  keV for D and  $W_{30} = 40$  keV for T. Figure 1a shows the distribution of the parallel component of D and T and Fig. 1b the distribution

in the cartesian component  $v_x$ , where  $x$  is perpendicular to  $\mathbf{B}$ . Figure 2 shows the contours of the axisymmetric three-dimensional distribution functions in coordinates  $v_{||}$  and  $v_{\perp}$ , and we see that two oppositely moving axisymmetric ion components are formed. Further, the relative velocities in each beam are small, so that self-collisions dominate and the two components have, approximately, shifted Maxwellian distributions. Although the distribution in pitch angle  $\mu \simeq \tan^{-1}(v_{\perp}/v_{||})$  is not negligible, angular spread does not disturb the oppositely directed character of the two beams.

### Power generated

To find the relative gain in fusion power to beam power, we compute the ratio

$$Q = \frac{E_r}{0.5S(W_{20} + W_{30})} \int f_2(\mathbf{v}_2) f_3(\mathbf{v}_3) \sigma_{DT} \times \quad (2)$$

$$\times \sigma_{DT}(|\mathbf{v}_2 - \mathbf{v}_3|) |\mathbf{v}_2 - \mathbf{v}_3| d\mathbf{v}_2 d\mathbf{v}_3$$

where  $\sigma_{DT}$  is the D-T nuclear fusion cross section, and  $E_r \equiv 17.6$  MeV is the energy released per fusion. The results are given as a function of  $T_e$  in Fig. 3a. In Figure 3b we give the

Fig. 2 Steady-state contours of the ion speed distribution function in DT. The deuterons (a) are injected at 60 keV,  $\theta = 4^\circ$ , and the tritons (b) at 40 keV,  $\theta = 176^\circ$ .  $f(\mathbf{v})$  is normalised to the value at the source. Ions decelerated to energies  $< 2T_e$  are assumed to have a lifetime  $\tau \simeq \tau_E$ , as given in Fig. 3b. Velocity units are relative.

Fig. 3 a, Fusion energy gain  $Q$  of the CBT for steady-state operation in DT (17.6 MeV per reaction) b, The confinement parameters ( $n_e \tau_E$  and  $n_e \tau_h$ );  $\tau_h$  is the total lifetime of injected ions,  $\tau_E$  is the electron energy confinement time, as well as the lifetime of ions after deceleration below  $2T_e$ .

confinement parameter  $n_e \tau_E = n_e \tau$  required for these  $T_e$ . It is seen that  $Q$  is larger than unity for electron temperatures in excess of 3.5 keV, and that the required  $n_e \tau_E$  for 'breakeven' is  $1.5 \times 10^{12} \text{ s cm}^{-3}$ . The  $Q$  values for the TCT are given for comparison. Also shown is  $\tau_h = (n_2 + n_3)/S$ , the required lifetime of the energetic ions; this value is appreciably larger than  $\tau_E$ .

In order that the reactor have net electrical power output,  $Q$  must satisfy the relationship  $Q > (\eta_b \eta_i)^{-1} - 1$ , where  $\eta_b$  is the efficiency of neutral-beam production, and  $\eta_i$  is the energy conversion efficiency in the blanket cooling system. Taking  $\eta_i = 0.35$ , and  $\eta_b = 0.7$  (which is quite feasible for low-energy beams<sup>21</sup>), we require  $Q > 3.0$ , so that  $T_e \geq 8.5$  keV, and  $n_e \tau_E \geq 1.3 \times 10^{13} \text{ cm}^{-3} \text{ s}$  (Fig. 3). A practical power producer may have to operate at somewhat larger values of  $n_e \tau_E$ . These conditions can, however, be greatly relaxed if a fissionable blanket is used, and even at  $Q \simeq 1$ , the device could be useful as a fusion test reactor.

In this analysis, we have neglected the effect of 3.5-MeV alpha particles resulting from fusion. Confined alphas will give up their energy almost entirely to the electrons, thereby allowing the same  $T_e$  to be obtained with a smaller  $n_e \tau_E$ . The required  $n_e \tau_E$  is reduced from the value in Fig. 3 by the factor  $(1 + 0.2\alpha Q)^{-1}$ , where  $\alpha$  is the fraction of alphas that slow down in the plasma.

### Plasma formation and stability

We now consider the formation of the energetic-ion distributions. Neutral beams of D and T are injected into the torus, and ionised. The relative velocity of the incoming D beam is small compared with the  $D^+$  velocity, so that charge exchange on  $D^+$  and ion impact ionisation on  $T^+$  are probably about equal. Charge exchange leads to an energetic secondary neutral of roughly half the energy of the injected neutral. Its loss would

reduce the efficiency of beam trapping by 25%, but estimates show there is a good chance that it too will be trapped by ion impact. Thus, the efficiency of trapping is probably reduced by not more than 10%.

The stability of the CBT plasma has been examined against homogeneous electromagnetic and electrostatic waves. We approximate the equilibrium by two shifted Maxwellian distribution of identical ions. We find stability against all electrostatic instabilities not in the neighbourhood of the ion cyclotron frequency, if the random temperature of each beam exceeds  $T_e/2$ , a criterion well satisfied by the CBT distribution functions. Thus the CBT is stable against the two-stream instability. The analysis of electrostatic instabilities near the ion cyclotron frequency is more complex, but detailed calculations indicate that the CBT is stable against both electrostatic and electromagnetic waves in this frequency range (F. W. Perkins, unpublished). Finally, a simple analysis approximating the beams by delta functions indicates stability against all electromagnetic modes not near the cyclotron frequency if the plasma energy density is smaller than the energy density of the confining magnetic field—a condition always satisfied. It appears, therefore,

that the steady-state CBT system is stable to all velocity-space modes.

We thank Y. C. Sun for carrying out the numerical Fokker-Planck calculation. We thank Dr H. P. Furth for many stimulating discussions, and also acknowledge helpful conversations with Drs H. L. Berk, J. Ostriker, and F. W. Perkins. This work was supported by US Energy Research, and Development Administration.

## Anti-correlated hard and soft X-ray intensity variations of the black-hole candidates Cyg X-1 and A0620–00

EXTENDED spectral measurements are now available at more than one time epoch for the powerful Monoceros transient, A0620–00, discovered by Elvis *et al.*<sup>1</sup>, and the binary source Cyg X-1. We here point out a basic similarity in the unusual spectral time variations of these sources. Both are black-hole candidates, Cyg X-1 by virtue of its orbital dynamics and A0620–00 as suggested by arguments based on the Eddington limit<sup>1</sup> and distance estimates of the optical counterpart. Thus the X-ray emission mechanism could be common.

The type of data obtained by the Ariel V satellite are summarised in Table 1. All the detectors use some form of spin modulation to eliminate background. In particular, measurements with the ST detector are made at two directions offset from the source position given by the RMC. The observed phase of the modulation is then used to confirm that the signal is being correctly detected.

Observations at a few keV indicate that Cyg X-1 switches between two states: a normal state at a low intensity, the

'low state', and an enhanced or 'high state'. Around 1975 May 9 a 'high' to 'low' transition was observed (see ref. 2). Figure 1 shows ST data for the 'high' state taken during May 4–10 and for the 'low' state during May 11–15. The error bars correspond to 1 s.d., determined by counting statistics, which dominates calibration and other systematic errors. Also shown are the CPC data given in ref. 2 for the 'high' and 'low' state. Note that while below ~ 7 keV the 'high' state indeed corresponds to a higher intensity, the change in intensity at higher energies, extending out to at least 150 keV, is in the opposite sense. During the 'low' state a power law

$$\frac{dN}{dE} = 3.3 E^{-1.81} \text{ photons cm}^{-2} \text{ s}^{-1} \text{ keV}^{-1}$$

(dashed line) represents most of the data, while during the 'high' state, a more complicated spectral form is required.

Qualitatively similar time variations are noticed for A0620–00, both within a restricted low-energy range during the initial turn-on (Ricketts *et al.*<sup>3</sup>), and now over a much wider energy range, as indicated by the ST observations during the decay phase. Figure 2 shows spectra at two epochs.

Table 1 Ariel V data

Detector and abbreviation	Area (cm <sup>2</sup> )	Detector axis tilt to satellite spin axis	Energy range (keV)	Institute and reference
CsI scintillator telescope (ST)	8	3°	26–1200	Imperial College Space Physics Group
Rotation modulation collimator (RMC)	102	0°	1.9–12	MSSL/Birmingham Dr G. Carpenter X-ray Astronomy Group, Birmingham University (personal communication)
Collimated proportional counter (CPC)	100	1.75°	1.5–20	Mullard Space Science Lab. Sanford <i>et al.</i> <sup>2</sup>
Sky survey experiment (SSE)	290	≈ 90°	2–18	Leicester University X-Ray Astronomy Group Ricketts <i>et al.</i> <sup>3</sup>

The first is 1975 mid-August when A0620-00 was near maximum intensity. The SSE data for August 22 and ST data for August 20-23 shown in Fig. 2 can be fitted with a single power law spectrum (solid line)

$$\frac{dN}{dE} = 3.5 \times 10^3 \times E^{-4.7} \text{ photons cm}^{-2} \text{ s}^{-1} \text{ keV}^{-1}$$

up to  $\sim 60$  keV, with an indication of hardening  $> 30$  keV to an exponent of  $\sim -2$ . Data for the second epoch in Fig. 2 are from the period October 16-19 for the ST detector, and October 19 for the RMC detector. Error bars for the ST data are again 1 s.d. from counting statistics, and systematic errors are expected to be small compared with this. We now note that whereas the mid-October soft X-ray intensity has decreased by a factor 5 or more, the 20-200 keV intensity seems to have increased by at least a factor 2. Moreover, a spectral break with two power laws is now definitely required to satisfy the totality of the October data. We suggest that the similar

**Fig. 1** Cyg X-1 X-ray spectra before and after the 1975 May 9 'high' to 'low' state transition measured by Ariel V detectors. The solid curves represent the data of Sanford *et al.*<sup>2</sup> while the dashed curve represents a power law fit.

spectral transitions illustrated in Figs 1 and 2 indicate comparable production mechanisms for Cyg X-1 and A0620-00.

In seeking to understand the observed time variations we suggest that the inverse Compton source model of Eardley *et al.*<sup>4</sup> for Cyg X-1, and by implication A0620-00, could provide a plausible mechanism. Carpenter *et al.*<sup>5</sup> suppose acceleration in an optically thin region of a source containing a hot electron gas operates like the Fermi mechanism<sup>6</sup>, with a fractional photon energy change per collision

$$\frac{dE}{E} \approx \frac{v^2}{c^2}$$

for electron velocity  $v$ . If the probability of escape of photons from the acceleration region, after  $N$  collisions, is proportional

**Fig. 2** A0620-00 X-ray spectra in mid-August 1975 and mid-October 1975, observed by Ariel V detectors. Various power law fits are indicated by the solid lines.

to  $\exp(-N/k)$ , where  $k$  is a constant, a power law photon spectrum will result. Changes in the low energy photon supply and in the photon diffusion parameters which could vary in different acceleration regions may account for the observed slope changes and breaks in the spectra of Figs 1 and 2.

We wish to thank the University of Birmingham Space Physics Group for use of data before publication.

## X-ray transient source at high galactic latitude and suggested extragalactic identification

THE discovery of a number of bright, transient X-ray sources in the Milky Way has been a feature of the first year in orbit of the Ariel V satellite (see, for example, refs 1-4). It is becoming clear from the all-sky data obtained by the Ariel V Sky Survey Experiment (SSE) that at least two distinct classes of (fainter) high latitude transient X-ray source also exist. A particularly interesting first example is reported here.

The SSE detector used in these observations has an effective area at 2-18 keV of 290 cm<sup>2</sup>, and sweeps around the satellite spin plane with a fan-beam collimator of 0.7° × 10° (FWHM), the larger dimension inclined at 65° to the plane. An X-ray source that is detected may be located along a 'line of position', determined by the instantaneous position of the collimator field of view. The width of this 'line of position' is set by the errors in the measurement and in the transfer from spacecraft to celestial coordinates and is a measure of the uncertainty in the source position. A significant improvement in the overall source location can generally be obtained by carrying out a 'cross scan', to obtain an ideally perpendicular 'line of position'. Further details of the SSE and its operation will be published elsewhere.

Our observations are summarised in Fig. 1 and record the discovery of a new X-ray source in Ursa Major, 65° from the galactic plane, in late May, 1975. No source has previously been reported in this region but an extended observation with the SSE during 1975 May 3-9 produced a 3σ signal corresponding to 1.2 Ariel counts s<sup>-1</sup> (= 3.3 Uhuru counts s<sup>-1</sup> for a Crab-like spectrum). It was not visible, at a 2σ upper limit of 1 Ariel count s<sup>-1</sup>, during 1975 May 9-18 but was present at a substantially higher intensity when the SSE again viewed this region on May 22. Continuous observation to June 1 showed the source to intensify further to a peak ~16 counts s<sup>-1</sup> on May 28 and then fade in an irregular manner over the following 4 days, while the source remained in the SSE field of view. Further extended observations in mid June, early July and again at the end of August showed the source to be still faintly visible at ~0.7 counts s<sup>-1</sup>. Since the Ariel V Sky Survey is in general deeper than any previous X-ray survey, it cannot yet be ruled out that the source has a normal X-ray intensity of ~0.7 counts s<sup>-1</sup>. If so, it should perhaps be described as highly variable rather than transient, with an order of magnitude increase over a period of 10-28 d, and an additional 'flare' lasting ~1 d, during which the intensity increased by a factor of ~2.

Fig. 1 X-ray light curve of A1103+38. Change of scale of the abscissa at MJD42559. Count-rate error bars are ±1σ. Upper limits are 2σ.

Fig. 2 90% confidence error box of A1103+38 superimposed on a composite of two adjacent, red Palomar Sky Survey prints. The suggested optical candidate MK421 (= B2 1101+38) is indicated lying 0.25° from the centre of the error box (+). The error box has coordinates:

	RA	dec.
Centroid	165.76	38.56
Corners	164.92	38.23
	165.34	38.14
	166.59	38.87
	166.17	38.97

Figure 2 is a copy of the Palomar Sky Survey plate for this region of the sky, on which has been superimposed the 90% confidence error box of the source, designated A1103+38. The narrow dimension of the box represents the line-of-position from the observations of the source near its peak brightness, and includes a statistical error of 0.03° (corresponding to a width of ±2σ, where

$$\sigma = \frac{\text{FWHM}}{\sqrt{6}} \frac{\sqrt{(2N_b + N_s)}}{N_s}$$

and  $N_b$  and  $N_s$  are the background and signal count rates) plus 0.07° representing the uncertainty in relating the spacecraft attitude to celestial coordinates. The broad (E-W) extension of the error box is from the cross scan line of position where the poorer statistics make the attitude error negligible in comparison.

A preliminary search of the error box for the optical counterpart of A1103+38 has produced three interesting candidates. Two, which are just outside the W corner of the box are IC2615 and IC2619, described in Dreyer's catalogue as faint, round, small and with a brighter middle or nucleus. From this early description it seems possible that either could be distant globular clusters located in the galactic halo (T. A. Matilsky, unpublished). The association of a class of variable, galactic sources with globular clusters has, of course, been firmly established<sup>5,6</sup>. The third, and preferred, candidate lies within the error box of A1103+38 and only 0.25° from the centroid position. This is the radio source B2 1101+38 (marked in Fig. 2), which has been identified<sup>7</sup> with the faint elliptical

galaxy MK421, distinguished by an unusually bright and optically variable nucleus. Ulrich has suggested<sup>8</sup> that this object might be of the BL Lacertae type based on the featureless continuum spectrum. Although later studies<sup>9</sup> have revealed faint absorption lines from the surrounding galaxy (yielding a redshift of 0.0308), a search of the Harvard archival plates<sup>10</sup> has shown rapid variability of an amplitude greater than for all other BL Lac-type objects, and exceeded only by two QSOs. The proposed identification with A1103+38 is necessarily subjective at this stage and depends mainly on the very unusual nature of MK421 and, in particular, the time scale of its optical variability ( $> 1$  mag over several days, ref. 12). The rarity of this type of high latitude X-ray source is also important. To date, it seems unique in its persistence. Several others detected by Ariel V last only hours (B.A.C. *et al.*, unpublished). On the other hand, several of the unidentified high latitude sources in the 3U catalogue are not seen by Ariel V, indicating variability of at least a factor of 5. It seems likely that objects of the BL Lac type are an intermediate class lying between galaxies and QSOs and it is clearly of considerable interest to establish whether, like QSOs, the active nuclei of BL Lac objects are powerful X-ray emitters. With several X-ray satellites now in orbit it should be possible to make more extended observations, coordinated with ground based studies at radio, optical and infrared wavelengths.

We are grateful to Dr M. V Penston for providing the overlay of Fig. 2 and to the Hale Observatories for permission to reproduce the Palomar chart. The Ariel V project is supported by the Science Research Council who also provide the research post of one of us (M.J.R.).

## Mass determination for the X-ray binary system Vela X-1

THE 6.9 mag B0.5 Ib supergiant HD77581 has been identified as the optical counterpart of the X-ray eclipsing binary system 3U0900-40 (Vela X-1)<sup>1,2</sup>, which eclipses with a period of  $8.95 \pm 0.02$  d. The discovery of regular X-ray pulses in Vela X-1 has also been reported<sup>3</sup>, with a mean pulse period of 282.9 s, modulated because of the radial velocity variation of the X-ray pulsar in its orbital motion. This makes Vela X-1 the third X-ray binary system in which the orbits of both the optical and the X-ray component can be studied, and the following orbital parameters have been derived<sup>4</sup>,  $e_x = 0.15 \pm 0.05$ ,  $\omega_x = 157^\circ \pm 24^\circ$  and  $K_x = 268 \pm 12$  km s<sup>-1</sup>. Analyses of the light curve of HD77581 have shown that the heating effect is too small to be detected<sup>5</sup>. Furthermore, the star is bright and the spectral lines are not very broad. This means that here the first relatively accurate direct mass determination of both the X-ray and the early-type supergiant components of an eclipsing X-ray binary becomes possible.

Earlier studies of the radial velocity variation of HD77581 have given contradictory results<sup>6,7</sup>. For the semi-amplitude  $K$  of the orbit, values between 19 and 40 km s<sup>-1</sup> and for the

Fig. 1 Radial velocity curve of HD77581 = Vela X-1 for a period of 8.966 d. Phase zero corresponds to mid-eclipse time. The points denote mean values of the measurements of lines of He I and heavier ions. Mean errors per plate are indicated by the length of the vertical bars.

eccentricity from 0.00 to 0.54 have been found. According to Wallerstein<sup>7</sup>, the radial velocity data of HD77581 do not allow a consistent solution of the orbit, because of mass transfer in the system. Here we show that a consistent solution can be obtained, however, provided that the lines of hydrogen—expected to be most sensitive to gas motions in the system—are excluded from the analysis. Our analysis of the radial velocity variations of HD77581 is based on 26 coude spectrograms, obtained with the 152-cm telescope of the European Southern Observatory, La Silla, Chile, in 4 observing runs between April 1973 and June 1975. The spectra were taken on Il-a-0 emulsion, over wavelengths from 3,600–4,950 Å. The dispersion of the plates is 12 Å mm<sup>-1</sup> or 20 Å mm<sup>-1</sup>. The plates obtained in the first observing period<sup>8</sup> have been remeasured independently for use in this analysis (Fig. 1).

The spectra were measured for line positions with the Grant comparator of the Kapteyn Astronomical Laboratory of the University of Groningen. All absorption features visible in the spectrum were measured, without selecting beforehand a particular set of lines. Some very weak lines were thus missed on some plates, but on the other hand, especially for the weak lines, it was considered an advantage to measure without a

predetermined expectation of where lines should be found. Lines of H I, He I, O II, N III, N II, Si III and Si IV were present in at least half of the spectra. From the measurements of the radial velocity of the interstellar Ca II K-line, we found  $\bar{v}_{Ca II} = 16.1 \pm 0.6$  (m.e.) and  $13.7 \pm 1.0$  km s<sup>-1</sup> for the 12 Å mm<sup>-1</sup> and the 20 Å mm<sup>-1</sup> spectra, respectively. To increase the homogeneity of the data we reduced the measurements of the 20 Å mm<sup>-1</sup> plates to the 12 Å mm<sup>-1</sup> system, by applying the correction of 2.4 km s<sup>-1</sup>.

To get an impression of the internal accuracy of these measurements five plates were measured twice. The differences in the mean velocity obtained from two such measurements of one plate vary between 0.3 and 4.2 km s<sup>-1</sup>; the s.d.m. per line for one plate varies from 8.0–11.5 km s<sup>-1</sup>.

In the analysis we used mean values of the radial velocity as obtained from the He I lines and from the lines of heavier ions. These average radial velocities are given in Table 1. A full table of all individual line radial velocity measurements will be published elsewhere.

With the computer program 'Orbit', based on a program of Wolfe *et al.*<sup>8</sup>, the best fitting radial-velocity curve through the points was computed. This was done for all lines of He I and the heavier ions together. Also separate solutions for the He I lines and the heavier ion lines were made. The radial velocity measurements were weighted according to  $w_i = 1/\sigma_i^2$ , where  $\sigma_i$  is the s.d.m. of the measurements. The average orbital period  $P$  determined in these solutions is  $8.966 \pm 0.005$  d, which agrees well with Hutchings' result<sup>6</sup> ( $P = 8.966 \pm 0.001$  d), based on radial velocity determinations by several observers, over a time interval of 17 yr. We therefore subsequently used this period as a fixed parameter in our calculations. The orbital parameters derived from all lines together—except the hydrogen lines—are given in Table 2. The errors quoted in Table 2 are 1σ (68% confidence) limits. The separate solutions for He I and the heavier ions are in good agreement with the mean solution (see Table 2), and give good agreement with the X-ray pulsar data, which for convenience are also given in Table 2. In particular the values of the eccentricity and the angle of periastron, which should be 180° apart for the optical and the X-ray solution, agree well (within the quoted accuracy intervals).

In our opinion this agreement lends confidence to the orbital character of the optical radial velocity variations; the non-orbital (gas streams, stellar wind fluctuations) component does not seem to have much effect on the results from He I and heavier elements. Using  $a_{opt} \sin i = 2.5 \pm 0.2 \cdot 10^6$  (1σ) as a compromise value, we find the following values for the system parameters

$$\begin{aligned} \text{mass ratio: } \mathcal{M}_{opt}/\mathcal{M}_X &= (a_X/a_{opt}) = 13.1 \pm 1.65 \\ \text{total mass: } (\mathcal{M}_{opt} + \mathcal{M}_X) \sin^3(i) &= 21.6 \pm 2.2 \mathcal{M}_\odot \end{aligned}$$

$\mathcal{M}_X \sin^3(i) = 1.52 \pm 0.22 \mathcal{M}_\odot$  and  $\mathcal{M}_{opt} \sin^3(i) = 20.0 \pm 2.1 \mathcal{M}_\odot$ . From a detailed analysis of the optical-light variations, Avni and Bahcall<sup>9</sup> have found that the inclination  $i$  should be  $> 74^\circ$  to get a consistent picture of both the observed light curve and the duration of the X-ray eclipse. Taking  $74^\circ$  and  $90^\circ$  as lower and upper limits of the angle of inclination we get

$$\mathcal{M}_X = 1.61 \pm 0.27 \mathcal{M}_\odot \text{ and } \mathcal{M}_{opt} = 21.2 \pm 2.6 \mathcal{M}_\odot.$$

All quoted errors in the mass parameters are 90% confidence limits. This result shows that the compact component is very probably too heavy to be a white dwarf.

If it is a white dwarf, its evolutionary history implies that it should consist mainly of carbon and oxygen<sup>10</sup>; the upper mass limit<sup>11</sup> for such white dwarfs is  $\sim 1.4 \mathcal{M}_\odot$ . Its most probable mass of  $1.61 \mathcal{M}_\odot$  is just consistent with the presently allowed theoretical masses of neutron stars<sup>12</sup> ( $\mathcal{M} \leq 1.6 \mathcal{M}_\odot$ ).

The mass determination of the supergiant allows a test of the theoretically computed evolution of massive stars, through a comparison with theoretical evolutionary tracks. The luminosity of HD77581 can be inferred in two ways. The spectral type and luminosity class (B0.5 Ib) provide, in principle, the absolute magnitude  $M_v$ , bolometric correction BC and effective temperature  $T_{eff}$ . Using the luminosity calibration of Blaauw<sup>13</sup> or Keenan<sup>14</sup> we derive  $M_v = -5.9 \pm 0.4$  mag. For the bolometric correction, values between 2.4 and 2.6 mag have been given<sup>15,16</sup>. This gives  $M_{bol} = -8.4 \pm 0.5$  mag. For the orbital parameters given here and by Rappaport and McClintock<sup>4</sup>, and assuming a minimum observed eclipse angle of  $34^\circ$ , Avni and Bahcall<sup>9</sup> derive for the radius of HD77581  $R = 30 R_\odot$ . For the effective temperature, values ranging from 22,000 K (ref. 17)–29,000 K (ref. 18) have been given for early B-type supergiants. Adopting  $T_{eff} = 25,000 \pm 4,000$  K we find  $M_{bol} = -9.0 \pm 0.75$  mag. From a comparison with evolutionary tracks<sup>19,20</sup> we then find the following values of the evolutionary mass:  $\mathcal{M}/\mathcal{M}_\odot = 22 \pm 7$  and  $30 \pm 10$ , respectively; these values, although not very accurate, are consistent with the presently determined value of  $21.2 \mathcal{M}_\odot \pm 2.4 \mathcal{M}_\odot$ . Therefore, the early-type supergiant in this X-ray binary system does not seem to be particularly under-massive for its spectral type (as has been suggested<sup>21</sup> for Cygnus X-1).

## Implications from the absence of a $^{41}\text{K}$ anomaly in an Allende inclusion

CLAYTON<sup>1</sup> has elaborated on his unorthodox interpretation<sup>2</sup> of the occurrence in meteorites of the decay products of the extinct radionuclides  $^{129}\text{I}$  and  $^{244}\text{Pu}$ . He has suggested that these radioactive species did not decay in the meteorites but rather in interstellar grains which, on the formation of the meteorites, were incorporated without much alteration. Thus, the concentration in the meteorites of the decay products does not reflect the time of meteorite formation relative to the cessation of nucleosynthesis but is essentially governed by the fraction of interstellar grains mixed with the meteoritic matter proper. If that is true, anomalies will occur in the isotopic composition of numerous elements. The decisive criterion of whether an over-abundance of a given isotope can be expected is the production yield during nucleosynthesis of a radioactive precursor; the half life of that precursor is of only minor importance.

Among the possible anomalies mentioned by Clayton is an excess of  $^{41}\text{K}$ . According to Woosley *et al.*<sup>3</sup> this nuclide is synthesised predominantly as  $^{41}\text{Ca}$ , its radioactive progenitor. Therefore, in an early condensate from the solar nebula, enriched in Ca relative to K,  $^{41}\text{K}$  should be over-abundant provided that no homogenisation of potassium has occurred later on. We wish to report on a potassium isotopic analysis performed on an inclusion from the Allende carbonaceous chondrite.

For three reasons Allende seems to be a promising meteorite. First, it is almost unanimously agreed that it contains inclusions of an early primary condensate from the solar nebula (for an alternative view see ref. 4). Second, variations in the isotopic composition of oxygen<sup>5</sup> and magnesium<sup>6,7</sup> in the inclusions show that a disequilibrium distribution has been frozen in and indicate that those two elements at least have not been homogenised isotopically during the subsequent history of the meteorite. Third, almost by definition, Ca, being a refractory element, is enriched in such inclusions, whereas potassium is depleted. The resultant Ca/K ratio is thus exceedingly high, which results in a high sensitivity for the detection of a possible contribution from  $^{41}\text{Ca}$  to  $^{41}\text{K}$ .

We conducted our experiment with a 10.6-mg sample of a white chondrule previously analysed by thermal neutron activation analysis<sup>8</sup>. (Although in the course of this analysis the sample was exposed to a dose of  $1.5 \times 10^{18}$  thermal neutrons  $\text{cm}^{-2}$ , it is of no consequence to the investigation.) After the sample was dissolved the potassium was separated on Dowex 50 WX8 and analysed by mass spectrometry. Details of the chemical procedure and the isotopic analysis have been given elsewhere<sup>9</sup>. Results pertinent to this discussion are—K-content:  $210 \pm 20$  p.p.m.; Ca/K:  $860 \pm 100$  (see ref. 8); potassium blank:  $3.4 \pm 0.5$   $\mu\text{g}$ ; measured ratios:  $^{39}\text{K}/^{41}\text{K} = 13.997 \pm 0.015$ ;  $^{41}\text{K}/^{40}\text{K} = 575.3 \pm 3.7$ .

As we made no attempt to determine absolute isotope abundances the measured ratios have to be normalised. We therefore analysed a terrestrial potassium standard. Using the NIER (ref. 10) value of  $^{39}\text{K}/^{41}\text{K} = 13.47$ , and assuming the mass discrimination between neighbouring isotopes to be constant, we obtained  $^{41}\text{K}/^{40}\text{K} = 584.87 \pm 0.8$  (mean value of

16 runs) which is in good agreement with that of 584.89 given by Burnett *et al.*<sup>11</sup> who normalised to the same  $^{39}\text{K}/^{41}\text{K}$  ratio.

Because it is necessary to normalise the measured ratios an unequivocal analysis of the Allende data is only possible if any potential anomaly occurs in the abundance of one isotope only. Thus, assuming that in the Allende inclusion the  $^{39}\text{K}/^{40}\text{K}$  ratio is identical to the terrestrial value our result shows that the enrichment in the abundance of  $^{41}\text{K}$  is  $\delta^{41}\text{K} = (0.55 \pm 1.3)\%$ . If the  $^{39}\text{K}/^{41}\text{K}$  ratios are the same in both cases  $\delta^{40}\text{K} = -(0.3 \pm 0.7)\%$ . It is worth mentioning that, within reasonable limits, the  $\delta$  values are rather insensitive to the ratios used for normalisation. A change in the choice for the terrestrial  $^{39}\text{K}/^{41}\text{K}$  by  $\pm 5\%$  results in even smaller, but comparable, relative changes of the  $\delta$  values.

Within the stated errors the isotopic composition of potassium from the Allende inclusion is indistinguishable from that of terrestrial potassium. This constrains certain interesting parameters. The absolute excess in the abundance of  $^{41}\text{K}$  is  $\Delta^{41}\text{K} = [\text{K}] \times \text{H} (^{41}\text{K}) \times \delta^{41}\text{K}$  where  $[\text{K}]$  is the potassium content (including blank) and  $\text{H} (^{41}\text{K})$  the isotopic abundance of  $^{41}\text{K}$ . This is equal to the amount of  $^{41}\text{Ca}$  ( $= ^{41}\text{Ca}/^{40}\text{Ca} \times [\text{Ca}] \times \text{H} (^{40}\text{Ca}) \times f$ ) which decayed in the sample. Assuming<sup>1,2</sup> that the condensation of Ca took place quickly after the synthesis of  $^{41}\text{Ca}$ , that is, that no correction has to be applied for its decay (half life  $1.3 \times 10^5$  yr) before condensation (see refs 1 and 2),  $f$  denotes the fraction of presolar Ca in the sample. The data presented here show that, on the  $3\sigma$  level ( $\delta^{41}\text{K} \leq 5\%$ ),  $^{41}\text{Ca}/^{40}\text{Ca} \cdot f \leq 10^{-5}$ . Clayton<sup>2</sup> reasons that for refractory elements like Ca,  $f \geq 0.1$ . Thus, in the presolar grains at the time of their formation the  $^{41}\text{Ca}/^{40}\text{Ca}$  ratio must have been  $\leq 10^{-4}$ . According to Peters *et al.*<sup>12</sup>, however, the production ratio in explosive carbon, oxygen, or silicon burning is about a factor of 30 higher ( $1/320$ ).

Of the numerous possibilities which could account for the discrepancy between our experimental result and theoretical prediction a few are worth listing.

- The cross sections relevant to the  $^{41}\text{Ca}/^{40}\text{Ca}$  production ratio are not known; they could be considerably lower than assumed<sup>12</sup>.

- Even for refractory elements the fraction,  $f$ , of presolar grains in the meteoritic matter may be lower than 0.1, although it is doubtful that with a 30-fold reduction the  $^{244}\text{Pu}$  data are still reconcilable with the model.

- Radioactive decay of  $^{41}\text{Ca}$  between cessation of nucleosynthesis and condensation of the grains may not be negligible after all; a free decay interval of about 0.5 Myr would be sufficient. In that case the number of possible isotope anomalies mentioned by Clayton<sup>1</sup> will be drastically reduced, as  $^{41}\text{Ca}$  has one of the longest half lives among the radioactive progenitors.

- Homogenisation of potassium and/or calcium may have occurred in the sample analysed. This would have wiped out, or drastically reduced, any anomaly which may have existed. A late addition of potassium of normal isotopic composition is not sufficient, however.

- The isotope anomaly in potassium may not be restricted to one isotope only, as has had to be assumed here for an unambiguous interpretation. Only a determination of the absolute abundance ratios without normalisation will allow that possibility to be checked.

As we realise that it would be helpful to know whether our sample shows anomalies in the isotopic composition of other elements, such as Mg, such measurements are planned.

## Devonian palaeogeography of the Orcadian Basin and the Great Glen Fault

STORETVEDT<sup>1</sup> has argued that Devonian palaeomagnetic results from Norway and northern Scotland indicate a post-Devonian sinistral displacement along the Great Glen Fault of some 200–300 km. This has been objected to on geological grounds by Mykura<sup>2</sup> and on palaeomagnetic grounds by

Turner *et al.*<sup>3</sup>. Here we present a simplistic Devonian palaeogeographical model of the Orcadian Basin based on observation of onshore sediments. We believe the model is compatible with only minor dextral displacement along the Great Glen Fault in post-Devonian times.

A variety of modes of displacement have been put forward for the Great Glen Fault. Some are based on pre-Devonian evidence<sup>4,5</sup> and are not considered relevant to our argument. We consider the following three:

First, sinistral movements of 200–300 km (ref. 1) or ~ 500 km (ref. 6).

Second, dextral movements of:

- (1) ~ 30 km on the Great Glen Fault s.s.<sup>7</sup>
- (2) ~ 65–80 km on the Walls Boundary Fault in Shetland<sup>8–11</sup>
- (3) a considerable movement on the Melby Fault in Shetland<sup>12</sup>

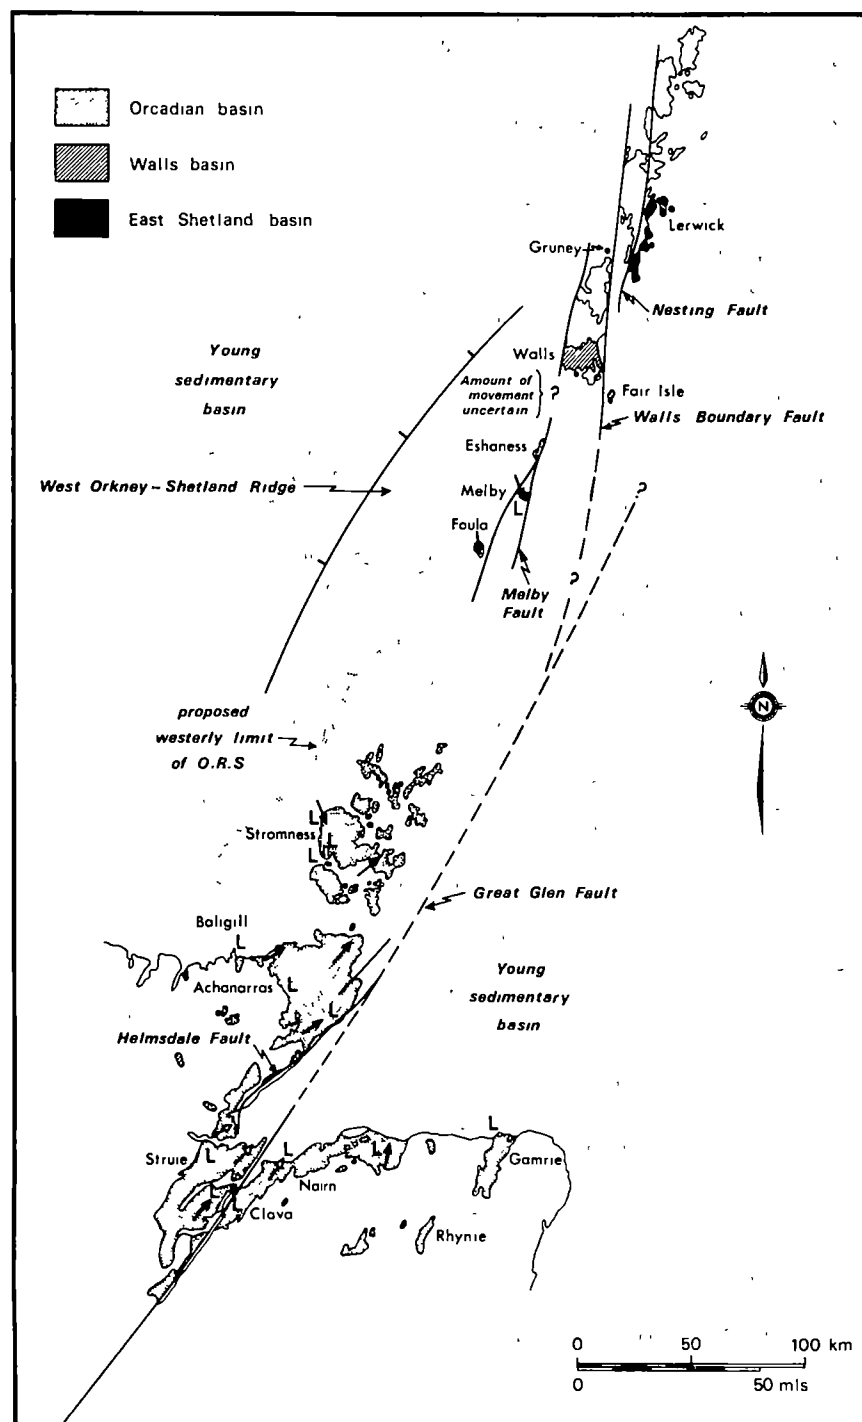

Fig. 1 Reconstruction of Devonian palaeogeography in the Orcadian Basin. Sources as described in the text, plus Watts<sup>21</sup>. L is the Achanarras limestone and equivalents. Open arrows show Upper ORS palaeocurrents (RA) and closed arrows show Middle ORS palaeocurrents (Orkney from Mykura<sup>12</sup>, elsewhere from R.N.D.).

- (4) ~ 50 km on the Helmsdale Fault<sup>8</sup>
- (5) a substantial movement on the Latheron Fault in south eastern Caithness<sup>13</sup>.

Third, normal movements:

- (1) Post-Jurassic movement of the Great Glen Fault s.s. associated with development of the Moray Firth Basin<sup>14</sup>
- (2) Post Jurassic movement of the Walls Boundary Fault associated with basin development to the south west of Shetland<sup>15</sup>.

Of the three distinct basins of ORS sedimentation in Shetland, considered to be juxtaposed by dextral faulting<sup>1,12</sup> only the westernmost had tangible connection with the Orcadian Basin to the south (Fig 1), that is, the similarity of the fauna of the Melby Fish Beds with those at Sandwick (Orkney) and Achanarras (Caithness). Mykura<sup>12</sup> has shown that a post-Devonian sinistral movement of 200–300 km is unlikely, as it places the dissimilar Orcadian and East Shetland sequences in juxtaposition. A movement of ~ 500 km certainly resolves the contradiction but has the great disadvantage of placing the ORS sediments of the southern Basin to the east of the Great Glen Fault system, in a position now occupied by the coast of Galway, western Ireland. Such a position is unlikely as the ORS sediments of the Orcadian Basin on both sides of the Great Glen Fault are very similar in character and show an identical history of development which is unique in the British Isles, and comprises:

- (1) Lower ORS (Upper Seigennian and Emsian) sedimentation of mainly alluvial character (ref. 16 and A. Collins, R.N.D. and R.A., unpublished).
- (2) Unconformity associated with mild earth movements.
- (3) Middle ORS (Eifelian and Givetian) sedimentation of mixed lacustrine and alluvial character.
- (4) Unconformity associated with earth movement and volcanism in Orkney.
- (5) Upper ORS (Frasnian and Lower Fammenian) sedimentation of alluvial character<sup>15</sup>.

During the extensive Middle ORS deposition faunal evidence indicates a most intimate connection between areas on either side of the Great Glen Fault system. Specifically the Achanarras Fish Bed fauna is represented in the southern part of the Orcadian Basin at, for example, Edderton and Cromarty to the west of the fault system and Clava, Nairn, Lethen Bar, Tynet Burn and Gamrie to the east (Fig. 1). The age equivalence of these beds is based on vertebrate faunas<sup>17,18</sup> and also on palynological data<sup>19</sup>. Furthermore, the zonal faunal assemblages recognised in the Caithness Flagstones<sup>13</sup> occur to the east of the Great Glen Fault system in the Nairn-Clava region in identical stratigraphic order<sup>20</sup>. At least 18 species of fish are, in fact, common to both sides of the fault system.

The existing outcrops of the Middle ORS are remnants of the western and southern margins of an elliptical basin elongated in a north-east-south-west direction (Fig 1). The original focus of sedimentation in this basin (as exposed) was in the Caithness-Orkney area where a distinctive, dominantly lacustrine, facies developed. Subsequently overlap to the north, west, south and south-east took place. In these latter areas alluvial deposits are more in evidence. Throughout the basin a rhythmic pattern of sedimentation was produced by variation in the level of Orcadian lakes. During high lake levels, when lake waters lapped directly against the underlying Caledonian basement, a distinctive marginal limestone facies was deposited<sup>21,22</sup>. This facies has recently been found on the south shore of the Moray Firth and confirms the overlap discussed above. Palaeocurrent vectors in both the Middle and Upper ORS support deposition of the sediments within a single basin (Fig. 1).

Within the palaeogeographic framework a relatively modest post-Devonian dextral shift of 30 km (ref. 7) is

acceptable and indeed produces a better 'fit' of Middle ORS outcrops in the Inverness area. There would seem to be no geological evidence to support large scale post-Devonian sinistral movement along the Great Glen Fault system although a variety of motions could have occurred in pre-Devonian times.

## Kinetic processes and thermal history of slowly cooling solids

In solids, the rates of kinetic processes such as volume diffusion and order-disorder transitions are extremely sensitive to temperature. At room temperatures they are so slow that crystalline solids normally preserve a substantial degree of thermodynamic disequilibrium over very long periods ( $> 10^9$  yr in some cases). At sufficiently high temperatures, on the other hand, some processes go so fast that a continuously varying state of equilibrium may be maintained as the temperature changes. When a solid cools steadily a transition occurs from the one state (continuous equilibrium) to the other (false equilibrium) in the neighbourhood of the closure temperature, which is defined below. Here I present a simple quantitative argument relating closure temperature to the cooling rate and kinetic parameters of a given kinetic system (see refs 1–6 for related work).

Closure temperature<sup>1</sup> is defined in Fig. 1. Curve I represents the equilibrium value of some chemical parameter  $x$ , and curve II its kinetically-controlled value. At high temperatures the two curves coincide. When the temperature decreases sufficiently the kinetically-controlled value begins to change more slowly than the equilibrium value, and the curves diverge. Eventually  $x$  reaches a constant, non-equilibrium value, corresponding to some earlier temperature (see Fig. 1), which is the closure temperature  $T_c$ . Slower rates of cooling allow more time for re-equilibration, and therefore lead to lower values of  $T_c$ .

Analytic derivations of closure temperature have been presented for some simple first-order kinetic systems<sup>1</sup>. A graphical solution has been attempted for one second-order system<sup>3</sup>. Here a physical argument is given which is applicable, in an approximate way, to all kinetic systems which obey the Arrhenius law. The argument compares a cooling time constant

with estimated isothermal reaction times at various temperatures.

For Arrhenius processes the reaction rate coefficient  $k(T)$  at absolute temperature  $T$  is given by

$$k(T) = k_0 \exp(-E/RT) \quad (1)$$

$E$  is the activation energy and  $k_0$  the frequency factor for the process, and  $R$  is the gas constant. For a slowly cooling system

Fig. 1 Kinetically controlled closure in cooling solids. *a*, Temperature against time; *b*, parameter  $x$  against time. (I), Equilibrium value of  $x$ ; (II), actual value of  $x$ .

$k$  diminishes roughly exponentially with time. If we make the approximation

$$T^{-1} = T_0^{-1} + \text{constant} \times t \quad (2)$$

Multiplying by  $E/R$  we absorb the above constant in the cooling time constant  $\tau$

$$E/RT = E/RT_0 + t/\tau \quad (3)$$

Substituting in (1) we obtain

$$k(t) = k(T_0) \exp(-t/\tau) \quad (4)$$

so that  $\tau$  is the time required for  $k$  to diminish by a factor  $e$  in the neighbourhood of  $T$ . The relationship between  $\tau$  and the cooling rate  $\dot{T}$  is found by differentiating (3) to be

$$\tau = -RT^2/E\dot{T} \quad (5)$$

We can now compare  $\tau$  with the time required for the kinetic process to go, say, half-way towards completion at constant

temperature, which must be inversely related to the rate coefficient, so we can write

$$kt_{1/2} = \alpha \quad (6)$$

(For a first-order process  $\alpha = 0.693$ ; for simple diffusion processes it is smaller and depends on the initial distribution and the geometry; for second or higher-order kinetics  $\alpha$  depends to some extent on both the actual value of  $x$  and its equilibrium value.) At high temperatures the process must reach equilibrium in a time which is short compared with the time required for  $k$  to diminish significantly, so we infer that  $t_{1/2} \ll \alpha$ . At low temperatures, on the other hand  $t_{1/2} \gg \alpha$ : that is to say, the process is so slow that negligible progress is made towards equilibrium before the rate constant has diminished to even lower value. Finally, in the transitional range, where the temperature cools through the value  $T_c$ ,  $t_{1/2}$  and  $\tau$  are of the same order of magnitude. Thus from (6) we have

$$\tau k(T_c) \simeq \alpha \quad (7)$$

Substituting for  $k(T_c)$  and taking logarithms we obtain immediately

$$E/RT_c \simeq \ln(\tau k_0/\alpha) \quad (8)$$

Analytical solutions for first-order kinetics and for simple diffusion processes<sup>1</sup>, give

$$E/RT_c = \ln(A\tau k_0) \quad (9)$$

in which  $k_0$  may be replaced by  $D_0/a^2$ , the frequency factor for a diffusing component in a system with characteristic dimension  $a$ . Thus it seems that equation (9) can be generalised to more complex kinetics by setting  $A \simeq \alpha^{-1} = (kt_{1/2})^{-1}$ . Assuming the boundary condition (curve I) to be linear in  $1/T$  over the transitional temperature range, and therefore a linear function of time, the constant  $A$  is 1.8 for first-order reactions, and 8.7, 27 and 55 for diffusion out of a plane slab, cylinder or sphere<sup>1</sup> comparison with equation (6) and (8) using data from Crank<sup>7</sup> shows that, in these systems, a better approximation to  $A$  is given by

$$A = 2/kt_{1/2} = 2/\alpha \quad (10)$$

This gives values of  $A$  which are too high by 60% for a first-order reaction, but only 20% for diffusion problems.

Eliminating  $\tau$  between equations (5) and (9), and setting  $T = T_c$ , we obtain

$$E/RT_c = \ln(-Ak_0RT_c^2/E\dot{T}) \quad (11)$$

which can be solved explicitly for  $\dot{T}$ , or iteratively for  $T_c$  ( $k_0$  can be replaced by  $D_0/a^2$  when appropriate). The relationship between  $T_c$  and  $\dot{T}$  is plotted in Fig. 2 for various values of activation energy  $E$ . Because of the logarithmic character of the equation,  $T_c$  is rather insensitive to cooling rate, especially at low temperatures and high activation energies. For example, at 60 kcalorie mol<sup>-1</sup> a change in the cooling rate by a factor of ten changes  $T_c$  by only 20° near 250°C, or 80° near 1,000°C. At 10 kcalorie mol<sup>-1</sup> the corresponding changes are 100° and 400°. The corollary is that observations of closure temperature must be very precise to yield useful information about cooling history. The best that has yet been achieved is represented by a study of nickel concentration profiles in iron meteorites, in which numerical modelling of the diffusion/cooling process led to uncertainties of  $\pm 15\%$ – $\pm 50\%$  in the estimated cooling rates<sup>8</sup>. On the other hand, an approximate knowledge of cooling rates may yield rather accurate predictions of closure temperature, which may be helpful in understanding how the properties of materials depend on their cooling history (see, for example, ref. 6).

Fig. 2 Relationship between closure temperature  $T_c$ , cooling rate  $\dot{T}$ , and kinetic parameters. Figures on curves denote values of activation energy  $E$  in kcalorie  $\text{mol}^{-1}$ . Star corresponds to example discussed in text.

As an example for which analytic solutions are not yet available, we may consider the  $\text{Fe}^{2+}$ -Mg order-disorder reaction in a cooling anthophyllite<sup>3</sup>. A closure temperature of 270 °C was estimated for the untreated sample, while laboratory kinetic studies<sup>9</sup> gave  $E = 61.6$  kcalorie  $\text{mol}^{-1}$  and  $k_0 = 8.6 \times 10^{17} \text{ yr}^{-1}$ . Inspection of the kinetic data<sup>9</sup> yields an estimate for  $A$  of  $\sim 10$ , from which, using equation (11) or Fig. 2 one can calculate a cooling rate of 13 °C per million years. Seifert and Virgo<sup>3</sup> estimated, graphically, a maximum cooling rate of 100 °C per million years for this material, while typical cooling rates in Alpine metamorphic rocks are 20 °C  $\text{Myr}^{-1}$  (refs 1, 10 and 11). The principal weakness in the calculation is uncertainty in  $A$ , since for a second-order reaction,  $t_{1/2}$  depends on the initial concentrations. In such cases, the best estimate of  $A$  (other than that obtained from a full analytical or numerical solution to the problem) could perhaps be obtained by estimating  $kt_{1/2}$  for an isothermal reaction which starts with a degree of disequilibrium comparable with that expected within the transition temperature range of the cooling system.

## Thermal conductivity of allotropic modifications of ice

THE pressure-temperature phase diagram of  $\text{H}_2\text{O}$  comprises several solid phases, differing in their crystal structure (Fig. 1)<sup>1</sup>. Ice offers an unusual opportunity for investigating how the different modes of stacking and the slight distortions of otherwise identical molecules influence the conduction of heat. There are no previous studies of the thermal conductivity of ice, except for the phase Ih at atmospheric pressure. We report here the first measurements of the thermal conductivity of the high pressure forms II, III, V and VI. Each of these modifications has a higher density, and a lower thermal conductivity, than ordinary ice, Ih. Ice Ih seems to be the first example of an insulator which has a decreasing thermal conductivity under increasing pressure. Our findings show that all these forms of ice have a positive thermal expansion coefficient.

Our measurements were carried out using the transient hot-wire method<sup>2</sup>, in which a pulse of constant electrical power is supplied to a metal wire immersed in a medium of the substance under study. An analysis of the change of temperature over time in the wire, as monitored by its electrical resistance, enables the thermal conductivity to be determined. The pulse length used was 0.6 s. Temperature data were acquired and reduced using a programmable desk calculator. We used a nickel wire, 0.1 mm in diameter, 40 mm long between the potential leads.

The wire was situated across the diameter of a Teflon cell similar to that described by Andersson and Bäckström<sup>3</sup>, but 70 mm in diameter. This cell was filled with doubly distilled  $\text{H}_2\text{O}$ , which was degassed by boiling. The cell was subjected to pressure in a piston-cylinder apparatus, cooled by circulating Freon.

Our measurements were made over a range of pressures going up to 0.65 GPa, and at temperatures down to -35 °C. Steady-state temperature measurements were taken using three thermocouples with their junctions located at different radial distances from the axis of the vessel. Phase transitions were detected using some or all of the following observations: discontinuous changes in the thermal conductivity,  $\lambda$ ; thermocouple responses indicating latent heat; and piston displacements indicating changes of volume. Whenever the measurements showed clearly that the system was fully within a single phase

Fig. 1 Phase diagram of  $\text{H}_2\text{O}$ .

region, the temperature differences within the cell were less than 0.2 °C. We were careful to ensure that temperature excursions of the Ni wire did not raise the temperature of the ice above the range of the modification under investigation.

Our investigations of the thermal expansion coefficient,  $\alpha$ , have revealed that an approximately adiabatic pressure increase or decrease always results in a temperature change of the same sign. Using the identity  $(\partial T/\partial P)_S = T\alpha/c_p$ , we conclude that  $\alpha$  is positive in the pressure-temperature region investigated, whereas it is known to have negative values for water and, according to one report<sup>1</sup>, for ice Ih at very low temperatures.

Our results for  $\lambda$  for each of the phases of ice are given in Table 1. Data for liquid H<sub>2</sub>O (see ref. 4) are quoted for comparison. Special efforts were not made to attain an absolute degree of accuracy, but our average value for ice Ih at -25 °C and atmospheric pressure— $\lambda = 2.38 \text{ W m}^{-1} \text{ K}^{-1}$ —is within the limits of error of other determinations<sup>5,6</sup>. We measured the conductivity of the five solid phases several times and in different orders in pressure-temperature space, and the results agreed to within 1 or 2 % in each case. The temperature variation of the conductivity in phase Ih was found to conform to the  $1/T$  dependence already reported<sup>5,6</sup>. But a startling fact emerged concerning the pressure dependence. We found that the thermal conductivity decreases by 6% in going from atmospheric pressure to 0.20 GPa, whereas all the insulators previously investigated have exhibited an increase<sup>7,8</sup>. In the other phases of ice no temperature or pressure dependence could be detected over the temperature-pressure region investigated.

A rough estimate of the phonon mean free path,  $L$  (some values of  $L$  are included in Table 1), may be obtained from the well known Debye formula

$$\lambda = c_p L / 3(\nu \kappa)^{1/2}$$

In calculating  $L$  we have taken the specific volumes,  $\nu$ , from

Table 1 Thermal conductivity of H<sub>2</sub>O

Phase	$T$ (°C)	$P$ (GPa)	$\lambda$ (W m <sup>-1</sup> K <sup>-1</sup> )	$L$ (nm)
Liquid	0	0.00	0.56	0.29
Ih	-25	0.00	2.38	1.20
II	-30	0.30	1.65	
III	-25	0.25	0.98	0.43
V	-25	0.50	1.24	0.44
VI	-20	0.65	1.54	0.60

Bridgman<sup>9</sup> and used his isothermal compressibilities except for ice Ih (see ref. 10) and liquid (see ref. 11), for which the adiabatic compressibilities are known. Furthermore, we have assumed the specific heat capacity to be the same in all the solid phases. The point to be noted is that, for phases III, V and VI,  $L$  is on average about twice the value that it is for the liquid, whereas for ice Ih it is four times as large.

Bridgman<sup>9</sup> has provided data for phase Ih, showing a rapid decrease of compressibility with pressure, which would lead to a similar decrease of  $L$ . But his atmospheric pressure value for compressibility is at variance with later work<sup>12</sup>. Thus, although it would be interesting to calculate the pressure dependence of  $L$  for ice Ih, we feel this cannot yet be done reliably.

We have considered the possibility that a single crystal of ice Ih present initially near atmospheric pressure would gradually transform into a polycrystalline mass, resulting in an increased grain scattering. Measuring  $\lambda$  for decreasing as well as increasing pressure, however, we obtained perfectly reproducible results, from which we conclude that changes in grain boundary scattering cannot be invoked to explain the pressure dependence.

The phonon mean free path,  $L$ , cannot be similarly computed for ice II, since the compressibility is unknown. It should be noted, however, that the thermal conductivity of this phase is clearly larger than for other phases with a comparable density. We tentatively attribute this to the proton order in the

structure of ice II, which does not exist in the other phases. We hope to shed light on the influence of proton order by making similar measurements on D<sub>2</sub>O and its mixtures with H<sub>2</sub>O.

## Intensity effects in the electrochemical photolysis of water at the TiO<sub>2</sub> electrode

FUJISHIMA and Honda<sup>1</sup> have described the photosensitised electrolysis of water on n-type TiO<sub>2</sub> single-crystal electrodes and proposed this reaction be used for solar-energy conversion. The process differs from conventional electrolysis since photocurrents can be generated without the application of an external potential, and thus direct conversion of light to electrical energy is possible. Since their report, several groups have investigated this system<sup>2-4</sup> but, as a consequence of the broad-band irradiation used, accurate quantum yields could not be determined. Here we report successful measurements of the variation of quantum efficiency with intensity. Our main finding is that these crystals become efficient converters if a small voltage is applied, even at intensities of 12 mW cm<sup>-2</sup>.

This is important since the degree to which sunlight can be focused without decreasing the quantum efficiency will determine whether these devices may be used economically. Intensity effects might be expected in this system since a major factor in determining the magnitude of the steady-state photocurrent is the recombination rate of the photoproduced valence-band holes and conduction-band electrons<sup>5</sup>.

To study these effects, a dual compartment electrochemical cell and single-crystal electrode were made<sup>1</sup>. A platinum cathode was used and a PAR-174 polarograph in the circuit allowed us to adjust the potential of the TiO<sub>2</sub> relative to a saturated calomel electrode (SCE). Small dark currents resulted from the application of this potential. When the TiO<sub>2</sub> electrode was illuminated, substantially higher currents were observed, and the difference between the observed current and the dark current was used to calculate the quantum efficiency of the process. The light source was a Coherent Radiation CR-8 argon ion laser emitting a doublet at 351 and 364 nm. The power incident on the electrode was varied through the use of neutral density filters, the resulting photocurrent was monitored, and the existence of a nonlinear intensity dependence was confirmed. The results depicted in Fig. 1 show marked deviation from linearity both at 0 and +2.0 V (SCE).

To obtain more data in the lower intensity range, the laser beam was directed through a beam expander on to the  $\text{TiO}_2$  surface. The resulting power loss was  $\sim 70\%$ , but with the focusing lens of the expander, it was possible to vary the size of the spot of light on the electrode surface from 0.2–2.0 cm in diameter, while maintaining constant total output power. This had the effect of varying intensity per unit area at the electrode. Three solutions having the same electrical conductivity but with different pH were used in the experiments. Results of irradiations performed at 0 V (SCE) are depicted in Fig. 2a. The dashed line represents the photocurrent expected if the quantum yield was unity and was intensity independent. Generation of the photocurrent in all three solutions becomes increasingly less efficient as intensity increases, and marked differences in behaviour are exhibited. The lowest efficiencies occur consistently for the acidic solution and the quantum yield at very low intensities is  $< 0.1$ . With the NaOH solution at intensities  $< 10 \text{ mW cm}^{-2}$ , the photocurrent is approximately linearly dependent on intensity, and the quantum yield calculated from the slope in this region is 0.7. This behaviour suggests that a pH-dependent process occurs at 0 V (SCE) at the surface of the electrode, and effects electron-hole recombination.

Fig. 1 The photocurrent as a function of intensity for irradiation of the  $\text{n-TiO}_2$  electrode in 0.51 N  $\text{HClO}_4$  for applied potentials of ( $\Delta$ , right axis) 0 V (SCE) and ( $\bullet$ , left axis) +2 V (SCE).

When the potential of the  $\text{TiO}_2$  electrode was raised to +1.0 V and the experiments repeated, the situation was substantially altered (Fig. 2b). Above  $12 \text{ mW cm}^{-2}$ , all three plots deviated from linearity, but even at the greatest intensity examined, the quantum yields were still high. The quantum yield of electrons at  $60 \text{ mW cm}^{-2}$  in acidic solution was 0.55 whereas in the basic solution it was 0.67. Below  $12 \text{ mW cm}^{-2}$ , the three curves are coincident and a nearly linear intensity dependence is obtained. The electron quantum yield calculated from the slope in this region is 0.85. For intensities  $< 0.5 \text{ mW cm}^{-2}$ , we have found quantum yields as high as 0.95.

Fig. 2 The intensity dependence of the photocurrent produced on irradiation of the  $\text{n-TiO}_2$  electrode (a), at 0 V (SCE), (b) at +1 V (SCE). ( $\circ$ ) 0.2 N  $\text{H}_2\text{SO}_4$ ,  $\kappa = 41.8 \times 10^{-3} \Omega^{-1} \text{ cm}^{-1}$ ; ( $\blacksquare$ ) 0.8 N  $\text{Na}_2\text{SO}_4$ ,  $\kappa = 41.3 \times 10^{-3} \Omega^{-1} \text{ cm}^{-1}$ ; ( $\triangle$ ) 0.225 N NaOH,  $\kappa = 41.0 \times 10^{-3} \Omega^{-1} \text{ cm}^{-1}$ .

The photoactive region for  $\text{n-TiO}_2$  is 300–400 nm (ref. 4). A total of  $\sim 2 \text{ mW cm}^{-2}$  of light in this region is available on a sunny day in our vicinity<sup>6</sup>. On the assumption that the quantum yield and intensity dependence are relatively independent of wavelength over this region, Fig. 2 can be used as an indication of the efficiency in the conditions specified. At 0 V (SCE) only  $\text{TiO}_2$  electrodes in strongly basic solutions are efficient in converting light energy into electricity. Moreover the efficiency will be dependent on the nature of the electrolyte, and if  $\text{OH}^-$  is consumed in the photolysis, it will decrease with time. At an applied potential of 1 V (SCE) however, the efficiency of the  $\text{TiO}_2$  system will be high and independent of solution pH. In addition, since the quantum yield remains relatively independent of intensity up to  $12 \text{ mW cm}^{-2}$ , some focusing of the incident radiation is allowed without a corresponding decrease in quantum efficiency.

The fact that the quantum efficiency approaches unity at low intensities for these wavelengths is significant since it suggests that further research should be directed towards broadening this wavelength range. Materials which had a photoactive region extending into the visible could utilise a larger proportion of the incident solar radiation.

Electrochemical oxidation of titanium metal to form an oxide layer<sup>7</sup>, and chemical vapour deposition of volatile titanium compounds to produce a polycrystalline  $\text{TiO}_2$  layer on suitable substrates<sup>2</sup>, have both been proposed as

cheaper alternatives to single crystal electrodes. The intensity dependence of the photocurrent at these electrodes can be expected to have a major role in evaluating their performance relative to the single crystal electrodes.

## Effect of nitrogen-containing plasmas on stability, NO formation and sooting of flames

WE have been developing methods for burning leaner fuel/air mixtures at faster rates and with less pollution than is achieved in conventional systems<sup>1-3</sup>. Mixtures of heat contents much below those corresponding to normal limits of flammability have been burned successfully at low temperatures using heat recirculation<sup>4,5</sup>. At temperatures much above the melting point of heat exchangers large increases in burning rates for a small input of electricity were achieved when radicals from plasma jets were injected, using a magnetically rotated arc to achieve rapid mixing<sup>6</sup>. We now report on further effects which can be induced using even a much smaller plasma jet (of about the size of a conventional sparking plug), the addition of much smaller proportions of electrical energy (~ 4% of the chemical throughput) and the absence of any magnetic field.

In an effort to approach practical conditions more closely, the combustion chamber was a model of a gas turbine flame tube provided by Ricardo & Co. Ltd, consisting of a cylindrical outer chamber (15 × 60 cm) fitted with a Perspex end-viewing window. The fuel is injected through a 'Sonicore' nozzle into a Pyrex mixing tube, where the combustion air from a centrifugal blower flows at velocities much in excess of those used in

Fig. 1 Flame stabilised by nitrogen-containing plasma.

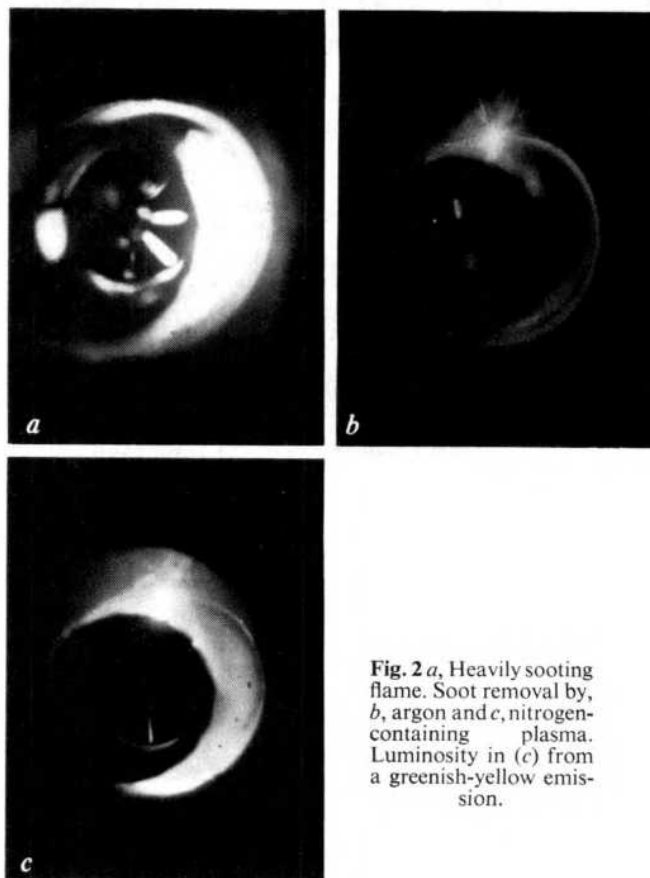

Fig. 2 a, Heavily sooting flame. Soot removal by, b, argon and c, nitrogen-containing plasma. Luminosity in (c) from a greenish-yellow emission.

previous work. Swirl vanes upstream of the nozzle aid mixing (these are visible in Fig. 2a-c).

To allow comparison with earlier work, nitrogen-containing plasmas were used (these had been found<sup>6</sup> to give marginally the best results) and were compared with 'inert' plasmas of argon alone. Once again, very large increases in stability were observed, to the point where flames could be maintained in mixtures so lean and flow velocities so high that normal flame stabilisation was impossible. Figure 1 shows such a flame anchored entirely to the nitrogen atom-containing wake of the plasma stream.

A new observation was the total disappearance of soot in the presence of the plasma, even when the latter was of argon alone and even in otherwise heavily sooting conditions. To achieve soot formation, toluene was injected with the propane fuel into the atomiser of the combustion chamber and Fig. 2a gives some impression of the luminosity of the flame which accompanied the heavy sooting. The result of injecting the argon plasma (Fig. 2b) is shown chiefly because colour photographs could not be published: the nitrogen-containing plasma (Fig. 2c) removes soot completely, probably under even more extreme conditions than does the argon plasma. There is, however, some luminosity visible in Fig. 2c: a greenish-yellow glow (also apparent under the conditions of Fig. 1) which is thought to result from some of the reactions of nitrogen atoms. This glow is seen to spiral down the length of the combustion chamber, because of the swirl vanes. Carbon luminosity disappears entirely in all cases, though black and white photographs do not show these distinctions.

Both chemical and physical mechanisms could account for soot suppression and the results, at this stage, do not allow us to attribute the effect uniquely to one or the other. Oxygen atoms (see below) and the OH produced in the next part of the radical chain could have this effect<sup>7</sup> but free electrons, which would be abundant in the plasma, have also been shown active in this way<sup>8</sup>.

It has been suggested that as regards flame stabilisation, at least, one of the relevant reaction steps is

There are likely to be several others, and even radiation from the plasma may exercise an effect. For example, it has been shown<sup>6</sup> that argon, though much less effective than nitrogen, is far from acting as an inert additive. Because of its exceedingly high temperature, a variety of reactions can occur at its interface with the other reactants; acetylene, for example, was found<sup>6</sup> when an argon plasma was injected into methane/air mixtures. In view of the effectiveness of nitrogen, however, it became desirable to consider whether the injection of nitrogen-containing plasmas would aggravate NO formation. Plasma-generated

In view of the success of these laboratory experiments, a car-battery operated plasma jet was tested in the exhaust system of a 1,200 cc saloon car and a considerable reduction of NO emission was achieved.

How flame stabilisation and NO removal can be associated becomes a little clearer if we consider the temperature dependence of the above-mentioned reactions. If one considers reaction (1) to be the main competitor for N atoms, and neglects the reverse of (1) and (2), as well as routes involving N atoms leading indirectly to nitric oxide, the following expression results

$$-d[\text{NO}]/dt = [\text{N}]\{k_2[\text{NO}] - k_1[\text{O}_2]\}$$

Therefore if  $k_2[\text{NO}] > k_1[\text{O}_2]$ , then nitric oxide may be destroyed at a rate proportional to  $[\text{N}]$ .

The temperature dependence of  $k_1$  ( $6.43 \times 10^9 T \exp(-6250/RT)$ ) and  $k_2$  ( $3 \times 10^{13} \exp(-334/RT)$ ) are shown in Fig. 3a; the low activation energy of reaction (2) makes it insensitive to temperature in the range of interest. When  $k_2[\text{NO}] = k_1[\text{O}_2]$  there will be no nitric oxide reduction. By plotting  $k_1[\text{O}_2]/k_2$  against temperature (Fig. 3b) it is possible to estimate a value of the lowest concentration of nitric oxide that could be established by N atom injection into nitric oxide-containing products (where the concentration was greater than the local steady state value of NO at a given temperature).

It is thus possible to postulate practical systems in which one plasma jet could fulfil both functions, one in the hot reaction zone and the other in the colder exhaust stream. This might be achieved, for example, by maintaining the discharge during parts of the combustion and exhaust cycle in a reciprocating engine, and by a suitable vortex in a continuous flow chamber.

Our current work is concerned with the analysis, by spectrographic and by other means, of the reactions occurring at the interface between plasmas of various constitutions and gases relevant in the combustion process. It seems already from these preliminary practical results, however, that it may be possible to design combustion systems in such a way that a small addition of electrical energy will facilitate the faster combustion of leaner mixtures simultaneously with the prevention of soot and nitric oxide in the products.

We thank R. W. Wheeler of Ricardo & Co. for collaboration on the car-exhaust experiments.

Fig. 3 Comparison of rates of reaction 1 and 2. a, Temperature dependences of rates constants; b, minimum nitric oxide concentration attainable for O<sub>2</sub> (i) 21% air (leanest limit), for example, an unthrottled engine at low load; (ii) 10%, unthrottled engine at high load; (iii) 5%, throttled engine, low load, high air/fuel ratio; (iv) 1%, throttled engine, idle or high load.

N atoms should, however, be able to reduce nitric oxide emissions by reversing the rate-determining Zel'dovich<sup>9</sup> step

To demonstrate this reaction taking place at atmospheric pressure, N atoms from the plasma were injected into fast flowing streams of nitric oxide in argon and synthetic exhaust gas mixes. Reductions in nitric oxide from 3,000 p.p.m. to a residual 80 p.p.m. were readily obtained in flows up to 250 l min<sup>-1</sup>.

## The pace of life

THE specific effects of population pressure on the quality of everyday life should be of pressing social and policy concern; and although population studies have proliferated in the behavioural sciences, research has focused primarily on fertility-related behaviours<sup>1,2</sup>. Moreover, the few social scientists interested in the relationship of the numbers of humans to individual human behaviour have been puzzled by a dearth of clear-cut effects<sup>3</sup>. This study reports preliminary analyses from a larger cross-cultural investigation of the quality of life. Following a suggestion from Lowin *et al.*<sup>4</sup>, we have systematically observed the rates of pedestrian locomotion over a constant distance in

15 cities and towns in six countries in Europe, Asia and North America. The results of these observations indicate that pace of life varies in a regular fashion with the size of the local population, regardless of the cultural setting.

Between 1972 and 1974 we had the opportunity to visit and collect observational data on the quality and pace of life from several varied locations on three continents. As part of these studies we sampled and measured the tempo at which local inhabitants simply walked the main streets of their cities and towns. Walking represents a standard human activity which previous research had suggested might be subject to the influence of local population size<sup>4</sup>. The locations in which data were collected were chosen to represent functionally parallel sites, 'downtown' or commercial areas like Wenceslas Square in Prague, Flatbush Avenue in Brooklyn, and Rehov Yerushalaim in Safed. In each location 50 feet (15.24 m) along the main walkway were first measured and then passers-by were timed unobtrusively from a vantage point opposite the walkway. All the data were collected on dry, sunny days of moderate temperatures (mean 24.1 °C). Subjects ( $N=309$ ) were selected from those who walked the distance alone and unencumbered. They were selected unsystematically within these constraints and, in all cases but one, equal numbers were chosen from people walking in each direction. The data for each setting were preserved in raw form until observations on all of the 15 sites had been collected.

Figure 1 shows the mean velocities at which the inhabitants of the cities and towns traversed a constant 50-foot

**Fig. 1** Walking velocity (over 50 feet) as a function of population size. The line drawn through the data is the calculated least squares fit (linear-log regression): coefficient of determination ( $r^2$ ) = 0.82 Slope,  $V = 0.86 \log P + 0.05$  ( $V$ , velocity;  $P$ , population). Population values (pop.) were derived from statistical abstracts or government guides;  $n$  is the number in a sample;  $t$  is the mean time (s) ( $\pm 1$  s.d.) to walk 50 feet: Czechoslovakia: Brno (pop., 341,948,  $n = 20$ ,  $t = 10.4 \pm 1.8$ ) and Prague (pop., 1,092,759,  $n = 20$ ,  $t = 8.5 \pm 1.3$ ) *Statistická ročenka CSSR* (SNTL, Prague, 1974); France: Corte (pop., 5,491,  $n = 13$ ,  $t = 15.1 \pm 1.8$ ) *Guide Michelin* (Pneu Michelin, Paris, 1973) and Bastia (pop., 49,375,  $n = 26$ ,  $t = 10.2 \pm 1.1$ ) *Annuaire Statistique de la France* (Institut National de la Statistique et des Études Économiques, Paris, 1973); Germany: Munich (pop., 1,340,000,  $n = 30$ ,  $t = 8.9 \pm 1.3$ ) *Statistisches Jahrbuch für die Bundesrepublik Deutschland* (W. Kohlhammer, Stuttgart, 1973); Greece: Psychro (pop., = 365,  $n = 10$ ,  $t = 18.1 \pm 4.1$ ) Crete by J. M. Christoforakis (S. Alexiou Sons, Heraklion, nd) and Itea (pop., 2,500,  $n = 10$ ,  $t = 22.0 \pm 8.6$ ), Iraklion (pop., 78,200,  $n = 20$ ,  $t = 13.0 \pm 2.5$ ), and Athens (pop., 867,023,  $n = 20$ ,  $t = 9.6 \pm 1.4$ ) *Statistical Yearbook of Greece* (Government Printer, Athens, 1973); Israel: Safed (pop., 14,000,  $n = 20$ ,  $t = 13.5 \pm 2.5$ ), Dimona (pop., 23,700,  $n = 20$ ,  $t = 15.3 \pm 10.6$ ), Netanya (pop., 70,700,  $n = 20$ ,  $t = 11.6 \pm 2.4$ ), and Jerusalem (pop., 304,500,  $n = 30$ ,  $t = 11.3 \pm 1.4$ ) *Statistical Abstract of Israel* (Government Printer, Jerusalem, 1973); and United States: New Haven, Connecticut (pop., 138,000,  $n = 20$ ,  $t = 11.4 \pm 1.8$ ), and Brooklyn, New York (pop., 2,602,000,  $n = 30$ ,  $t = 9.9 \pm 1.0$ ) *Statistical Abstract of the United States* (US Government Printing Office, Washington, 1973).

distance. Statistical analyses showed significant variation among sample mean times to walk the distance ( $F=14.69$ , d.f.=14/84,  $P < 0.001$ ). In Fig. 1, velocity is plotted against log population for the location (the total number of people living within the city limits<sup>5,6</sup>). As can be seen, the relationship between walking velocity and size of the local population is suitably characterised as linear, and the coefficient of correlation between these variables ( $r=0.91$ ) is significant beyond the 0.001 level of confidence (two-tailed test). These results suggest that a highly predictable relationship exists between the pace of life which characterises a locale and the size of its population.

Further, a comparison of cities with towns (breakpoint for a Standard Metropolitan Statistical Area<sup>7</sup> > 200,000) shows that average walking time for city dwellers (mean = 9.8 s) significantly exceeded that of their town counterparts (mean = 13.4 s) ( $t=7.66$ , d.f.=307,  $P < 0.001$ ). Similarly, nearly every intranational comparison indicated that city dwellers move at significantly greater speeds than their smaller town compatriots. Both these analyses further corroborate the notion that city life, at least in these Western locations, is carried on at an increased tempo<sup>4</sup>.

What explains the regularity with which locomotion velocity and population covary? Recent analyses of population pressures on behaviour suggest that "the number of individuals who must interact, rather than density, is the variable that produces substantial effects on human behaviour."<sup>8</sup> In addition, the crowding that accompanies larger groups of humans has been defined operationally to include not only numbers of people, but also the perception of personal restriction<sup>8</sup> and increased levels of social stimulation<sup>9</sup>. Both latter concepts covary with the size of the population. In view of this, crowding has been thought to motivate specific timing and avoidance behaviours that reduce tension and social interference. Milgram<sup>10</sup>, for example, has proposed an organising theory of psychological behaviour in cities that is based on a systems concept directly related to this view of crowding. According to his "overload" hypothesis, the volume of stimulation which characterises highly populated areas and typically overloads the processing capacity of the individual is reduced by cognitive and behavioural adaptations—usually withdrawal responses—which in turn facilitate purposeful action. These adaptive mechanisms eventually evolve into behavioural norms and, assuming this interpretation, increased walking speeds serve to minimise environmental stimulation. The data on the pace of life presented here reflect an adaptation to the continuum of population effects<sup>10,11</sup>. Thus, although our samples are relatively small and the communities were not randomly selected, our data suggest that the immediate social and physical environment exert a strong control over individual behaviour. They imply that demographic circumstances affect the quality of life, psychological experience, and motor action of humans in a fairly predictable manner, even in varied cultures.

We thank James T Fawcett and Julian J. Edney for a critical reading of the manuscript and Harold Sackowitz for statistical advice.

## Mortality and the 1974 fuel crisis

SOME comment is needed on the report by Brown *et al.*<sup>1</sup> in which the authors claim that the low mortality they noted in San Francisco and Alameda Counties in the first quarter of 1974 might have arisen from the reduction of gasoline sales during the fuel crisis. This is an interesting proposition, but the further details that the authors are examining on the more usual determinants of seasonal and secular variations in mortality (weather conditions and the prevalence of respiratory infections), and on urban/rural comparisons will be required before any judgment can be made on possible cause-and-effect relationships. In the meantime we make a few comments on their work, and present some related data from Britain.

Brown *et al.* have provided very little information on which to assess the significance of the variations in quarterly death rates. The actual numbers of deaths involved have not been quoted (although these can be estimated from a knowledge of the total populations), and beyond stating that the first-quarter rates for the years 1970–73 were “rather homogeneous”, there is little indication of the extent of year-to-year fluctuations.

The comment that the greatest change occurred in the under-45 age group, and the least among those aged over 65 is surprising, in view of the low death rates in the former group. Normally, mortality in the over-65 group dominates the total death rates, and it is this group that shows the greatest changes in mortality in epidemics of influenza or in extreme weather conditions. Presumably age-specific death rates had been calculated, but these were not shown. Although it is unlikely that there would have been any change in age distribution within either area during the five years concerned sufficient to affect comparisons of total death rates from one year to another, the contrast in death rates between San Francisco and Alameda Counties suggests a major difference in age distribution between these two areas.

In view of their suggestion that the effect on mortality is related to the concentrations of pollutants from motor vehicles, it is surprising that results of measurements of, for example, carbon monoxide, have not been quoted. Apart from variations in the emission of pollutants from one period to another, the prevailing weather conditions are important in determining the actual concentrations found in streets.

**Table 1** Annual death rates in Greater London for 1971–75

Year	Annual death rates* per thousand for the quarters ending			
	March	June	Sept.	Dec.
1971	12.8	11.2	10.0	11.7
1972	13.5	11.1	10.1	12.4
1973	13.3	11.0	9.9	12.0
1974	13.3	11.1	10.3	12.0
1975	13	12	10	—

\*Death rates as published by the Office of Population Censuses and Surveys<sup>2</sup>, subject to modification in relation to revised estimates of population, and to final adjustments of deaths in relation to exact date and place of occurrence. The numbers of deaths per quarter range from 18,000 to 25,000.

**Table 2** Annual death rates in Greater London for 1955–57

Year	Annual death rates* per thousand for the quarters ending			
	March	June	Sept.	Dec.
1955	14.3	9.7	8.2	10.4
1956	14.8	9.7	8.4	10.6
1957	11.3	9.7	8.7	13.2

\*Death rates as published in the Registrar General's Quarterly Returns<sup>2</sup>. The numbers of deaths per quarter range from 17,000 to 30,000. Greater London was not identified separately in the records in other years around this period, and the definition of the area differs slightly from that in Table 1.

Earlier work by Hexter and Goldsmith<sup>3</sup>, based on daily mortality records in Los Angeles County, showed that a model including regression on the logarithm of the daily mean concentration of carbon monoxide was capable of accounting for a marginally greater proportion of the variance in deaths than one involving trend, cyclic variations and temperature, without added pollution variables. The interpretation of such findings is, however, difficult since some of the variables involved are correlated with one another, and in these circumstances ordinary least squares estimates of the regression coefficients are unsatisfactory<sup>3</sup>.

Relationships between daily mortality and concentrations of pollutants from heating sources (smoke and sulphur dioxide) have been studied in London<sup>4–6</sup>, but the possibility of associations with pollutants from traffic have not so far been considered. Inspection of the records of death rates for each quarter of the year as published for Greater London<sup>7</sup> for the past five years (Table 1) does not reveal any reduction in mortality in the first quarter of 1974 when, as in California, there was a marked reduction in the use of cars as a result of the fuel crisis (and a more important feature in London, affecting the emission of pollution both from heating and from vehicles was the limitation in the use of fuels for heating and power, with the imposition of a three-day working week).

It is of interest also to consider an earlier period, during the Suez crisis in the early months of 1957, when as a result of petrol rationing there was a major reduction in the use of cars, and substantial changes in carbon monoxide concentrations were noted in central London<sup>8</sup>. The death rates for Greater London on a quarterly basis during the three years 1955–57 (ref. 9) are shown in Table 2.

The relatively low mortality rate in the first quarter of 1957, and the high mortality rate in the last quarter were features common to the records for the whole of England and Wales. The rise at the end of the year was related to the Asian influenza epidemic, and the low death rate in the first quarter was attributed to the mild weather<sup>10</sup>. There have been other March quarters in recent decades with low mortality (for example 1948, 1935) and some with high mortality, related to cold weather (as in 1963 (see ref. 11)) or to influenza epidemics. Further evidence of the important effects of temperature on deaths from heart disease has been reported by Bull and Morton<sup>12</sup>. Much caution is therefore required before ascribing changes in mortality to other environmental factors, and it is necessary to examine a long series of data with influenza epidemics, periods of extreme weather conditions, or episodes of unusually high or low pollution in a variety of combinations with one another before the relative importance of each of these factors can be judged satisfactorily.

In addition to the published quarterly and weekly returns of deaths, special daily tabulations have been prepared for London for a number of years, and more recently these have been extended to other urban areas and to England

and Wales as a whole. A detailed analysis of these is already in progress, and some of the findings on the effects of several environmental factors will be published shortly. Meanwhile we await with great interest the further results and analyses promised by the Berkeley workers.

THE paper by Waller and Lawther<sup>1</sup> commenting on our report of a decrease in mortality during the 1974 fuel crisis<sup>2</sup> raises some interesting and important points. We chose two separate counties to examine the possible effects on mortality of the fuel crisis for the purposes of testing consistency. Although both Alameda and San Francisco Counties are in the San Francisco Bay Area, they vary somewhat in age and racial composition, in density of population, in occupational structure, and in weather conditions. Yet both counties showed a drop in mortality during the first quarter of 1974.

Why no such mortality decrease was seen in London

on the basis of variation in such factors, but we have not yet investigated the possible interaction of all these factors.

A further possibility is that the decrease in mortality is part of a secular trend. We should be in a better position to answer this question when later data become available.

Waller and Lawther suggest that measurements of specific pollutants ought to have been presented. For several reasons we decided that our investigation should not hinge on variations in observed pollutant levels. First, we have become aware of significant technical problems in the actual measurement and recording of pollutant levels. Further, in San Francisco and Alameda Counties, there are only five air-sampling stations for a total population of one-and-three-quarter million people. Thus, reported pollutant levels are at best a very indirect guide to human exposure. Also, one must distinguish between the exposure of the general population to ambient levels of pollutants and the localised over-exposure of people in and around motor vehicles. We do, however, intend to publish ambient pollutant levels in the larger paper to follow. In response to Waller and Lawther's other questions: the number and rates of deaths per quarter are given in Table 1.

It should be stressed that the data from the two counties were collected differently. The Alameda County deaths are reported by place of occurrence, and for that county the figures in Table 1 should be accurate. The San Francisco deaths are reported by place of residence. As the San Francisco figures are from early reports, they may not include some deaths among San Francisco residents who died out of the county, and death reports received by the Registry after March 31, 1974. When these latter deaths are included, the 1974 mortality figure for San Francisco (but not for Alameda) may be higher than the one quoted.

Waller and Lawther are correct in noting the great absolute difference in the death rates between these two counties. This difference cannot be wholly explained by the older age distribution in San Francisco, but is presumably the result of other ethnic and environmental factors. We

**Table 1** First quarter deaths and death rates per 100,000 population. All causes excluding motor vehicle accidents

\* Excludes the cities of Berkeley and Albany, which have separate death registries.

during the first quarter of 1974 is not clear. One may speculate that the three-day working week and the consequent social disruption, the apparent decrease in home heating, and many other factors might have affected overall mortality in a way that would 'mask' any effect on mortality of the decrease in gasoline consumption.

The other possibility for the discrepancy between our findings and the London findings is that raised by Waller and Lawther, that is, factors other than the change in gasoline consumption may have been responsible for the decrease in mortality (in the San Francisco Bay Area). We have examined separately the variation in rainfall, temperature and air stability that occurred in the first quarters of 1970-74 and in each case 1974 was fairly typical. Similarly, the change in the number of deaths from influenza and pneumonia over the 1970-74 period does not seem to vary with the mortality rates of the counties in question. We have not been able to explain the decreased mortality in 1974

have taken account of the change from year to year in the population size of each county, but not of any change in internal composition, as such figures were not available to us. Our assertion that the greatest proportionate change occurred for those under the age of 45 is based on the percentage change using the average death rates for the comparison years as baseline. Of course, the absolute rates are much higher in those over the age of 65 but the greatest proportionate change was in the younger age groups. This preliminary analysis of the effect within age strata was not simultaneously tested by race and sex; consequently, no clear-cut conclusions can be drawn until this is accomplished.

We are heartened that other investigators have begun to look at populations and areas very different from our own to corroborate or refute our findings. We sincerely hope that these efforts will continue. We would hope that analysis by cause of death, and of the other factors which may mag-

nify or diminish observable changes in mortality during the fuel crisis period will also continue.

## Wild mynahs mimic wild primates

THE remarkable accuracy with which captive hill mynahs (*Gracula religiosa*) mimic human speech and other sounds is well known<sup>1</sup>. How this ability functions in nature was entirely speculative until Bertram<sup>2</sup> conducted an extensive field study of hill mynahs in India. Bertram<sup>2</sup> found that hill mynahs in India imitate the calls of other hill mynahs, but never heard a wild mynah imitate another species.

A different situation prevails on Siberut Island, off the west coast of Sumatra, Indonesia. During a 14-week study (1 July–7 October, 1972) of primates in rain forest near the Sirimuri River in southern Siberut<sup>3</sup>, I noted several instances of wild *G. religiosa* imitating a particular loud alarm call of Kloss's gibbon (*Hylobates klossii*) and loud spacing call of male pig-tailed langurs (*Simias concolor*).

I saw hill mynahs daily in the study area, usually in groups of 2–10 individuals. The gibbon call that they imitated is a tonal trill at a frequency of ~1 kHz and an average duration of 1 s (21 sonagrams). The langur call that they mimic is a panting-like sound, produced by 3–5, or more, exhalation–inhalation cycles, at a frequency of ~500 Hz (1 sonagram). Mynah imitations of these calls sound much like the originals but are distinguishable by ear as being mynah calls rather than primate calls just as readily as mynah renditions of human speech can be recognised by ear.

Mynahs imitated calls immediately after the primates produced them. From 16–30 September, 1972, I noted the frequency with which male pig-tailed langur calls were followed by mynah imitations of the calls. Out of 12 instances of calling by one or more male pig-tailed langurs, 10 were followed within seconds by imitations of the call by one or more mynahs. Comparable data were not obtained for mimicking of gibbon alarm trills because I heard none during this period.

Neither gibbon alarm trills nor the male pig-tailed langur call was a common component of the forest background noise during this study. Only 12 bouts of gibbon alarm trills, distributed over 8 days, were heard during the 99 days of study. Pig-tailed langur calls were never heard during the first 11 weeks of the study, but occurred on two-thirds of the days during the final three weeks of study. R. L. Tilson (in preparation) has confirmed that calling by pig-tailed langurs occurs sporadically.

Three kinds of loud primate calls are, at particular times of day, regular components of background noise in the study area. These are the songs of male and female Kloss's gibbons and spacing calls of male Mentawai langurs (*Presbytis potenziani*). None of these calls was imitated by mynahs, in spite of the fact that the Mentawai langur call is rather similar to the pig-tailed langur call which is mimicked. This suggests that perhaps only infrequently occurring vocal signals of other species are mimicked by mynahs. I did not determine whether mynahs imitate vocalisations of other species of birds in the study area.

These findings suggest that such mimicking behaviour is not, as previously thought<sup>2</sup>, just an artefact of confinement

## Wild birds detect quinine on artificial Batesian models

EVIDENCE I acquired during an experiment on the evolution of Batesian mimicry indicated that under some circumstances birds can detect quinine dihydrochloride on flour–lard pastry baits. The results of some previous mimicry experiments<sup>1–5</sup>, in which pastry baits were presented to wild birds, may need to be re-evaluated because of their tacit assumption that birds can only detect by taste the quinine used to make the models unpalatable. Quinine salts used were the hydrochloride<sup>2,3</sup> or dihydrochloride<sup>1,5</sup>. Pilecki and O'Donald's "solution of quinine"<sup>4</sup> was presumably quinine hydrochloride, which they used previously. Quinine monohydrochloride has only 1:16 solubility<sup>6</sup>, so Morrell and Turner<sup>2</sup> probably used the more soluble dihydrochloride to make their 75% solution. Birds in an experiment of Ikin and Turner<sup>1</sup> took nearly as many perfect mimics of two different models as palatable controls, though very few models (70% quinine) were taken. These authors suggested that birds in previous experiments<sup>2,5</sup> may have distinguished "models from 'perfect' mimics, possibly because the quinine causes a slight yellowing of the pastry". So far as I can determine, however, a specific control for detection of quinine has never been conducted.

The intent of my original experiment was to test the hypothesis that the models evolve more slowly than the mimics due to stabilising selection<sup>7</sup>; that is, deviant individual models are subject to predation because birds fail to recognise them as unpalatable. Until my suspicions about detection of quinine by birds were aroused, I used the following procedure in the study. Birds were trained to avoid unpalatable yellow models and palatable (Batesian) yellow mimics, and to choose palatable pink controls. All baits were painted with black patterns. The position of a single black stripe distinguished models from mimics, while controls were painted with four other patterns. I planned next to test avoidance of models with altered black patterns. During training, two scrub jays (*Aphelocoma coerulescens*) avoided yellow model baits treated with a 5% quinine solution (Q-yellow) and yellow mimics (non-Q-yellow, dipped in distilled water). They chose controls (non-Q-pink, distilled water) significantly more than models and mimics combined ( $\chi^2 = 127.12$ ,  $P < 0.001$ , see Table 1b). Other birds feeding on the baits—6–20 Golden-crowned sparrows (*Zonotrichia atricapilla*), two to six brown towhees (*Pipilo fuscus*), one to two rufous-sided towhees (*P. erythrophthalmus*) and one to two California thrashers (*Toxostoma redivivum*)—did not discriminate among model, mimic and control. I increased the unpalatability of the model, using 60% quinine dihydrochloride for the rest of the experiment. The birds other than jays then chose non-Q-yellow mimics significantly more than Q-yellow models ( $\chi^2 = 29.35$ ,  $P < 0.001$ , Table 1c). The jays continued to avoid both Q and non-Q-yellow baits significantly.

The first indication that some birds detected quinine visually or olfactorily was that only 12 Q-yellow baits were taken during the 4 d when 60% quinine was used initially, although at least 17 birds in addition to jays were seen feeding on the first day alone (Table 1c). I was certain that the birds did not taste baits without attacking them. I used field glasses to watch

Table 1 Experimental details and results

Date (1973)	Model	Mimic	Control	No. presented	No. taken, all birds	No. taken, scrub jays only
(a) January 19, 20, 22-24	5% Q-yellow			250	109	39
			non-Q-pink	250	202	127
(b) January 27, 28, 31	5% Q-yellow			300	66	
		non-Q-yellow		300	76	2 yellow*
			non-Q-pink	300	218	133
(c) February 15-18	Q-yellow			200	12	0
		non-Q-yellow		200	57	0
			non-Q-pink	200	160	102
(d) March 15	Q-pink			50	0	0
		non-Q-pink		50	43	33 pink*
			non-Q-green†	50	21	16

Tests were run at Stanford between 0800 and 1000 each fair day between January 19 and March 28, 1973, and sessions were continued for 20 min or until about 10 of the most heavily predated class of baits remained. Baits were presented in random order, 10 cm apart in a rectangular or square array on a secluded lawn, and were not replaced when taken. Feeding was continuously observed during sessions; the number of each colour taken by each species was recorded. A test for colour preference had been conducted for 5 d before January 19. Given 50 unpatterned non-Q-pink and 50 unpatterned non-Q-yellow baits per session, the birds ate more of the latter, although the difference was not significant. Models were then designated yellow. Treatment of models was with 60% quinine, except during (a) and (b).

\*Q and non-Q indistinguishable through field glasses, but jays must have taken only non-Q-pink during (d), since no models were taken by any birds.

†Green baits were not cryptic on the dormant grass.

Table 2 Quinine detection test

Date (1973)	Unpatterned baits	No. presented	No. taken, all birds	No. taken, scrub jays only
March 22	Q-pink	50	1	
	non-Q-pink	50	39	22*
March 28	Q-yellow	50	3	2†
	non-Q-yellow	50	20	0

Since mimics became the preferred prey in the previous test, non-Q controls made of different coloured pastry were no longer necessary. Differences shown are all significant at the 0.001 level except predation on yellow by jays.  $\chi^2$  values for predation on Q-pink against non-Q-pink: jays, 18.18; other birds, 14.22. For predation on Q-yellow against non-Q-yellow, by birds other than jays,  $\chi^2 = 17.19$ .

\*Indistinguishable, but at most one was Q-pink.

†Determined by my retrieving and tasting baits after jays dropped them

all feeding, and the birds never brought the tips of their beaks close to one bait and subsequently chose another, nor were there beak marks on baits that were not taken.

When it was obvious that a specific test for perception of quinine was necessary, the birds were trained for 3 d on unpatterned, non-Q-pink and non-Q-green baits to accustom them to new green controls. I then tested avoidance of a new model—Q-pink baits painted with the same black pattern as the previous yellow model. All birds avoided them (Table 1d). Although they had never before seen a quinine-treated pink bait, these birds could distinguish between Q-pink and non-Q-baits. To determine whether this discrimination was made by learning the patterns that had been painted on the baits or by perceiving the quinine, unpatterned pink baits—50 Q and 50 non-Q—were presented in random order, 10 cm apart in a square array. Position within the square identified uneaten baits as to treatment; baits not taken remained undisturbed by the birds. Table 2 shows that discrimination was based solely on the presence of quinine. The test was repeated using unpatterned Q-yellow and non-Q-yellow baits. Although the jays had so far taken a mean of 36.5 baits per session, they took only two baits, subsequently identified as quinine-treated. The other birds avoided the Q-yellow baits ( $P < 0.001$ ).

Clearly these birds detected 60% quinine-treated baits without tasting. Since jays distinguished Q from non-Q baits when the pastry was pink and were apparently unable to do so with yellow pastry, their discrimination was probably made on a visual, rather than an olfactory basis. That jays took only non-Q-pink controls during the aborted experiment (Table 1c) was a further indication that they could not distinguish between Q-yellow and non-Q-yellow baits, although the other

birds could do so with 60% quinine. Future experiments on mimicry using pastry baits must include a control to determine that the predators cannot perceive the unpalatable substance itself if baits are merely dipped into a solution. The unpalatable compound may have to be injected into baits, as Alcock<sup>8</sup> did with quinine-treated mealworms, or otherwise hidden within the pastry. This is effective if the birds do not swallow food whole, but break it up and thus taste the quinine. For birds to learn to avoid a model, it must have a punishing aspect, either an unpleasant taste or a distinct taste combined with emesis, such as quinine sulphate<sup>9</sup> provides.

The birds in my investigation made a very fine discrimination; I could not see the quinine on the baits. Certainly birds can and do make choices based on very small differences between food items; for example, cliff swallows have been known to select the non-stinging drones among flying bees<sup>10</sup>. It has, however, been pointed out<sup>11</sup> that predators do not need to avoid models and mimics completely for mimicry to evolve—only that better mimics must be avoided more frequently than less perfect mimics.

I thank P. R. Ehrlich and R. W. Holm for reading the manuscript, and E. G. Cruze and J. G. Terhune for technical help.

## Aggregation response of nymphs to pheromone(s) produced by males of the tick *Amblyomma hebraeum* (Koch)

No aggregation response by tick nymphs to a pheromone(s) produced by males had been described, although such a response had been demonstrated in adults<sup>1-3</sup>. We have now shown that males of the hard tick *Amblyomma hebraeum* (Koch) produce a material(s) which induces aggregation of nymphs suggesting an assembly pheromone(s) (Fig. 1). The presence of this pheromone is demonstrated by biological observations and by experimentation with a choice chamber<sup>4</sup>.

Males of *A. hebraeum* which readily attach to the host, were placed on the ears and on shaved areas of the back of rabbits (*Lepus europaeus* Pallas) and on the ears and scrotum of Guernsey calves. Hexane extracts were made by washing males of *A. hebraeum*, which had previously fed for 8 d on a calf. The extracts were concentrated to 1 ml (100 males) by vacuum distillation and were applied, drop by drop, discrete areas (a circle about 3 cm in diameter) on the ears and backs of rabbits, and on the ears

Fig. 1 Assembly of *Amblyomma hebraeum* nymphs (a) to male ticks which had attached to the host 8 d previously (b), to hexane extract of fed males. The method of extraction was described previously<sup>5</sup>.

Fig. 2 Percentage assembly of *A. hebraeum* nymphs to males after various periods of feeding on scrotum of calves. Vertical line represents s.e.m.

and scrotum of calves. Test areas were enclosed with large cloth sleeves and a relatively large number of unfed nymphs was deposited in the sleeves. After 24 h the sleeves were removed and the number and area of attachment of the nymphs were recorded (Table 1). No nymphs released on a host aggregated around females which had attached to a host 5 d previously or to nymphs which had attached 4 d previously.

As a control, nymphs were exposed in a similar manner to hosts which were not infested with males or were not treated with hexane extracts of males. On control hosts, nymphs attached readily, but were evenly distributed through the area covered by the cloth sleeves and no clusters of attaching nymphs were formed.

As free blood or damaged tissues around the site of attachment might have resulted in attraction of nymphs, wounds were created on the ears of rabbits using a sharp needle. Nymphs in cloth sleeves exposed to ears treated in this way showed no clustering of attaching nymphs to either free blood or damaged areas.

The time required by nymphs for attachment to the hosts on which males were attached, or to areas of the hosts which had been treated with hexane extracts of fed males, was significantly ( $P < 0.005$ ) shorter than in untreated control animals. The percentage of males emerging from nymphs which developed on hosts which had males attached, was compared with the percentage of males emerging from nymphs which developed on control animals. From all the tests examined  $46.4 \pm 8.21\%$  were males from nymphs which attached in clusters in association with a male and  $49.4 \pm 6.85\%$  were males from those that emerged from nymphs which had not aggregated around a male on the host. This small difference was subjected to statistical analysis using the  $t$  test and found to be not significant.

Table 1 Rate of assembly of *A. hebraeum* nymphs around *A. hebraeum* males

Area of host	% Assembly of nymphs (mean $\pm$ s.e.) around males which had attached to the hosts 8 d previously	% Assembly of nymphs (mean $\pm$ s.e.) attached to area where hexane extract of males was previously applied	% Assembly of nymphs (mean $\pm$ s.e.) attached to area where pure hexane was previously applied
Rabbit ear	82.1 $\pm$ 4.02	86.5 $\pm$ 3.72	7.2 $\pm$ 1.78
Rabbit back	93.3 $\pm$ 1.71	92.1 $\pm$ 2.01	9.2 $\pm$ 3.12
Calf ear	93.6 $\pm$ 1.60	84.4 $\pm$ 3.86	6.5 $\pm$ 2.08
Calf scrotum	79.5 $\pm$ 3.34	90.9 $\pm$ 4.72	2.9 $\pm$ 1.45

This clearly indicates that all nymphs are attracted to a mature male on the host, irrespective of whether they are destined to develop as males or females.

The unfed males on the host did not attract nymphs, so further examination was necessary to determine the duration of the feeding period before males would attract nymphs (Fig. 2). Larvae did not respond to the hexane extracts of adult males to which nymphs clearly responded.

In each of the tests in the choice-chamber 100 unfed nymphs were placed in the lower arm of a Y-shaped glass tube, the ends of which were enclosed with fine nylon mesh. By connecting a vacuum pump to the lower arm of the Y-tube an airflow was produced. Tick nymphs were introduced to the lower arm while test materials were placed on the anterior arms of the choice chamber. In each test two materials were compared and three counts of the distribution of the nymphs were made at 10-min intervals. After three counts all nymphs in the system were collected and reintroduced to the lower arm of the Y-tube. Each test was replicated six times. The various materials that were checked in the choice chamber were: fed males, partly engorged females, partly engorged nymphs, unfed males, unfed females, unfed nymphs, hexane extract of males and pure hexane.

The results of a series of tests showed significant ( $P < 0.002$ ;  $t$  test for paired observations) attraction of nymphs only in the tests in which fed males or hexane extract of fed males were present.

We have shown that males which fed for 8 d, or the hexane extract from such males significantly attracted nymphs, whereas males which had not been fed, or partially engorged females as well as partly engorged nymphs presented no attraction to nymphs.

We thank Dr H. Parolis for assistance and Professor R. Galun for reviewing the manuscript.

## Position-dependent development of tobacco meristems

THE apical meristems of angiosperms exhibit indeterminate growth during vegetative development and determinate growth in the production of thorns and flowers<sup>1</sup>. The mechanism(s) controlling the conversion from indeterminate

to determinate growth is poorly understood, although photoperiod and temperature have been shown in many plants to be important environmental signals for flower induction<sup>2</sup>. In 'day-neutral' plants, which are not strictly regulated by photoperiod, the conversion of their meristems to the determinate flowering condition seems to be endogenously regulated. We have examined this conversion in *Nicotiana tabacum* cv. Wisconsin 38, a day-neutral plant. Our data show that a uniform number of nodes is produced before conversion, and this pattern of meristem development is regulated by information supplied to the meristem by the plant.

Wisconsin 38 tobacco exhibits limited growth because its terminal meristem differentiates into a flower. It has strong apical dominance and its vegetative axillary buds are all arrested after the initiation of eight or nine leaf primordia. In certain environmental conditions the number of nodes produced by the terminal meristem is very uniform<sup>3</sup>, and we have observed this pattern of growth in numerous plants at various times of the year. In one set of thirty plants, an average of 35.4 nodes was produced (s.d. = 1.0).

We examined the conversion from indeterminate to determinate growth by taking the number of nodes produced by axillary buds (a single bud in the axil of each leaf) as a function of their position on the main axis. In our first experiments, plants at anthesis (first flower open) were decapitated at various internodes and the uppermost axillary bud was allowed to develop. These buds replaced approximately the number of nodes removed, with the higher buds producing fewer nodes than the lower buds (Table 1). This differential growth response might be related to the developmental state of the plant, and so we decapitated some plants at 3 stages before anthesis; when the inflorescence was visible, when the terminal meristem had just become reproductive, and when it was still vegetative (Table 1). In all cases the higher buds produced fewer nodes, suggesting that

Table 1 Nodes produced by terminal and axillary buds

State of development of decapitated plant*	Node number of bud that developed after decapitation	No. of nodes produced by bud in column two ( $\pm$ s.d.)
Anthesis (not decapitated)	Terminal	35.4 $\pm$ 1.0
Terminal meristem vegetative	1	42.8 $\pm$ 1.0
	9	28.3 $\pm$ 2.9
Reproductive terminal meristem just initiated	1	40.5 $\pm$ 1.7
	12	28.5 $\pm$ 0.6
Inflorescence visible	5	36.6 $\pm$ 1.9
	17	25.2 $\pm$ 2.5
Anthesis (first flower open)	5	39.0 $\pm$ 3.2
	17	23.2 $\pm$ 3.1
	22	13.8 $\pm$ 0.5

\*Plants were grown from seed under standard greenhouse conditions. Decapitations were made at the internode above the bud indicated and several of the axillary buds below this bud were removed so as to promote its growth. The first node is considered to be the node which produces the first leaf that hangs over the edge of a 7-inch pot. About five or six leaves are produced before this 'first' node. Nodes were numbered acropetally with node number 1 at the base.

developmental response of a bud is a function of its position on the stem. This position-dependent response could be a function of the age of the bud, of its actual position, or of the state of differentiation of the vascular connections between the bud and the main axis.

The developmental potential of isolated buds was examined by rooting buds without the use of exogenous phytohormones, and growing them to maturity. Twenty-five buds from various nodes of several plants produced 36.1 nodes (s.d.=3), indicating that they had no 'memory' of their original position, which suggests that a bud's pattern of development may depend on information received from the plant. To examine this, we grafted buds in four patterns; apical bud to apical internode, apical bud to basal internode, basal bud to basal internode, and basal bud to apical internode (Table 2). When the 21st bud was grafted to the 22nd internode and released from apical dominance by decapitation, it produced twice as many nodes as the intact 22nd bud released from apical dominance (25.3 as against 13.8), and when grafted to the 6th internode, about three times as many (37.3). A 5th bud grafted to a 6th internode produced about the same number as an intact 5th bud (41.5 as against 39.0) but  $\sim 1/3$  fewer when grafted to the 22nd internode (27.3). These results clearly show that the number of nodes produced can be altered by moving the bud up or down on the stem. The increased number of nodes produced by an apical bud that was grafted into an apical position was, however, puzzling. Since grafting involves significant injury as well as the establishment of new vascular connections, we examined the growth pattern of apical buds after severance of the vascular connections and tissues below the bud by a horizontal incision. As with grafting, this treatment resulted in an increased number of nodes (Table 2). The increased number of nodes produced is probably not primarily a response to injury, but rather reflects an altered movement of materials from the main axis to the bud and vice versa.

Our experiments have shown that the number of nodes produced by an intact axillary meristem is a function of its position on the stem. Three lines of evidence suggest that the apical meristem does not autonomously control the number of nodes produced; first, all rooted buds produce about the same number of nodes; second, grafted buds can produce more or fewer nodes than expected from the bud if it had remained intact; and third, when the tissues below a bud are cut, the bud produces more nodes than expected. Thus, the meristem seems to respond to information from the plant since the developmental pattern of a grafted bud can be altered by moving it up or down the plant. The increased number of nodes produced by grafting or cutting the tissues below an apical bud suggests, however, that appropriate transmission of this information may not occur through newly regenerated tissues. It is also possible that the temporary separation of the bud from the lower part of the plant may disrupt a positional information signal and thereby lead to an altered developmental response. In any event, the state of differentiation of the tissues connecting the bud with the main axis seems to be very important in maintaining developmental growth potential.

The observations that *N. tabacum* plants produce a uniform number of nodes in certain environmental conditions<sup>3</sup> and that various axillary buds from a single plant can express different growth potentials<sup>4,5</sup> are not unique. The experimental demonstration that the number of nodes produced by an organised meristem before commencing determinate growth is a function of the total number of nodes in the plant has not, however, been reported previously. This suggests that the terminal meristem (an axillary meristem—grafted or intact—becomes the terminal meristem after decapitation) receives information from the plant which orients the cells of the meristem in terms of their place on the main axis. This orientation in turn

Table 2 Nodes produced after grafting or wounding

Treatment	Node number of bud that developed†	No. of nodes produced by bud in column two ( $\pm$ s.d.)
Grafting*		
21st bud to 22nd internode	21	25.3 $\pm$ 2.1
21st bud to 6th internode	21	37.3 $\pm$ 1.3
5th bud to 6th internode	5	41.5 $\pm$ 2.6
5th bud to 22nd internode	5	27.7 $\pm$ 0.4
Wounding		
Decapitated—not wounded	26	15.8 $\pm$ 3.8
Decapitated—wounded below node 26†	26	22.5 $\pm$ 0.6

\*The bud to be grafted was removed by cutting round the bud through the vascular tissues to the pith and then lifting off the patch containing the bud. At the graft site the bud was slipped into a T-shaped cut and wrapped with parafilm for several days. After 10 d the plant was decapitated above the grafted bud.

†Plants were wounded by making a cut 1.5 cm below the bud and half way through the stem. Post-wound treatment was the same as for grafted buds.

‡Nodes were numbered acropetally with node number 1 at the base.

determines the future developmental pattern. The orientation signal might be one or more chemical gradients which change as the number of nodes increases, and at a critical value of the concentration of the chemicals, the meristem cells alter their gene expression so that floral development ensues. This idea is supported by the work of Schwabe and Al-Doori<sup>6</sup> who proposed that a gibberellic acid (GA) gradient in the black currant (*Ribes nigrum*) may be responsible for the flowering response of axillary meristems. They have shown that the ability of an axillary meristem to flower in short-day photoperiods is directly related to its position on the main axis, and that this response is correlated with the GA gradient.

This regulation of pattern development may be analogous to a model of animal pattern development, where differential gene expression is thought to be intimately related to the orientation of a cell within a developing structure or organism, and that this orientation involves the reception and interpretation of a positional information signal<sup>7</sup>. Although the model has not often been used in studies of pattern development in plants<sup>1,7</sup>, positionally-related development of shoots and leaves has been observed in numerous plants<sup>4,5,8,9</sup>. These observations and the above results suggest that the use of a positional information model could introduce new ways of examining and interpreting developmental patterns in plant systems.

We thank Dr Ian M. Sussex for his help, and Dr Walter Auclair for criticism. We are indebted to Mr Len Sablitz and his staff for their care of the plants. This work was supported by grants from the American Cancer Society and the National Institutes of Health.

## Unique Golgi apparatus and vesicle formation in a red alga

THE morphology of the Golgi apparatus, as well as the kind and quantity of Golgi-derived vesicles, has been observed to change considerably during carposporogenesis (production of diploid reproductive spores<sup>1</sup>) in red algae<sup>2,3</sup>. In *Polysiphonia* the Golgi is initially active in the production of vesicles destined for wall formation (unpublished), the same function as reported in other red algae<sup>2,3</sup>. At this stage in early development, crystalline structures termed "striated vesicles" have been observed to form within rough endoplasmic reticulum (ER)<sup>2,4</sup>. As carpospore development proceeds the striated vesicles diminish in size and eventually disappear (unpublished). Coinciding with this disappearance is a unique change in the form and function of the Golgi apparatus. The striated vesicles are replaced in the cytoplasm by Golgi-derived vesicles with a crystalline content, their structure and periodicity being different from the striated vesicles. The Golgi apparatus gradually differentiates into its new role, and is not replaced by a new system. Golgi with a similar morphology and function have not been observed before for any cell.

Sexual plants of *Polysiphonia novae-angliae* Taylor were collected in July 1972, at Naushon Island, and in June 1973, at West Falmouth, Massachusetts. The methods used to prepare for electron microscopy have been described before<sup>4</sup>. Figure 1 shows completely differentiated Golgi active in the formation of vesicles with a crystalline content. Mitochondria (m, Fig. 1a) are observed at the base of the forming Golgi face, a situation which is typical throughout carpospore differentiation<sup>2,3</sup>. Proximal cisternae arise from the fusion of ER-derived vesicles which contain a dark osmiophilic material (arrows, Fig. 1c). The periphery of proximal cisternae are swollen with dark osmiophilic regions surrounded by a less dense material (a, Fig. 1a-c). As cisternae mature and are displaced towards the distal Golgi face, the material surrounding the dark osmiophilic regions becomes fibrous with a distinctive pattern and spacing (b, Fig. 1a-c). The osmiophilic regions are not continuous, but somewhat spherical and periodically spaced within a single cisterna. Therefore, they may appear absent in some sections. The fibrous structure gives way to a dark grey, uniformly stained vesicle at the distal pole (c, Fig. 1a and b). The osmiophilic regions then disappear (d, Fig. 1b) as the cut off vesicles take on a fibrous crystalline pattern (e, Fig. 1a, b and d). Ribosomes are not observed to be associated with the membrane surrounding these Golgi-derived vesicles. The vesicles remain in the cytoplasm for a short period in development and then gradually disappear. At this time the Golgi apparatus once again changes in form and function, producing yet another kind of vesicle (unpublished).

It is interesting that the change in Golgi function reported here corresponds exactly with the disappearance of the striated vesicles formed by the rough ER. There may be some correlation between this disappearance and the concurring Golgi differentiation. The dark osmiophilic regions seen in developing cisternae arise during the formation of cisternae, the material having the same appearance as the contents of the fusing ER vesicles at the proximal face. As the periphery of the maturing cisternae enlarge, most contents undergo structural change whereas the osmiophilic regions seem unaltered until near maturity. Contents therefore seem segregated in individual developing cisternae, one transferred from the ER, the other synthesised within the Golgi. Only in mature vesicles do the contents become uniform. Several different types of

**Fig. 1** a, Mature Golgi apparatus active in the production of crystalline vesicles. Mitochondria (m) are located at the base of the proximal Golgi face when sectioned through that region. a, Initial stage in maturation of cisternae. Note the dark osmiophilic region surrounded by a less dense material. b, Stage in maturation of cisternae. Osmiophilic regions are surrounded by a fibrous material. c, Vesicle just before crystalline structure arises. d, Osmiophilic region disappearing in mature vesicle. e, Separated vesicles with crystalline structure. secretory cells are known to use the Golgi apparatus for the concentration and transport of protein to the exterior of the cell<sup>5-7</sup>. The combination of protein with other products during this process has likewise been suggested<sup>6,7</sup>. Crystalline structures described within other cells have consistently been determined to be at least partially proteinaceous<sup>9,10</sup>. This is the first observation of Golgi-derived vesicles with a crystalline content; since these vesicles are

retained in the cytoplasm only for a short period during development, evidence suggests that the Golgi has a role in the transformation and turnover of protein within differentiating carpospores. Golgi apparatus with a similar fine structure and function have not been reported before.

## Possible regeneration of $\gamma$ -aminobutyric acid-containing fibres into irides transplanted into the central nervous system

IRIDES transplanted into the central nervous system (CNS) of the rat provide a good substrate for regenerative ingrowth of central noradrenergic and cholinergic fibres to 'reinnervate' the denervated iris<sup>1-3</sup>. Fluorescence histochemistry or acetylcholinesterase staining reveals that the regenerating noradrenergic or cholinergic fibres will produce an innervation that closely mimics the original noradrenergic or cholinergic innervation<sup>1-3</sup>. Physiological experiments<sup>4</sup> on portal vein transplants indicate that functional adrenergic and cholinergic terminals are formed, and it seems likely that functional neuromuscular junctions are also re-established in the iris transplants. In addition to supporting the ingrowth of noradrenergic and cholinergic fibres, fluorescence histochemistry<sup>5</sup> reveals that 5-hydroxytryptamine- and dopamine-containing fibres will also grow into iris transplants, albeit less extensively than noradrenergic fibres. This ability of the iris to support regenerative ingrowth by fibres not entirely appropriate for normal reinnervation suggested to us that the iris might also support regenerative ingrowth by fibres containing putative amino acid transmitters.

As a possible marker for  $\gamma$ -aminobutyric acid (GABA) terminals we choose to measure the GABA synthetic enzyme, glutamic acid decarboxylase (GAD). GAD is located in nerve terminals and is concentrated in areas of the brain where GABA is believed to act as a neurotransmitter<sup>6,7</sup>. We demonstrate here that irides transplanted into the adult rat CNS show increasing levels of glutamic acid decarboxylase consistent with the ingrowth of GAD containing fibres. In addition, using a microdansylation assay<sup>8</sup> we have measured the more concentrated amino acids in the transplants and in normal and sympathectomised irides, and found substantial increases in levels of GABA, glutamate and glutamine in the transplants, which would be consistent with regenerative ingrowth of fibres

containing relatively high concentrations of these amino acids.

The experiments were carried out on adult female Sprague-Dawley rats (180-200 g body weight). Autologous transplantations of the iris were made in two brain sites; one in the hippocampal fimbria and the rostral hippocampus (CA3), as described earlier<sup>3</sup>, and a second in the head of the caudate nucleus (unpublished). In both sites the transplants survive well with little bleeding and become reinnervated by acetylcholinesterase-containing fibres, and in the caudate site by dopamine-containing fibres as well. All animals were subjected to cranial sympathectomy through bilateral extirpation of the superior cervical ganglia. In addition, as a control site, irides were transplanted to the anterior eye chamber<sup>3</sup>. In one experiment irides transplanted to the caudate nucleus 21 d earlier were transplanted to the anterior eye chamber. Here, they were allowed to survive for another 4 d. GAD levels were initially measured by <sup>14</sup>CO<sub>2</sub> evolution<sup>9,10</sup> in the presence of 0.5% Triton X-100, a concentration recently shown<sup>11</sup> to reduce the possible formation of <sup>14</sup>CO<sub>2</sub> by glutamate entering the tricarboxylic acid cycle as a ketoglutarate.

The results are summarised in Fig. 1, and the assay conditions given in more detail in Table 1. In both the caudate nucleus and the fimbrial-hippocampal site there was a marked increase in GAD in the transplants, its appearance following a time development similar to that of the in-

**Table 1** Comparison of glutamic acid decarboxylase activity in normal and sympathectomised irides, and in irides transplanted to caudate and fimbrial sites

	GABA production (nmol per mg protein per h)	<sup>14</sup> CO <sub>2</sub> production (nmol per mg protein per h)
Normal iris	< 0.080 (3)	2.38 ± 0.6 (12)
Sympathectomised iris	< 0.080 (3)	3.38 ± 0.7 (6)
Iris transplant to anterior eye chamber (26 d after transplantation)	—	2.7 ± 1.7 (6)
Caudate transplant (21 d GABA production, or 26 d <sup>14</sup> CO <sub>2</sub> production)	4.47 ± 1.16 (5)**	14.9 ± 1.2 (6)*
Fimbrial transplant (21 d GABA production or 14 d <sup>14</sup> CO <sub>2</sub> production)	4.23 ± 0.67 (3)**	10.5 ± 1.6 (6)*

Values are means ± s.d. Means were derived by Student's *t* test (two tailed) \**P* < 0.05, \*\**P* < 0.01. The figures in parentheses are numbers of replicates. <sup>14</sup>CO<sub>2</sub> production was measured using the micromodification of the method of Albers and Brady<sup>9</sup> described by Fonnum *et al.*<sup>10</sup>. DL-1-<sup>14</sup>C-glutamate (58 mCi mmol<sup>-1</sup>, New England Nuclear) was used as substrate. 2 µl of an iris homogenate (≈ 1.0 mg per 20 µl buffer) was incubated for 1 h with a substrate containing final concentrations: L-1-<sup>14</sup>C-glutamate, 0.30 mM; K-L-glutamate, 4.03 mM; potassium phosphate buffer (pH 6.5), 40.3 mM; pyridoxal-5-phosphate, 0.260 mM; dithiothreitol, 2.38 mM and 0.5% Triton X-100. <sup>14</sup>CO<sub>2</sub> was evolved by adding a drop of 1 M sulphuric acid and <sup>14</sup>CO<sub>2</sub> collected in a separate microtube containing 50 µl solene (Packard). <sup>14</sup>C-GABA production was measured using L-(U)-<sup>14</sup>C-glutamate (290 mCi mmol<sup>-1</sup>, Radiochemical Centre, Amersham). 10 µl of iris homogenate (≈ 1.0 mg per 10 µl) was incubated for 3 h with a substrate containing final concentrations: L-(U)-<sup>14</sup>C-glutamate, 0.17 mM; K-L-glutamate, 3.4 mM; potassium phosphate buffer (pH 6.5), 34 mM; pyridoxal-5-phosphate, 0.44 mM; dithiothreitol, 3.9 mM; 0.25% Triton X-100 and 1.35 µM amino-oxycetic acid. The reaction was stopped by addition of 0.96 N perchloric acid, the protein centrifuged down and the pellet used for protein determination by the method of Lowry *et al.*<sup>13</sup>. The supernatant (20 µl) after neutralisation with 2 M potassium carbonate was reacted with 20 µl dansyl chloride (2 mg ml<sup>-1</sup>) (British Drug Houses) for 2 h, evaporated to dryness and taken up in 20 µl acetone-acetic acid (3:2, v/v). The total volume was applied to full size polyamide plates and dansyl GABA separated by chromatography as described by Joseph and Haliday<sup>7</sup>. <sup>14</sup>C-GABA standards were taken through the procedure to correct for recovery. There was no spread of the labelled substrate (dansyl glutamate) to contaminate the dansyl GABA spot and no significant radioactivity was detected outside these spots. The limit of sensitivity of this assay, double the blank value, was equivalent to ≈ 0.25 pmol.

**Fig. 1** Glutamic acid decarboxylase activity of irides transplanted to a fimbrial-hippocampal site (—), a caudate site (---) and an ocular site (.....). Values are means  $\pm$   $\sigma$  of at least five separate determinations at each time point. Differences from normal iris were compared using Student's *t* test (two tailed) \**P* < 0.05, \*\**P* < 0.01.

growth of regenerating monoaminergic and cholinergic fibres (see refs 2, 3 and unpublished observations). The increase in GAD cannot be a response to denervation alone, as sympathectomy (Table 1) does not significantly alter the level of GAD in the iris. Moreover, the increase in GAD does not occur after transplantation of the iris to the anterior eye chamber (Fig. 1). In fact, there seemed to be a temporary decrease in GAD levels suggesting that some of the GAD activity of the normal iris might reside in the muscle coat which, during the early stages after transplantation, undergoes degeneration<sup>12</sup>.

The reduction in <sup>14</sup>CO<sub>2</sub> production seen in the 4-d-old irides transplanted to the anterior eye chamber indicates the problems of correlating <sup>14</sup>CO<sub>2</sub> evolution with glutamic acid decarboxylase activity. For this reason we felt it necessary to also measure GAD by GABA production from L-(U)-<sup>14</sup>C-glutamate (Table 1). The results show that in both the caudate and the fimbrial-hippocampal sites definite GABA formation occurred in the transplanted irides, whereas GAD activity was low or absent in the normal or sympathectomised irides. Measured in this way there was a 100-fold increase in GAD activity in the CNS implants over the normal or sympathectomised irides. The

average GAD activity of the transplants measured by <sup>14</sup>C-GABA formation was, however, less than that observed with the CO<sub>2</sub> evolution assay. These differences were not great and could readily be explained by the normal variations in GAD activity of the transplants and by the fact that the GAD assay is undoubtedly no longer linear after 3 h incubation. Three hours was chosen, to ensure sufficient counts in the dansyl-GABA spot; the apparent GAD activity would be greater if the incubation were performed over 1 h. The very small amount of GABA formed in the normal iris (in some cases no formation was detected) confirms our suggestion that basal level of GAD activity in the normal iris as measured by <sup>14</sup>CO<sub>2</sub> production is not related to GABA formation but rather probably represents glutamate metabolism by other pathways to yield <sup>14</sup>CO<sub>2</sub>.

In addition to demonstrating the appearance of significant levels of GAD in the transplanted irides it was of great interest to look at changes in the levels of amino acids in the irides after transplantation to the two brain sites (Table 2). In both the caudate and fimbrial-hippocampal sites there were significant increases in GABA, glutamate and glutamine above the levels in normal or sympathectomised irides. In contrast, the levels of taurine, glycine and aspartate did not change significantly. The level of GABA (2.3–2.5  $\mu$ mol per g protein) correlates well with the level of GAD (20–30  $\mu$ mol per h per g protein) and the ratio of GABA–GAD is similar to that found in the caudate nucleus or hippocampus and other sites believed to contain GABA terminals<sup>14,15</sup>. Glutamine may have an important role in GABA metabolism or ammonia formation<sup>16</sup>. It seems possible, therefore, that the appearance of GABA and glutamine in the central implants both reflect the ingrowth of GABA-ergic fibres. This might be the case with glutamate as well, but it also seems possible that glutamate could be found in a separate, glutamate-rich fibre type (see refs 15, 17–20).

These various results are consistent with a growth into the transplanted irides of GABA-synthesising and GABA-containing elements from the brain tissue surrounding the transplantation site. There are two possible, though unlikely, objections to this interpretation. First, the increased GAD and amino acid levels could arise from a growth of fragments of retinal tissue (which contain both GAD and GABA) which might be attached to the iris transplant. This can be excluded, however, since adult retinal tissue does not survive transplantation to the CNS sites used

**Table 2** Amino acid levels in transplants from fimbrial-hippocampal and caudate sites (21 d post transplantation)

Amino acid	Normal iris ( <i>n</i> = 3)	Sympathectomised iris ( <i>n</i> = 3)	Caudate transplant ( <i>n</i> = 5)	Fimbrial-hippocampal transplant ( <i>n</i> = 4)	Caudate nucleus ( <i>n</i> = 3)	Hippocampus ( <i>n</i> = 4)

Taurine	4.01 $\pm$ 0.87	4.22 $\pm$ 0.54	3.41 $\pm$ 0.4	4.0 $\pm$ 0.87	5.82 $\pm$ 0.25	4.75 $\pm$ 0.28

Levels in transplants are compared with amino acid levels in the normal and sympathectomised iris and with levels in the caudate nucleus and hippocampus. Units are  $\mu$ mol per 100 mg protein.

Means were compared with Student's *t* test (two tailed) \**P* < 0.05, †*P* < 0.01, ‡*P* < 0.001. ( ) indicate significance if normal and sympathectomised iris data are pooled for comparison with fimbrial and caudate transplants. Amino acid levels were determined using the microdansylation assay for amino acids described in detail by Joseph and Haliday<sup>7</sup>. Because of the small amounts of tissue in the iris samples (0.8–1.5 mg wet weight) the samples were homogenised in 10  $\mu$ l of 0.48 M perchloric acid, and after centrifuging 2  $\mu$ l of the <sup>14</sup>C-amino acid mixture (GABA, glycine, glutamine, glutamate and aspartate, Radiochemical Centre, Amersham) and 2  $\mu$ l 2 M potassium carbonate were added to the supernatant and the sample again centrifuged to remove the precipitated perchlorate. An aliquot of the supernatant (2  $\mu$ l) was reacted with <sup>3</sup>H-dansyl chloride (5.1 mCi  $\mu$ mol<sup>-1</sup>, Radiochemical Centre, Amersham) for 30 min at room temperature after which the sample was evaporated to dryness. The dansylated sample was redissolved in 5  $\mu$ l acetone–acetic acid (3:2, v/v) and 0.3  $\mu$ l applied to small polyamide plates 3.5 cm<sup>2</sup>. The dansylated amino acids were separated using the solvents described by Joseph and Haliday<sup>7</sup>, the spots visualised, cut out and the <sup>3</sup>H–<sup>14</sup>C ratio determined by two-channel liquid scintillation spectrometry. The <sup>3</sup>H–<sup>14</sup>C ratio is independent of recovery and degree of dansylation. Suitable standards and blocks are run simultaneously and the amount of amino acid determined from standard values. Protein content of the pellets was determined by the method of Lowry *et al.*<sup>13</sup>.

**Table 3** Effects of chloride ions (as sodium chloride) on apparent GAD activity in irides transplanted into caudate nucleus (21 d survival), in control caudate nucleus tissue, and in tissue from the pineal gland

	No chloride in incubation mix (GAD)	200 mM chloride in incubation mix (GAD)	Enzyme assayed	Irides transplanted from caudate nucleus (21 d survival) to anterior eye chamber (4 d survival)	Irides transplanted to caudate nucleus (26 d survival)
Irides transplanted to caudate nucleus (21 d survival)	12±3.2	6.1±3.4*	GAD	ND	14.9±1.2
Pineal gland	9.3±1.1	8.9±1.0	ChAT	< 0.14(*)	89±10
Caudate nucleus	223±14	129±21*	AAD	ND	5.9±0.4

The table also shows the effects of retransplantation on GAD activity, choline acetyltransferase activity (ChAT) and aromatic amino acid decarboxylase activity (AAD) in irides transplanted to the caudate nucleus and then retransplanted into the anterior eye chamber of a different rat. For comparison, enzyme levels from iris transplants removed from the caudate nucleus site after 26 d and then assayed for ChAT, AAD and GAD are shown (this paper and Emson, Björklund and Stenevi, unpublished). Values are means ± s.d. Units are nmol per mg protein per h. Means were compared using Student's *t* test (two tailed) on paired or unpaired samples. \**P* < 0.001, (\*) paired *t* test, *P* < 0.001. ND = not detectable.

(unpublished observations), and since identical transplants to the anterior eye chamber (which is a comparable or even better transplantation site than the brain) did not show the increased GAD levels. Second, it might be argued that, in removing the iris transplants from the brain, we are also removing trace amounts of surrounding tissue rich in GAD and amino acids. We were aware of this possibility and paid particular attention during dissection to removing all brain tissue fragments visible under high magnification in the dissection microscope. Random identical specimens were also taken for microscopic analysis showing that the amount of adhering tissue was minimal, at least up to ~ 1 month after transplantation. The amount of tissue adhering would, moreover, need to be fairly substantial to account for the GAD levels observed. The GAD level in the caudate nucleus is 217 μmol per h per g protein<sup>14</sup>, whereas the GAD activity in the best caudate implants was 30–40 μmol per h per g protein. To account for the weight GAD activity in a transplant (~ 0.8 mg wet weight) we would need ~ 100 μg of adhering tissue, an amount we would be most unlikely to fail to detect. It is also obvious that if adhering tissue would account for the observed increases in amino acid levels in the transplants, then the increases should reflect the relative abundance of the various amino acids in the tissue surrounding the transplant. This was not the case (see Table 2).

Thus, it seems likely that the observed increases in enzyme and amino acid levels in the centrally transplanted irides resulted from the growth of tissue elements from the surrounding, lesioned brain tissue. To the extent that GAD and the GABA-GAD ratio can be taken as good markers for GABA-containing terminals in the brain, the GAD and GABA levels in the implanted tissue should provide good measures of the sprouting of regenerating GABA-ergic fibres into the implant from the lesioned brain tissue. The likely origin of such sprouting GABA- and GAD-containing fibres would in both the caudate and the hippocampal sites seem to be the local GABA-ergic interneurons which have been demonstrated in these brain regions<sup>21,22</sup>.

The most obvious difficulty in the interpretation of the present findings is to evaluate the contribution of glial cells to the observed increases in enzyme and amino acid levels in the transplanted irides. The strong increase in glutamine in the transplants might be an indication for this, since this amino acid may be relatively concentrated in glial cells<sup>16</sup>. Also GAD is known to occur in glial cells<sup>16</sup>, and we could not exclude the possibility that the GAD (as well as the GABA and glutamate) we measure is located at least partly in glial cells. To obtain further evidence of the neuronal localisation of the GAD activity, we carried out an experiment designed to effect a denervation of the reinnervated transplant. Irides were transplanted to the caudate nucleus as above, and allowed to survive 21 d.

After 21 d, when the GAD levels in the transplant (as measured by the CO<sub>2</sub> evolution assay) were near maximal, the animals were killed, and the transplants dissected out from the caudate nucleus. The iris was then retransplanted into the anterior eye chamber of another rat. Here, the iris remained for 4 more days—a survival time that would allow for the degeneration of fibres that had previously regenerated into the transplant—and was then assayed for GAD, choline acetyltransferase (ChAT) and aromatic amino acid decarboxylase (AAD). As shown in Table 3 there was a complete or almost complete loss of all three enzymes. These results are consistent with a degeneration of cholinergic, dopaminergic and GABA containing terminals that had grown into the transplant while being in the caudate nucleus. A further pointer to the probable neuronal origin of the GAD in the transplant is shown by its response to Cl<sup>-</sup> ions<sup>23</sup>. GAD activity in the pineal gland, which is believed to be exclusively glial in origin, was not significantly reduced by the addition of Cl<sup>-</sup> ions, whereas the activity in the transplants—like that in the caudate nucleus—was reduced some 50% (*P* < 0.001).

Very little is known about the regeneration of GABA neurons. Baxter and Torralba<sup>24,25</sup> have provided some evidence for regeneration of GABA neurons in insects. Recent studies (see refs 2 and 3) have shown that many non-myelinated axon systems in the adult mammalian CNS have a high capacity for regenerative sprouting. The present results are compatible with the idea that this is the case also for non-myelinated GABA-ergic interneurons in the hippocampus and the caudate nucleus. If this is so our observations constitute the first direct evidence for regeneration of GABA neurones in the adult mammalian CNS.

## Absence of transient tritanopia after adaptation to very intense yellow light

STILES reported<sup>1</sup> that after the eye had been adapted to light of high intensity and long wavelength, its sensitivity to violet test flashes did not recover according to the familiar dark-adaptation curve. Instead the threshold intensity for detecting short-wavelength flashes increased when the adapting field was turned off, and the peak sensitivity of the eye lay at long wavelengths. Yet it was by using very similar conditions that Auerbach and Wald<sup>2</sup> isolated a photoreceptor with peak sensitivity in the violet. This contradiction has not been resolved. Transient tritanopia (as we have provisionally termed the loss of sensitivity found by Stiles) has been reported by others<sup>3-6</sup> and an electrophysiological counterpart has been described<sup>7</sup>, but equally there are findings that resemble the contrasting result of Auerbach and Wald<sup>8,9</sup>. Attempting to resolve this contradiction, we have discovered a second surprising property of transient tritanopia.

Although our previous measurements had shown that the phenomenon occurred over a large range of adaptation intensities, and became more marked as the intensity of the adaptation field increased<sup>10</sup>, we had not used fields quite as intense as the 6.0–7.0 log trolands used by those who had found that adaptation left the eye blue-sensitive, rather than blue-blind. Moreover, the suprathreshold hue-shift described previously<sup>5</sup> does not occur if the adapting field is too bright. Stiles worked with a red field of 4.3 log trolands. We have therefore measured sensitivity to short wavelengths after adaptation to retinal illuminances that varied over the range 1.1–6.0 log trolands.

Blue (445 nm) test flashes were presented 400 ms after extinction of a yellow adapting field. Target flashes subtended 1° of visual angle, were presented to the fovea and lasted 15 ms. To secure very intense adapting fields, the interference filter previously used in the adapting beam<sup>5</sup> was replaced by a gelatin spectral filter (Ilford No. 626) which has a peak transmission at 575 nm and a bandwidth at half height of 35 nm. The test flashes and the adapting field were concentric and were presented in Maxwellian view. Fixation was guided by four illuminated points that were arranged in a diamond with a vertical and horizontal separation of 3° and were adjusted in intensity so that they were just clearly visible against a particular adaptation field. For 3 s every 18 s the adapting field was interrupted by a dark interval and a single target flash was presented 400 ms after the field had been turned off. (We chose 400 ms because at this delay the brief increase in threshold found for white light<sup>11</sup> has ceased, but transient tritanopia is still marked<sup>1</sup>.) The experiment was under computer

Fig. 1 Ordinate, threshold intensity at which blue target detected; abscissa, intensity of adapting field. ○, Log threshold intensity for detecting blue flash when a steady yellow field is present (conventional increment-threshold function); ●, threshold 400 ms after adapting field has been turned off (means of two runs). Field intensity marked *a* corresponds to adaptation level that gave results of Fig. 2, that marked *b* corresponds to level that gave results of Fig. 3. Observers: I.D.M. (upper panel), P.G.P. (lower panel).

control and the threshold for detecting the flash on 50% of trials was measured by a double staircase procedure<sup>12</sup>. No data were gathered until the field had been cycling on and off for 4 min. Each estimate of the threshold was based on 50 trials.

Figure 1 shows results for two observers. When the field was present and was between 2.0 and 4.5 log trolands the mechanism responsible for detection was that termed  $\pi_1$  by Stiles: note that transient tritanopia occurred even for fields that did not significantly adapt  $\pi_1$  in the steady state. As the field increased to 5.0 log trolands there was an increasing difference between the threshold measured in the steady state and that measured 400 ms after the adapting field had been turned off. As Fig. 2 shows, however, the mechanism mediating detection of the flashes after extinction of a field of 4.58 log trolands had the spectral sensitivity of  $\pi_1$ , Stiles' green-sensitive mechanism, and thus the true extent of the suppression of the blue cone mechanism is concealed in this range of adaptation illu-

minance the theoretical threshold for  $\pi_1$  must lie above the solid circles of Fig. 1.

The most unexpected results were found at an adaptation illuminance of about 5.0 log trolands. As the field that was turned off became brighter, the threshold fell precipitously. In other words, the eye became more sensitive to short wavelengths as the luminance of an adapting field was increased. Moreover, it was now a blue-sensitive mechanism that became responsible for detection of the 445-nm targets. Figure 3 shows the spectral sensitivity of the eye 400 ms after a field of 5.47 log trolands has been turned off; this can be compared with Auerbach and Wald's Fig. 4 (ref. 2) and contrasted with our Fig. 2.

It now seems clear why there are two apparently contradictory reports in the literature. Stiles<sup>1</sup> used an adapting field of 4.3 log trolands whereas those who did not report transient tritanopia<sup>2,8,9</sup> used more intense fields. (The experiment of Norren and Padmos<sup>8</sup> has a second relevant feature: an initial white bleaching field was replaced by an intense long wavelength field designed to preserve the light adaptation of the red- and green-sensitive mechanism while the recovery of the blue-sensitive cones was followed. If transient tritanopia arises when a recovering long-wavelength mechanism inhibits or masks the signals from the blue-sensitive cones<sup>5</sup>, we should not expect the phenomenon in the conditions used by Norren and Padmos.) A difficulty for this resolution is posed by the results of Das<sup>3</sup>, who reported transient tritanopia after adaptation to a field of " $1.86 \times 10^6$  trolands"; but there is a discrepancy between this value and the abscissa of his Fig. 1.

The recovery of sensitivity at adaptation illuminances above 5.0 log trolands is sudden: in the case of both observers the function relating threshold to adaptation illuminance has a maximum slope steeper than  $-2$ . Although little is known about this phenomenon, the recovery looks like a disinhibition and a working hypothesis might be that the point at which the threshold collapses represents the retinal illuminance at which some mech-

**Fig. 2** Sensitivity of eye to short wavelengths 400 ms after a yellow adapting field of 4.58 log trolands has been turned off. Ordinate, reciprocal of intensity required to detect a test flash of varying wavelength. Conditions as for main experiment, except that several test wavelengths and only one adaptation intensity were used. Observer: P.G.P. Solid curve, Stiles' field sensitivity function for  $\pi_4$  displaced vertically to give best fit to experimental points.

**Fig. 3** Spectral sensitivity of eye 400 ms after extinction of a yellow field of 5.47 log trolands. Ordinate, reciprocal of intensity required to detect a test flash of varying wavelength. Observer: P.G.P. Solid function fitted to short wavelength points is Stiles' field sensitivity function for  $\pi_1$ .

anism more sensitive to the long wavelength field has become too bleached, or otherwise too refractory, to inhibit or mask the blue-sensitive mechanism during early dark adaptation. Thus our results add to the suspicion<sup>8</sup> that transient tritanopia represents not a direct effect of the extinction of the field on the blue cones but the inhibition or masking of the signals of the blue cones by a mechanism with different spectral sensitivity. The collapse of transient tritanopia in Fig. 1 occurs at approximately the field intensity at which the mechanism termed  $\pi_3$  by Stiles replaces  $\pi_1$  in the normal increment-threshold function: the inhibition seen in transient tritanopia is possibly related to an inhibition that marks the difference between  $\pi_1$  and  $\pi_3$  in the steady state. ' $\pi_1$ ' may represent those conditions in which the gain of the blue-sensitive mechanism is controlled by a long wavelength mechanism as well as by quanta absorbed directly by the blue-sensitive pigment.

Fields of  $\sim 10^8$  trolands bleach a substantial fraction of the rhodopsin in the retina within 30 s (ref. 13) and prolonged observation of such fields (for example, in making the measurements of Fig. 3) left us with after-images that lasted for as long as 7 d. Stiles has told us that he noticed such after-images when working in similar conditions, and Brindley<sup>14</sup> reported an after-image lasting 8 months, which was the cumulative result of repeated adaptation to high intensities. Although we can ourselves detect no permanent damage, we recommend caution in repeating our measurements: only one eye should be used and the possible dangers should be explained to all subjects.

## Restoration of sensitivity of cultured hepatoma cells to cyclic nucleotides shows permissive effect of dexamethasone

CULTURED rat hepatoma cell lines H-35, HTC and RLC respond to glucocorticoid hormones and have revealed details of how these steroids regulate the activity of tyrosine aminotransferase (TAT) that could not have been learned using intact liver<sup>1–4</sup>. Unfortunately, the apparent lack of other regulatory mechanisms normally present in liver often limits the usefulness of these lines. For example, although cyclic AMP or its dibutyryl derivative reproducibly cause a several-fold induction of TAT in adult<sup>5</sup> and foetal rat liver<sup>6</sup> and in the H-35 (refs 7 and 8) and RLC<sup>9</sup> hepatoma cell lines, these compounds have generally been found to be ineffective inducers of HTC cell tyrosine aminotransferase<sup>8–10</sup>. Taken with the demonstration that HTC cells have marginally detectable levels of adenylate cyclase and cyclic AMP, this insensitivity to cyclic nucleotides led to the suggestion that glucocorticoid induction does not depend on cyclic AMP<sup>10</sup>. The following evidence suggests that the converse may not be true: TAT induction by dibutyryl cyclic AMP (db cyclic AMP) in adult rat liver is reduced by adrenalectomy<sup>11</sup>; combinations of db cyclic AMP and steroids result in synergistic induction in rat liver and liver organ culture<sup>5</sup>; and cortisol increases the absolute degree of induction of TAT by db cyclic AMP in some responsive hepatoma cell lines<sup>8,12</sup>. This putative inter-relationship could be clarified if a cell line, otherwise unresponsive to cyclic nucleotides, could be made to respond to these agents by adrenal steroid hormones. This report describes such an accomplishment and suggests that HTC cells are a model system for studies of the permissive effects of glucocorticoid hormones.

Addition of 1 mM db cyclic AMP to HTC cells grown in suspension for 1–5 d in modified Swim's S77 medium<sup>9</sup> results in no increase in TAT activity over the basal value (Fig. 1). This lack of induction<sup>10</sup> has repeatedly been demonstrated in our line of HTC cells and those of others<sup>8,9</sup> and thus seems to represent a stable trait. Two groups have found a small (35–50%) increase in TAT activity when db cyclic AMP was added to monolayer cultures of HTC cells<sup>12,13</sup>. If significant, this induction may reflect different culture conditions or variant strains, and resolution of this difference awaits further experimentation. Supplementation of the standard medium with 5  $\mu$ M dexamethasone results in 15- to 20-fold induction of HTC cell TAT, a process which has been shown to be attributable to an increased rate of synthesis of the enzyme<sup>3</sup>. Addition of 1 mM db cyclic AMP to these steroid-treated cells results in a further increase in TAT-specific activity (Fig. 1). This 'reinduction'—so-called because it is again possible to elicit a response associated with normal hepatocytes, and to differentiate it from superinduction<sup>4</sup> and deinduction<sup>14</sup> which define specific aspects of TAT regulation—is evident 24 h after addition of dexamethasone to the medium, persists for at least 5 d if hormone is kept in the

medium, and has been consistently demonstrated for the past 18 months. The extent of reinduction, greatest on day 4 of this experiment, represents an increase in activity of 100 mU per mg protein, and thus is equivalent to a tenfold induction over the basal value of 10 mU per mg protein. Reinduction requires specific nucleotides. Although *N*<sup>6</sup>-monobutyryl cyclic AMP is also effective, cyclic AMP, cyclic GMP, adenosine and sodium butyrate do not work (data not shown).

The kinetics of reinduction are shown in Fig. 2. TAT activity begins to increase 60–90 min after addition of db cyclic AMP and maximal levels are achieved between 4–6 h. This time course resembles that seen when db cyclic AMP is added to RLC cells, a cell line in which we have found TAT to be inducible in the absence of glucocorticoid hormones<sup>9</sup>.

To investigate whether reinduction of TAT in HTC cells requires protein synthesis, 0.1 mM cycloheximide was added 30 min before addition of db cyclic AMP. This concentration, which inhibits protein synthesis by 95% and prevents steroid induction if added before the hormone<sup>2</sup>, also completely blocks the additional induction of TAT seen when 1 mM db cyclic AMP is added to HTC cells grown in medium supplemented with dexamethasone (Table 1). Thus continued protein synthesis is required for the expression of reinduction. Preliminary experiments using a highly specific anti-TAT antibody suggest that there is a parallel increase in TAT antigenic and catalytic activity with reinduction, and that there is a specific increase in the rate of synthesis of the enzyme. Reinduction thus seems

**Fig. 1** Restoration of sensitivity of HTC cells to db cyclic AMP. HTC cells were grown in a modified Swim's S77 medium<sup>9</sup> supplemented with 5% foetal calf and 5% calf sera heat inactivated at 56 °C for 30 min, or in this medium containing 5  $\mu$ M dexamethasone (gift of Merck, Sharpe and Dohme), and were diluted with the appropriate medium every other day to maintain cells in log growth. Aliquots of cells were removed from each culture daily and adjusted to a concentration of 500,000 cells ml<sup>-1</sup>, then db cyclic AMP (Boehringer-Mannheim) was added to a final concentration of 1 mM. Four hours later TAT specific activity, equivalent to nmol *p*-hydroxyphenylpyruvate formed per mg protein per min, was determined<sup>9</sup>. Cells grown in absence of dexamethasone before (■) and after (→□) addition of db cyclic AMP; cells grown in the presence of dexamethasone before (●) and after (→○) addition of the nucleotide. Daily variation in TAT activity in cells grown in dexamethasone probably reflects induction from the serum in fresh medium<sup>22</sup>.

Fig. 2 Time curve of reinduction. HTC cells taken from cultures on day 4 of the experiment described in Fig. 1 were resuspended at a concentration of 500,000 cells  $\text{ml}^{-1}$  in modified S77 medium  $\pm$  dexamethasone. Dibutyl cyclic AMP (1 mM) was added to half of each culture and samples were taken for determination of TAT activity at times indicated on abscissa. Control cells without (□) or with (■) db cyclic AMP; dexamethasone-treated cells without (○) or with (●) nucleotide.

to involve mechanisms similar to the induction of TAT by steroid hormones<sup>3</sup>.

Shortly after glucocorticoid hormones were discovered, Ingle proposed that they have a general role in enabling maximal metabolic rates of processes essential to homeostasis<sup>15</sup>. Subsequently several permissive effects involving a variety of processes have been elucidated. Among these effects are those of adrenaline on gluconeogenesis<sup>16</sup>, glycogenolysis<sup>17</sup> and lipolysis<sup>18</sup>, of mammary tumour virus production<sup>19</sup>, of glucagon on amino acid transport into isolated hepatocytes<sup>20</sup>, and of growth factor stimulation of fibroblast proliferation<sup>21</sup>. The reinduction of TAT by db cyclic AMP in the strain of HTC cells used in this study is of interest because the steroid is not just enhancing a response (as in the other examples of TAT induction<sup>5,8,11,12</sup>) but rather is absolutely required. Although little is known about the mechanism(s) of any permissive effect, a great deal is known about the regulation of TAT. A well defined cultured cell system is thus available for investigating this important action of glucocorticoid hormones.

The lack of regulatory mechanism in cultured cells is

Table 1 TAT activity (nmol per mg protein per min)

Additions	S77 medium	S77 + DEX medium
None	8.1	74.6
Dibutyl cyclic AMP	8.2	151.6
Dibutyl cyclic AMP + cycloheximide	7.9	87.2

Effect of inhibition of protein synthesis on reinduction. Cultures of HTC cells grown for 6 d in either S77 medium or S77 + dexamethasone, were each divided into three samples and resuspended at 500,000 cells  $\text{ml}^{-1}$ . Cycloheximide (0.1 mM, Sigma) was added to one sample from each culture; 30 min later 1 mM db cyclic AMP was added to each of these, and to a second sample. One sample from each original culture received nothing. Four hours after addition of the db cyclic AMP, TAT activity was determined in all samples. These results are representative of four similar experiments.

commonly ascribed to deletion or inactivation of genes during transformation or adaptation of cells to permanent growth in culture, but may also result from failure of the artificial milieu to support such processes. This demonstration of the restoration of a regulatory step by the addition of a hormone to the culture medium suggests that proper culture conditions may restore other apparently 'lost' functions in cultured hepatoma cells.

## Role of serum in protease-induced stimulation of 3T3 cell division past the monolayer stage

TREATMENT of a confluent, quiescent 3T3 mouse embryo fibroblast cell monolayer with low concentrations of various proteases is sufficient to induce a new round of cell division<sup>1,2</sup>. It was suggested that modification of the 3T3 surface conformation from the non-agglutinable to the agglutinable state after protease treatment might have been responsible for the initiation of this round of cell division. More recently, however, Glynn *et al.*<sup>3</sup> demonstrated that modification of the 3T3 cell surface from the agglutinable to the non-agglutinable state was not sufficient in itself to induce a new round of cell division. In the light of this and other unpublished work from our laboratory I have re-evaluated the role of various culture conditions in the induction of 3T3 cell division after a brief treatment with Pronase. I found that induction of cell division after treatment of a confluent 3T3 monolayer with protease depends both qualitatively and quantitatively on the serum in the growth medium and that this requirement varies from cell line to cell line. Furthermore, my results suggest that the modification in surface architecture detected as enhanced agglutinability after brief proteolysis is not sufficient to induce a new round of cell division.

As Table 1 shows, four of the 3T3 cell lines tested showed remarkably different serum requirements for growth to the monolayer stage, which we have somewhat arbitrarily put at  $2.0 \times 10^4$  cells per  $\text{cm}^2$ . For example, the cell line designated 3T3<sub>3</sub> grows to the monolayer stage in Dulbecco's

**Fig. 1** Protease stimulation of different 3T3 cell lines in various concentrations of calf serum. The various 3T3 cell lines were plated at  $2.0 \times 10^3$  cells per  $\text{cm}^2$  and then grown to confluency in DME+10% calf serum. After 2 d at the monolayer stage the cells were washed once with sterile, phosphate-buffered 0.16 M NaCl (pH 7.2) (PBS). The cells were incubated for 5 min with 10  $\mu\text{g}$  of Pronase in 1.0 ml sterile PBS at room temperature. Cells were then washed with sterile PBS. DME plus the desired concentration of calf serum was then added back to the cells. Cells were counted every 12 h after stimulation. a, 3T3<sub>3</sub>; b, 3T3<sub>5</sub>; c, 3T3<sub>7</sub>; d, 3T3<sub>10</sub>. □, DME+3% calf serum; △, DME+5% calf serum; ■, DME+7% calf serum; ▲, DME+10% calf serum; ●, conditioned media; ○, untreated monolayer. "Conditioned" medium is defined in the legend to Table 1. The untreated monolayer refers to cells which, after growth to the monolayer, were not treated with Pronase or fresh calf serum and which serve as a base line from which the percentage stimulation is determined.

modified Eagle's medium (DME) plus as little as 3% calf serum while the 3T3<sub>10</sub> cell line requires DME plus 10% calf serum to reach the monolayer. Cell lines 3T3<sub>3</sub> and 3T3<sub>7</sub> have intermediate serum requirements, growing to  $2.0 \times 10^4$  cells per  $\text{cm}^2$  in DME plus 5% or 7% calf serum, respectively. Although two of these cell lines (3T3<sub>3</sub> and 3T3<sub>7</sub>) can grow to confluency in relatively low concentrations of calf serum, these lines do not significantly overgrow the monolayer when grown from low density in DME+10% calf serum.

I investigated the ability of DME plus various concentrations of calf serum to re-initiate cell division past the monolayer stage. As Table 2 shows, these cell lines vary considerably in terms of the concentration of calf serum necessary to stimulate a round of division past the monolayer. For example, 3T3<sub>3</sub> shows a 30% increase in cell number when DME+5% calf serum is added to the confluent cells whereas the other cell lines show no more than a 10% increase in cell number after a change of medium to DME+5% calf serum. In this same regard 3T3<sub>3</sub> cells show almost a 95% increase in cell number when DME+10% calf serum is added to the confluent cells, whereas 3T3<sub>10</sub> cells show only a 15% increase in cell number after a media change to DME+10% calf serum. 3T3<sub>3</sub> and 3T3<sub>7</sub> cells show responses to the various serum concentrations intermediate to 3T3<sub>3</sub> and 3T3<sub>10</sub>. None of the cell lines shows more than a 15% increase in cell number when DME plus that concentration of serum necessary for growth to

confluency is added to cells which have been grown to the monolayer stage in DME+10% calf serum.

To determine whether the differences in serum concentration required for subconfluent growth influenced the ability of the cells to overgrow the monolayer after protease treatment, each cell line was grown to confluency in DME+10% calf serum and then pulsed with Pronase as described in the legend to Fig. 1. As can be seen, there was significant induction of cell division after protease treatment only at a concentration of calf serum equal to or above that required for growth to the monolayer stage. After stimulation of each cell line in medium containing the minimal concentration of fresh calf serum sufficient to maintain cell division at a subconfluent density, a 65–75% increase in cell number was observed within 30 h of the initial stimulation. Only the 3T3<sub>3</sub> cell line showed a greater than 75% increase in cell number after treatment with Pronase.

To evaluate properly the effect of protease on the induction of cell division it is necessary to compare the stimulation of cell division observed before and after addition of fresh calf serum. Comparison of Fig. 1 and Table 2 shows that protease treatment lowered the concentration of fresh calf serum necessary for significant induction of cell division past the monolayer. For example, whereas 3T3<sub>3</sub>+DME containing 3% calf serum showed only a 10% induction of cell division (Table 2), 3T3<sub>3</sub> cells treated with protease before addition of DME+3% serum showed a 90% increase in cell number. Similar results have been obtained with the other three cell lines (compare Fig. 1 and Table 2).

**Fig. 2** Effect of ISI and Gibco calf serum on subconfluent cell growth and protease-stimulated overgrowth. 3T3<sub>10</sub> cells were plated at  $2.5 \times 10^3$  cells per  $\text{cm}^2$  in DME+10% ISI calf serum or 10% Gibco calf serum. Cell counts were taken daily during the next 6 d. Inset: 3T3<sub>10</sub> cells grown to confluency in DME+10% ISI calf serum or 10% Gibco calf serum were treated with 10  $\mu\text{g}$  of Pronase per ml PBS and then DME+10% ISI or 10% Gibco calf serum was added back to the cells at the monolayer. Cell counts were performed every 12 h for the next 72 h. ●, DME containing 10% Gibco calf serum; ■, DME containing 10% ISI calf serum; ○, Pronase 10  $\mu\text{g}$   $\text{ml}^{-1}$  + DME containing 10% Gibco calf serum; □, Pronase 10  $\mu\text{g}$   $\text{ml}^{-1}$  + DME containing 10% ISI calf serum. Addition of fresh 10% Gibco calf serum to cells at the monolayer without previous protease treatment produced an increase in cell number of approximately 15%. The addition of fresh 10% ISI serum to cells at the monolayer without previous protease treatment produced less than a 10% increase in cell number.

Table 1 Serum requirements of individual cell lines

Cell line	Final cell density cells per cm <sup>2</sup> × 10 <sup>-4</sup>				
	DME+3% calf serum	DME+5% calf serum	DME+7% calf serum	DME+10% calf serum	Conditioned medium
3T3 <sub>3</sub>	2.2	2.5	3.0	3.2	2.5
3T3 <sub>5</sub>	1.5	2.0	2.4	2.6	1.75
3T3 <sub>7</sub>	0.35	1.0	2.5	3.0	0.75
3T3 <sub>10</sub>	0.30	0.675	1.1	2.5	0.30

Saturation density was determined by plating cells at approximately  $2.0 \times 10^3$  per cm<sup>2</sup> in DME plus the given concentration of calf serum and counting cells daily for the next 7 d (ref. 2). A complete monolayer is formed with these cells at approximately  $2.0 \times 10^4$  cells per cm<sup>2</sup>. Cell size remained approximately the same for all cell lines tested. Cell lines originally derived from an NIH Swiss mouse embryo fibroblast (3T3) cell line were used throughout. The original line was obtained as clone 41 from Dr G. J. Todaro. Random stocks of this original clone had been stored in liquid nitrogen at different intervals during the past 5 yr. Four of these cell stocks were used. All cell lines were maintained at 37.5 °C in a moist incubator in which the CO<sub>2</sub> tension was held at 5%. Dulbecco's modified Eagle's medium (DME) plus 10% calf serum and 1% penicillin-streptomycin was used as growth medium for all stock cultures. The cells were demonstrated to be free of contamination with pleuro-pneumonia-like organisms (PPLO) at the time of the experiments, by both autoradiography<sup>6</sup> and mycoplasma broth media<sup>7</sup>. No cell line was maintained in culture for more than 20 passages. Frozen stocks were removed from liquid N<sub>2</sub> at intervals during the course of the experiments. "Conditioned" medium was produced by plating each cell line at  $2.0 \times 10^3$  cells per cm<sup>2</sup> in DME+10% calf serum and allowing the cells to grow in this medium for 5 d at which time the medium was removed and filtered. In this regard it must be noted that the term "conditioned" medium refers to medium taken from specific cell lines. Thus the "conditioned" medium which is added back to 3T3<sub>3</sub> cells is media which have been depleted by 3T3<sub>3</sub> cells while "conditioned" media which are added to 3T3<sub>10</sub> cells have been depleted by 3T3<sub>10</sub> cells. Since these cell lines have different serum requirements for growth it might be expected that the "conditioned" media produced by the two cell types might also vary.

Significantly, comparison of Table 2 and Fig. 1 demonstrates that 3T3<sub>3</sub> is the only cell line which, after growth to confluency, can be stimulated to divide in the presence of "conditioned" medium (see legend to Table 1 for definition of "conditioned" medium).

To determine whether the ability of serum to support growth past the monolayer varied with different lots of calf serum, Pronase stimulation of 3T3<sub>10</sub> cells was studied with three different sera. Figure 2 shows that subconfluent

It has been suggested that the surface modification detected as enhanced agglutinability with plant lectins, which results from mild protease treatment of a confluent monolayer, might be necessary for induction of cell division past the monolayer stage<sup>1</sup>.

The surface change detected as enhanced agglutinability is not sufficient for induction of cell division past the monolayer stage. Although 3T3<sub>10</sub> cells treated with 10 µg of Pronase per ml of sterile phosphate-buffered saline show

Table 2 Initiation of cell division past the monolayer by serum

Cell line	Final cell density per cm <sup>2</sup> × 10 <sup>-4</sup>	Cell density (per cm <sup>2</sup> × 10 <sup>-4</sup> ) after addition of DME at the indicated concentration of fresh calf serum to confluent cells					Conditioned medium
		3%	5%	7%	10%		
3T3 <sub>3</sub>	3.2	3.5	4.16	5.6	6.2		3.7
3T3 <sub>5</sub>	2.6	2.6	2.9	3.12	4.55		2.8
3T3 <sub>7</sub>	3.0	3.2	3.3	3.5	4.1		3.0
3T3 <sub>10</sub>	2.6	2.6	2.4	2.7	2.9		2.4

Each cell line was grown to confluency in DME+10% calf serum. The cells were left at confluency for 48 h and then the medium was changed to DME + the desired concentration of calf serum. Cell counts were performed every 12 h. In this table only the final cell density reached 48 h after the change of media is reported. "Conditioned" medium is defined in the legend to Table 1.

growth of the 3T3<sub>10</sub> cells is identical in calf serum obtained from Gibco (Lot No. C345417) and ISI (Lot No. 716C312). But as Fig. 2 shows, this lot of ISI sera did not support protease-induced cell division past the monolayer stage. This suggests that the serum components necessary for protease induction of cell division past the monolayer are either present in reduced amounts or missing completely from this lot of ISI sera. Calf serum obtained from Flow Laboratories was similar in its growth promoting characteristics to that of the Gibco calf serum used throughout these experiments.

enhanced agglutinability with wheat germ agglutinin and concanavalin A immediately after treatment (Table 3), these cells will complete a round of cell division only when exposed to DME plus fresh 10% calf serum (Fig. 1). Thus, as Glynn *et al.* suggested<sup>3</sup>, modification of the surface architecture from the non-agglutinable to the agglutinable state is not sufficient in itself to reinitiate the cell cycle in 3T3 cells at high density.

The work presented here suggests that the efficiency of protease-induced reinitiation of cell division varies from cell clone to cell clone, even within the 3T3 cell line. The

Table 3 Effect of protease on 3T3<sub>10</sub> cell growth and agglutination

Cell line	Final cell density (cells per cm <sup>2</sup> × 10 <sup>-4</sup> )		% Agglutination			
	Control	Plus Pronase	25 µg ml <sup>-1</sup> con A	25 µg ml <sup>-1</sup> WGA	25 µg ml <sup>-1</sup> con A	25 µg ml <sup>-1</sup> WGA
3T3 <sub>10</sub>	3.0	4.8	10%	10%	90%	95%

All agglutinations were performed as before<sup>3</sup>. DME+10% calf serum was added to the 3T3<sub>10</sub> cells after Pronase treatment. In the growth experiments "control" 3T3<sub>10</sub> cells were treated with DME+10% calf serum without previous Pronase treatment. With regards agglutination, control cells refer to cells before Pronase treatment. All protease treatments were performed with 10 µg Pronase per ml of sterile PBS for 5 min at 22 °C. Concanavalin A was prepared according to the techniques of Agrawal and Goldstein<sup>4</sup>, while wheat germ agglutinin (WGA) was prepared according to Nagata and Burger<sup>5</sup>.

relative efficiency of "protease-induced overgrowth" of the monolayer seems to correlate with the serum requirement which each cell clone expresses for sub-confluent growth. Thus in our work only those 3T3 cell lines which can grow to the monolayer in 3% calf serum seem able to respond to protease-induced reinitiation of the cell cycle without requiring the further addition of fresh serum to the growth medium.

In addition to this quantitative serum requirement there seems to be a qualitative requirement for a serum component(s) which is apparently not required for subconfluent growth but which is essential for growth past the monolayer. This conclusion stems from the observation that some calf sera which I tested, although able to support subconfluent growth, were unable to support growth of Pronase-treated cells past the monolayer.

Continuing work in our laboratory suggests that 3T3 cells may be peculiarly susceptible to induction of cell division after limited proteolysis. Attempts to induce other murine and rodent cell lines to reinitiate cell division after Pronase treatment have proved unsuccessful, even in media conditions which the work reported here suggests should be adequate for overgrowth.

Thus a working hypothesis is that limited protease digestion of the 3T3 cell membrane may act to increase the efficiency of utilisation of serum by a cell at the monolayer, thereby reinitiating cell division past the monolayer. This reinterpretation of earlier work is in substantial agreement with Holley's suggestion<sup>8</sup> that modification of the cell membrane may serve to increase the transport of serum nutrients or growth factors into the cell, and in this way lead to a reinitiation of the cell cycle. Reference 9 has a more extended discussion of the role of protease in cell growth.

This work was supported in part by a grant from the Damon Runyon Foundation and an institutional grant to the College of Medicine from the American Cancer Society. I thank Dr Philip Laipis for critical review of the manuscript.

## Specificity and reversibility of interferon ganglioside interaction

RECENT studies have indicated that antiviral action of interferon is triggered by interaction with the cell membrane: Sepharose-bound mouse interferon (IF-Sepharose) retains its antiviral activity, and direct contact with the target cells is necessary to produce the antiviral effect<sup>1,2</sup>. Cells stimulated by double-stranded polyriboinosinic-polyribocytidylic acid to produce interferon are not protected from viral infection in the presence of interferon antiserum, indicating that interferon acts only after it has left the cells in which it is produced<sup>3</sup>. The same conclusion has been drawn from experiments with ouabain which inhibits the action, but not the production of primate interferon: cells stimulated to produce interferon fail to become antiviral in the presence of ouabain<sup>4</sup>.

We have shown previously that preincubation of mouse

L cells with *Phaseolus vulgaris* phytohaemagglutinin (PHA) blocks interferon action, suggesting the involvement of PHA-binding sites on the cell surface in cell membrane-interferon interaction<sup>5</sup>. We further demonstrated that Sepharose-bound mouse interferon is inhibited after preincubation with gangliosides, that soluble interferon binds to Sepharose-bound gangliosides, and that binding to gangliosides is inhibited by PHA<sup>6</sup>. Since gangliosides are cell membrane constituents whose carbohydrate portion faces the outside of the cell, we have investigated whether interferon-ganglioside interaction involves binding to the carbohydrate moiety of the gangliosides, thus supporting our hypothesis that interferon can interact with gangliosides on the outside of the cell membrane *in vivo*.

As Table 1 shows, when mouse IF-Sepharose was incubated with various glycolipids at comparable concentrations, pronounced inhibition of antiviral activity was observed with G<sub>M2</sub>, in accord with previous results<sup>6</sup>. Very little inhibition by G<sub>M3</sub> was seen in the conditions used, suggesting that the terminal *N*-acetyl-galactosaminy residue is an important constituent of the inhibitory molecule (see legend to Table 1). The same is true for terminal sialic acid as shown by the lack of inhibition obtained with ganglioTri-Cer. Both globoTri-Cer and globoTet-Cer (globoside) likewise were not inhibitory. They differ from G<sub>M2</sub> by the absence of sialic acid and by the fact that the galactosyl residue of lactosyl ceramide is substituted by an  $\alpha$ -1,4-linked galactosyl residue (globoTri-Cer) which in globoTet-Cer is further substituted by  $\beta$ -1,3-linked *N*-acetyl-galactosamine. GloboTri-Cer resulted in a slightly turbid solution in water, whereas ganglioTri-Cer yielded a turbid suspension, yet finely dispersed. Therefore in further experiments IF-Sepharose was preincubated with ethanolic solutions of the glycolipids. IF-Sepharose was first washed with absolute ethanol, which had little effect on its antiviral activity, then incubated with glycolipid solutions in ethanol followed by washing with water as described in the legend to Table 1. In these conditions only globoTet-Cer remained largely insoluble. The data corroborate those obtained with aqueous solutions, though G<sub>M3</sub> showed slight inhibition of antiviral activity. It seems that in ethanol, lower concentrations of G<sub>M2</sub> are required for complete inhibition, presumably because it forms micelles when dissolved in water. Since modification of the carbohydrate portion of G<sub>M2</sub> results in reduced inhibition or no inhibition, it seems that inhibitory ganglioside molecules bind through their carbohydrate portion to the interferon molecule and that optimal binding and inhibition require a lactosyl residue with galactose substituted by both a 2,3-linked sialic acid and a  $\beta$ -1,4-linked *N*-acetyl-galactosamine.

There is further support that ganglioside binding to interferon is not due to interaction of its lipid portion with hydrophobic sites on the interferon molecule. It was not possible to restore antiviral activity by washing IF-Sepharose, completely inhibited after preincubation with bovine brain gangliosides<sup>6</sup>, with 50% ethylene glycol. Such treatment reverses hydrophobic binding of human interferon to Sepharose columns containing covalently linked albumin<sup>12</sup>, or to CH-Sepharose<sup>13</sup>.

If inhibition of antiviral activity by gangliosides is due to specific interaction of interferon with carbohydrate constituents on the ganglioside molecule, it should be possible to reverse inhibition using saccharides resembling part or all of the carbohydrate structure of G<sub>M2</sub>. As Table 2 shows, when ganglioside-inhibited IF-Sepharose beads were washed with sialyl-lactose at pH 2, almost all antiviral activity reappeared. Washing with lactose or sialic acid alone had little effect. But when both sialic acid and lactose were present, antiviral activity was partially restored. Thus interferon seems to act like a lectin that is specific for at least the sialyl-lactose portion on the ganglioside molecule. At pH 7.0 and comparable concentrations neither sialyl-

**Table 1** Inhibition of antiviral activity of IF-Sepharese by glycolipids

IF-Sepharese preincubated with	Virus yield (% of control) after treatment of L cells with IF-Sepharese preincubated with glycolipids in:	
	Water	Ethanol
Nothing	0.7	2.5
G <sub>M2</sub>	51*	100
G <sub>M3</sub>	1	16
ganglioTri-Cer	1	5
globoTri-Cer	0.8	4.7
globoTet-Cer	1.2	5

IF-Sepharese prepared as before<sup>1,2</sup> was treated with glycolipids by incubating  $5 \times 10^4$  beads with 0.3 ml of a glycolipid solution in either water ( $3 \text{ mg ml}^{-1}$ ) or absolute ethanol ( $1 \text{ mg ml}^{-1}$ ). Beads preincubated with ethanolic solutions were washed first with absolute ethanol (twice, 2 ml). Incubation was for 75 min at  $37^\circ\text{C}$ . The beads were then washed twice with 2 ml water and suspended in 1 ml Eagle's minimal essential medium plus Hanks salts without serum (MEM). G<sub>M2</sub> was obtained from human brain<sup>7</sup>, G<sub>M3</sub> from bovine spleen<sup>7</sup>, ganglioTri-Cer from guinea pig erythrocytes<sup>8</sup>, globoTri-Cer from rabbit erythrocytes<sup>9</sup>, and globoTet-Cer from pig heart<sup>9</sup>. All glycolipids were essentially pure compounds according to thin layer chromatography and gas-liquid chromatography-mass spectrometry<sup>10,11</sup>. Suspensions of glycolipids not immediately soluble were heated to  $50^\circ\text{C}$  followed by two to four ultrasonic shocks of 2–3 s in a Heat Systems Sonifier (Model W185) at 50-W output. Mouse L cells were cultivated at  $37^\circ\text{C}$  in 35-mm plastic dishes ( $10^6$  cells per dish) in MEM, containing 10% calf serum. After removal of medium, cells were incubated for 6 h at  $37^\circ\text{C}$  with 1-ml suspensions of IF-Sepharese at a ratio of one bead per 20 cells. After removal of beads, cells were challenged with encephalomyocarditis virus (EMC) at a multiplicity of infection of 1. Virus yield was determined after 16 h of incubation at  $37^\circ\text{C}$  by counting plaque-forming units (PFU). The control virus yield per plate in the absence of interferon was  $6 \times 10^7$  PFU for the experiment with aqueous solutions and  $1.6 \times 10^8$  PFU for that with ethanolic solutions of glycolipids. We reported previously inhibition of mouse IF-Sepharese by a preparation of G<sub>M3</sub> containing both the acetyl and the glycolyl neuraminic acid derivatives<sup>6</sup>. Since that experiment was not carried out simultaneously with those testing the effects of the other individual gangliosides and since a different preparation of IF-Sepharese was used, the observed degree of inhibition by G<sub>M3</sub> in our earlier report is not directly comparable with that of the other gangliosides and to the results reported here. We found subsequently that different preparations of IF-Sepharese are inhibited to a different extent by the same quantity of a given ganglioside in the preincubation mixture. But in all IF-Sepharese preparations tested the relative order of effectiveness of the gangliosides as inhibitors remained the same:  $G_{M2} \geq G_{T1} > G_{M1} \geq G_{D1a} > G_{M3}$ . These variations might be due to different amounts of contaminating proteins or glycoproteins bound to the Sepharese particles, as the interferon preparations used for coupling to Sepharese were not purified extensively<sup>1,2</sup>. When the same IF-Sepharese preparation was used, the degree of inhibition observed by a given amount of a ganglioside was reproducible in different experiments. Gangliosides are designated according to Svennerholm<sup>7</sup>: G<sub>M3</sub>, 3-O-(N-acetyl) neuraminyl-4-O-β-galactosyl-O-glucosyl-ceramide; G<sub>M2</sub>, 4-O-β-N-acetyl-galactosaminyl (3-O-(N-acetyl)neuraminyl)-4-O-β-galactosyl-O-glucosyl-ceramide; G<sub>M1</sub>, 3-O-β-galactosyl-4-O-β-N-acetyl-galactosaminyl (3-O-(N-acetyl) neuraminyl)-4-O-β-galactosyl-O-glucosyl-ceramide; G<sub>D1a</sub>, 3-O-(N-acetyl) neuraminyl-3-O-β-galactosyl-4-O-β-N-acetyl-galactosaminyl (3-O-(N-acetyl) neuraminyl)-4-O-β-galactosyl-O-glucosyl-ceramide; G<sub>T1</sub>, 3-O-(N-acetyl) neuraminyl-3-O-β-galactosyl-4-O-β-N-acetyl-galactosaminyl (8-O-(N-acetyl) neuraminyl-3-O-(N-acetyl) neuraminyl)-4-O-β-galactosyl-O-glucosyl-ceramide. Other abbreviations used are: globoTri-Cer, 4-O-α-galactosyl-4-O-β-galactosyl-O-glucosyl-ceramide; globoTet-Cer, 3-O-β-N-acetyl-galactosaminyl-4-O-α-galactosyl-4-O-β-galactosyl-O-glucosyl-ceramide; ganglioTri-Cer, 4-O-β-N-acetyl-galactosaminyl-4-O-β-galactosyl-O-glucosyl-ceramide; sialyl-lactose, 3-O-(N-acetyl)neuraminyl-4-O-β-galactosyl-O-glucose. All sugars are of the D configuration \*At  $2 \text{ mg ml}^{-1}$  in the preincubation mixture.

lactose nor the mixture of lactose and sialic acid restored antiviral activity of ganglioside-inhibited IF-Sepharese to any great extent, suggesting that the negative charge on the sialyl residues at neutral pH impedes replacement of the ganglioside molecules from interferon. It should be pointed out that in the determinations of antiviral activity only differences greater than twofold were considered significant.

We could not assess whether the complete tetrasac-

charide unit of G<sub>M2</sub> is superior to sialyl-lactose in displacing inhibitory gangliosides from IF-Sepharese, since this tetrasaccharide was not available. In displacement experiments in which suboptimal concentrations of sialyl-lactose were used during washing of ganglioside-inhibited IF-Sepharese beads in otherwise identical conditions, N-acetyl-galactosamine did not enhance the effect of sialyl-lactose. Thus there was no difference in the virus yield after treatment of L cells with ganglioside-inhibited IF-Sepharese subsequently washed at pH 2.0 or pH 7.0 with 0.02 M sialyl-lactose, compared with experiments in which a solution containing 0.02 M sialyl-lactose plus 0.5 M N-acetyl-galactosamine was used for washing. Similarly, when 0.5 M N-acetyl-galactosamine was included with 0.1 M lactose and 0.1 M sialic acid in the solution used to remove bound gangliosides from IF-Sepharese, the effect observed with the mixture of sialic acid and lactose alone was not enhanced.

Since most glycoproteins contain terminal sialic acid often bound to penultimate galactosyl units, we surveyed some of these glycoproteins for possible inhibitory action on the antiviral activity of interferon. In these experiments  $5 \times 10^4$  IF-Sepharese beads were preincubated with 0.3 ml glycoprotein solution in water for 1 h at  $37^\circ\text{C}$  followed by washing with phosphate-buffered saline (PBS) (twice 2 ml). None of the following materials ( $20 \text{ mg ml}^{-1}$ ) had any effect on antiviral activity: Fetuin (Sigma), bovine submaxillary mucin (Sigma), rabbit α- and γ-globulins (Nutritional Biochemicals), human chorionic gonadotropin (Ayerst). Thus inhibition of IF-Sepharese not only requires the presence of sialyl or sialyl-galactosyl residues on a glycoconjugate, but seems to be more specific.

The fact that shortening of the saccharide portion of G<sub>M2</sub> can partially or completely prevent inhibition of interferon, supports our conclusion that interferon interacts with the carbohydrate moiety of this molecule. Substitution of the G<sub>M2</sub> tetrasaccharide unit by β-1,3-linked galactose as in G<sub>M1</sub> and higher gangliosides, has little influence on inhibitory potency<sup>6</sup>. Reversal of ganglioside inhibition by sialyl-lactose indicates that at least part of the binding site on the inter-

IF-Sepharese not preincubated with gangliosides	0.3	0.3

IF-Sepharese ( $5 \times 10^4$  beads) was incubated with 0.3 ml of a solution of mixed gangliosides from bovine brain (Sigma, type III,  $2 \text{ mg ml}^{-1}$ ) for 75 min at  $37^\circ\text{C}$ . The beads were washed twice with 2 ml of water to remove unbound gangliosides. They were then suspended in 0.4 ml of the indicated saccharide solutions either in 0.2 M glycine-HCl buffer at pH 2.0 or in 0.3 M sodium phosphate buffer, pH 7.0. The pH was readjusted where necessary. After incubation at  $37^\circ\text{C}$  for 30 min with occasional stirring the supernatant solution was removed, and the beads were washed twice more with 2 ml of water and finally suspended in 1 ml of MEM. The major constituents present in the mixed ganglioside preparation used were G<sub>M1</sub> and G<sub>D1a</sub>, as revealed by thin-layer chromatography in chloroform-methanol-2.5 N ammonia (60:40:9; v/v). The sialyl-lactose used was from bovine colostrum (Sigma) and contained approximately 85% of the 2,3-linked and approximately 15% of the 2,6-linked N-acetyl-neuraminyl derivatives. Antiviral activity was determined as described in the legend to Table 1. The control virus yield per plate was  $10^8$  PFU. ND, not determined.

feron molecule is directed towards this trisaccharide unit. The fact that neither sialic acid nor lactose alone can reverse inhibition of IF-Sepharose by gangliosides, whereas a mixture of both is effective to some extent, supports our conclusion that the binding site for interferon includes both sugar residues. This is analogous to the observed inhibition of PHA-induced red cell agglutination by an erythrocyte glycopeptide that contains the PHA receptor site: although removal of galactose from this glycopeptide abolishes its agglutination-inhibitory activity, neither galactose alone nor  $\beta$ -galactosyl-*N*-acetyl-glucosaminyl-containing oligosaccharides are inhibitors of PHA-induced haemagglutination. Thus, although galactosyl residues are essential for PHA binding, the complete binding site seems to include further saccharide units<sup>14</sup>.

The relatively poor inhibition observed with  $G_{M3}$  suggests that optimal binding of interferon to gangliosides includes interaction with the  $\beta$ -1,4-linked *N*-acetyl-galactosaminyl residue as well. This hypothesis could be substantiated further by comparing the relative efficiencies of removing inhibitory gangliosides from IF-Sepharose using either sialyl-lactose or the tetrasaccharide derived from  $G_{M2}$ . Thus with the latter, lower concentrations should be sufficient to restore completely antiviral activity of ganglioside-inhibited IF-Sepharose. It is not obvious why sialyl-lactose reverses ganglioside inhibition at pH 2.0 but not at pH 7.0. Possibly the negative charges on the ganglioside molecules at pH 7.0 repel the negatively charged sialyl-lactose residues sufficiently to prevent successful competition of the trisaccharide with the bound gangliosides. This phenomenon would not occur at pH 2.0, where sialyl residues are uncharged.

Cells transformed by RNA and DNA viruses often have altered ganglioside patterns<sup>15,16</sup>. For example, transformation of mouse cells by murine sarcoma virus (Moloney strain) yields decreased levels of  $G_{M2}$  and higher gangliosides in the cell membrane<sup>17</sup>. Virus transformation often results in decreased sensitivity to the antiviral effect of interferon<sup>18</sup>. Involvement of higher gangliosides in the cell membrane receptor sites for interferon could explain the poor antiviral response of some transformed cells. Preincubation of SV40-transformed mouse cells with gangliosides increases their sensitivity towards the antiviral effect of interferon, in accord with such a hypothesis<sup>19</sup>.

Binding of interferon to Sepharose-bound gangliosides<sup>9</sup> and elution with the appropriate saccharide solutions suggests a way to purify interferon by affinity chromatography. Such studies are in progress.

We thank Dr C. Chany for interferon and Dr S. Grossberg for L cells and virus. We thank both of them for helpful discussions. ## Thrombin-sensitive surface protein of cultured chick embryo cells

THROMBIN, a serine protease with great specificity, is a potent mitogen for resting chick embryo fibroblasts in culture<sup>1-3</sup>. So far only a limited number of peptide bonds in a few native proteins have been found to be sensitive to proteolysis by thrombin, namely four Arg-Gly bonds in fibrinogen<sup>4</sup> and a few arginyl and lysyl bonds in actin<sup>5</sup>. It is likely therefore that the number of fibroblast surface proteins susceptible to this protease will also be limited, whereas with trypsin, many surface proteins are attacked. Thus thrombin may be an excellent probe for studies of the role of changes in cell surface composition during mitogenesis or cell-cell interaction. A large, external transformation sensitive (LETS) protein<sup>6-10</sup>, postulated<sup>10,11</sup> to be involved in cellular growth control, is insensitive to thrombin<sup>2</sup>. This observation led to the conclusion that the removal of LETS is not a necessary condition for cell growth when a protease is used to stimulate growth.

Using a lactoperoxidase-catalysed <sup>125</sup>I-iodine labelling technique, we were unable previously to detect decisively any thrombin-sensitive chick fibroblast surface protein. Yet since thrombin has a potent effect on chick embryo fibroblasts, it seemed likely that some surface protein is sensitive to its proteolytic activity. Identification of such a protein may be important not only for the understanding of cell surface composition, but also for the elucidation of the mechanism of protease-induced mitogenesis.

We have found that when <sup>125</sup>I-iodine is substituted for <sup>125</sup>I-iodine in lactoperoxidase-catalysed iodination, the method greatly increases the number of surface proteins detectable by gel electrophoresis and autoradiography. This observation led to the finding reported here that there is a thrombin-sensitive protein with an apparent molecular weight of 205,000 on the surface of chick cells.

Until recently, the usual procedure for iodination of proteins has involved <sup>125</sup>I-iodide, mainly because of its more convenient long half life (60 d). When autoradiograms of slab gels of solubilised, iodinated cells are made, however, <sup>125</sup>I-iodide yields poor resolution because of its high energy gamma emission. A  $\beta$ -emitting iodine isotope would overcome this difficulty, since  $\beta$  radiation is captured more efficiently by the photographic emulsion than is  $\gamma$  radiation; the scattering effect is greatly reduced and resolution much improved. The combination of the use of <sup>131</sup>I-iodide instead of <sup>125</sup>I-iodide and a gradient polyacrylamide gel is recommended. The improvement in analytical power offsets the inconvenience of a shorter half life (8 d).

As Fig. 1 shows, use of <sup>131</sup>I-iodide and electrophoresis on sodium dodecyl sulphate (SDS)-polyacrylamide gradient slab gels makes possible detection of a large number

**Fig. 1** Autoradiograms of SDS-polyacrylamide gradient gels of proteins labelled by lactoperoxidase-catalysed iodination of chick fibroblasts after the following treatment at 37 °C in Dulbecco's modified Eagle's medium (DEM) kept in a 10% CO<sub>2</sub> incubator. *a*, Untreated control, resting secondary chick cells prepared by seeding  $4 \times 10^5$  cells per 35-mm dish in DEM+0.5% calf serum (Grand Island Biological) for 3 d; *b*, trypsin at  $0.2 \mu\text{g ml}^{-1}$  for 4 h; *c*, trypsin at  $0.1 \mu\text{g ml}^{-1}$  for 4 h; *d*, insulin at  $5 \mu\text{g ml}^{-1}$  for 4 h; *e*, insulin at  $1 \mu\text{g ml}^{-1}$  for 4 h; *f*, thrombin at  $50 \mu\text{g ml}^{-1}$  for 30 min; *g*, thrombin at  $20 \mu\text{g ml}^{-1}$  for 4 h; *h*, thrombin at  $2 \mu\text{g ml}^{-1}$  for 24 h; *i*, thrombin at  $1 \mu\text{g ml}^{-1}$  for 2 h. Washed cells were iodinated in 1 ml of Dulbecco's phosphate-buffered saline containing 0.9 mM CaCl<sub>2</sub> and 0.9 mM MgCl<sub>2</sub> with addition of 20  $\mu\text{g}$  of lactoperoxidase (Worthington) further purified by chromatography on a Sephadex G-100 column, 50  $\mu\text{Ci}$  of carrier-free Na<sup>125</sup>I (New England Nuclear) in 0.1 N NaOH, and 2.4 nmol of NaI. The reaction was initiated by addition of 5  $\mu\text{mol}$  of glucose and 0.015 U of glucose oxidase (Sigma). Reactions were terminated after 15 min by five washes of ice-cold Ca<sup>2+</sup>- and Mg<sup>2+</sup>-free phosphate-buffered saline solution. The cells were then dissolved in electrophoresis sample buffer containing 2% SDS, 1% mercaptoethanol and 2 mM phenylmethane sulphonyl fluoride. Slab gel electrophoresis was carried out as described previously<sup>2</sup> except that the acrylamide gradient was 6–15%. The radioactivity loaded on a slab gel was 20,000 c.p.m. for each sample. The slab gel was dried and subjected to autoradiography on Kodak RP Royal X-Omat X-ray film for 3–24 h. The standards used for molecular weight determination are myosin,  $\beta$ -galactosidase, bovine serum albumin, actin and chymotrypsinogen.

of iodlatable proteins, many more than in previous results<sup>2-4,7-10</sup>. Most of the bands in the autoradiogram are sharp and well defined compared with other reports where <sup>125</sup>Iodide was used. We find that one band (indicated by an arrow) is sensitive to thrombin. Column *f* shows that after treating the cells for 30 min with a high concentration of thrombin ( $50 \mu\text{g ml}^{-1}$ ) this protein can no longer be detected when compared with the external proteins from a control culture of resting chick cells (column *a*).

The experimental conditions for columns *g*, *h* and *i*, respectively, are: resting chick cells treated with thrombin at  $20 \mu\text{g ml}^{-1}$  for 4 h,  $2 \mu\text{g ml}^{-1}$  for 24 h and  $1 \mu\text{g ml}^{-1}$  for 2 h. A significant observation has been that in all these conditions one iodlatable protein of molecular weight 205,000 was consistently sensitive to thrombin. Figure 2 shows microdensitometer scans of two of the gel strips (*a* and *g*) of Fig. 1. These scans confirm quantitatively the absence of only one iodlatable cell surface protein after treatment of chick embryo fibroblasts with thrombin. This thrombin-sensitive protein, as expected, is also sensitive to trypsin.

As in the previous report where <sup>125</sup>Iodide was used, we find that LETS protein is not removed by thrombin treat-

ment<sup>2</sup>. LETS protein stands out even more clearly as the most prominent cell surface protein in cases where <sup>131</sup>Iodine was used in place of <sup>125</sup>Iodide. As columns *b* and *c* show, both LETS and the 205,000 protein were removed by trypsin. On the other hand, insulin at  $1 \mu\text{g ml}^{-1}$  or  $5 \mu\text{g ml}^{-1}$  for 4 h does not remove thrombin-sensitive protein (columns *d* and *e*).

When serum proteins were labelled with <sup>131</sup>Iodine by lactoperoxidase-catalysed reaction, no iodlatable protein comigrating with the thrombin-sensitive protein was detected. Furthermore, the availability of this thrombin-sensitive protein for iodination on the cell surface is not serum dependent. Chick embryo cells passaged in serum-free medium (but supplemented with insulin at  $5 \mu\text{g ml}^{-1}$ ) have the same amount of thrombin-sensitive protein as that of cells grown in 10% serum. Finally, sparse, exponentially growing chick cells incubated in 10% serum have only a very small amount of thrombin-sensitive protein. Therefore, it is unlikely that this protein is a component of serum. Since it has been established<sup>6-10</sup> that lactoperoxidase-catalysed iodination labels only proteins on the surface of cells, this thrombin-sensitive protein is probably an external cell-surface protein. The possibility that this thrombin-sensitive protein is released by dead cells in culture is ruled out because we used only cultures of secondary chick cells, which have no detectable. Trypan blue-positive cells both before and after iodination.

The role of the 205,000 protein is unknown. It is possible

**Fig. 2** Densitometric scans of gel strips *a* and *g* of Fig. 1. Two of the autoradiograms shown in Fig. 1 (*a* and *g*) were scanned by a Canalco Model G 11 densitometer with a digital integrator (Autolab 6300) attachment. Since the thrombin-treated cultures (*f*–*i*) gave essentially the same scanning results only *g* was shown in this figure. The scan of gel strip *a* represents the untreated control. Thrombin-sensitive proteins are indicated by an arrow.

that thrombin attacks the 205,000 protein proteolytically and that this event triggers renewed cell proliferation. Alternatively, the effect of thrombin on the resting cell might be stimulation of cell proliferation by some unknown mechanism concerned with altered cell-cell interaction in the absence of the external 205,000 protein. These two possibilities are being investigated.

Cell-surface proteins (including membrane proteins and surface coat proteins) are undoubtedly important in many complex biological phenomena. Progress in these studies has been slow because the role of a surface protein is always difficult to establish. An ideal way for the assignment of biological function to a surface component is the use of cell mutants lacking a specific protein(s). Alternatively, if a protease probe is available that can specifically alter one surface protein, the assignment of its function may be achieved by comparison with a control culture in which a protease has not been included. Use of highly specific proteases such as those involved in blood coagulation, for example, thrombin, factor X<sub>a</sub> and IX<sub>a</sub>, may prove to be fruitful for such work.

We thank Dr D. F. Waugh for highly purified bovine thrombin and Dr P. W. Robbins for chick embryo fibroblasts. ## New structural characteristic of the large glycopeptides from transformed cells

IN comparative gel filtration of glycopeptides obtained from the surface of normal and transformed cells, an increased concentration of fucosyl glycopeptides of apparently large molecular weight was observed for cells transformed by viral, chemical and spontaneous methods<sup>1-7</sup>. This is considered to be an expression of transformed phenotype, since in cells transformed by a temperature-sensitive (*ts*) mutant of Rous sarcoma virus, the heavy glycopeptides increased only at the permissive temperature. Based on the results of sialidase treatment, it was suggested that the presence of extra sialic acid is responsible for the higher molecular weight nature of the glycopeptides from transformed cells<sup>4,6</sup>.

In this communication, however, we present evidence that the differences are not that simple, but are more

Fig. 1 Sephadex G-50 column chromatography of fucose-labelled glycopeptides from trypsinates of normal and polyoma transformed cells. BHK<sub>21-11</sub> cells and the cells transformed by polyoma virus were grown at 37 °C in plastic Petri dishes (growth area 78 cm<sup>2</sup>) containing 10 ml of Eagle's MEM supplemented with 10% foetal calf serum and antibiotics in a humidified CO<sub>2</sub> incubator. The inoculum was 1 × 10<sup>6</sup> cells per dish. Three days after plating, 30 µCi of <sup>3</sup>H-fucose (4.4 Ci mmol<sup>-1</sup>) or 3 µCi of <sup>14</sup>C-fucose (50.8 mCi mmol<sup>-1</sup>) was added to each dish. After 24 h, the cultures were washed twice with Earle's solution, and treated with 5 ml of 0.1% trypsin (Difco) in Earle's solution lacking CaCl<sub>2</sub> and MgSO<sub>4</sub> and containing 0.016% EDTA for 5 min at room temperature. Then the medium was carefully decanted and centrifuged at 500g for 5 min to remove any loose cells. The supernatant (termed as 'trypsinates') was digested with Pronase for 3 d adding 1 mg ml<sup>-1</sup> of Pronase every day. Then, Pronase was inactivated by heating at 100 °C for 5 min, and the digests were applied to a column of Sephadex G-50, fine (1.0 × 125 cm). The column was equilibrated and eluted with 0.1 M pyridine-acetate buffer, pH 5.5. Fractions (1 ml) were collected. Aliquots (0.3 ml) were removed for counting, and the rest of the material was pooled as the large glycopeptides (fraction 56 to 62) and the small glycopeptides (fraction 64 to 74), lyophilised and stored. The figure shows a typical double labelling experiment in which the glycopeptides from BHK cells (○) were labelled with <sup>14</sup>C and those from polyoma-transformed BHK cells (●) were labelled with <sup>3</sup>H. The standard glycopeptides, (Man)<sub>5</sub>(GlcNAc)<sub>2</sub>N-(<sup>14</sup>C)acetyl-Asn (molecular weight 1,393), <sup>14</sup>C-acetylated bovine IgG glycopeptides (molecular weight ~2,000) and <sup>14</sup>C-acetylated unit B glycopeptides of thyroglobulin (molecular weight ~3,000) were eluted in fractions 77-78, 72 and 66, respectively. Molecular weight of the large and the small glycopeptides was estimated by the method of Andrews<sup>18</sup>.

extensive, possibly including both galactose and N-acetylglucosamine.

The fucose-labelled large glycopeptides were prepared from the trypsinates of polyoma-transformed BHK cells, and the small glycopeptides from the trypsinates of the normal and the polyoma-transformed cells (Fig. 1). In agreement with the work of Warren *et al.*<sup>3,4</sup>, the large glycopeptides were more enriched in transformed cells. On paper electrophoresis at pH 5.4, the large glycopeptides migrated faster to the positive pole than the small glycopeptides. Neuraminidase treatment of these glycopeptides converted most of them into neutral glycopeptides, indicating that the negative charge of these glycopeptides arose from sialic acid. We could also, therefore, confirm that the large glycopeptides have more sialic acids than the small glycopeptides.

These glycopeptides were studied comparatively by affinity column chromatography on concanavalin A (con A)-Sephacrose<sup>8</sup>. About 70% of the small glycopeptides from both normal and polyoma-transformed cells were bound to the column. Most of the bound glycopeptides

**Fig. 2** Affinity column chromatography of glycopeptides on con A-Sepharose. *a*, The small glycopeptides from BHK cells; *b*, the small glycopeptides from polyoma-transformed BHK cells; *c*, the large glycopeptides from polyoma-transformed BHK cells, and *d*, the large glycopeptides from polyoma-transformed BHK cells treated with neuraminidase alone (.....) or with neuraminidase,  $\beta$ -galactosidase and  $\beta$ -N-acetylglucosaminidase (—). Glycopeptides and their derivatives were applied to a column of con A-Sepharose (Pharmacia, Sweden) equilibrated with 0.01 M Tris-HCl buffer, pH 7.5 containing 0.1 M NaCl. The column was washed with 10 ml of the above buffer, and then eluted with 10 ml of the same buffer containing 0.1 M methyl  $\alpha$ -mannoside. Fractions (1 ml) were collected. Then con A-Sepharose was extracted with 5 ml of 1% SDS at 100 °C for 2 min. Glycopeptides in 0.02 ml of 0.1 M phosphate buffer, pH 6.0 were mixed with 0.01 ml of neuraminidase from *Clostridium perfringens* (0.01 units, Sigma) and were incubated at 37 °C for 2 h. The neuraminidase-treated glycopeptides were heated at 100 °C for 5 min and adjusted to pH 4.0 by the addition of 0.01 ml of 0.15 M citrate-phosphate buffer, pH 3.0. Then, 0.04 ml each of  $\beta$ -galactosidase<sup>17</sup> (0.64 U) and  $\beta$ -N-acetylglucosaminidase<sup>18</sup> (3.7 U) from jack bean meal were added and the mixture was incubated at 37 °C for 16 h with a small amount of toluene.

were eluted by 0.1 M methyl  $\alpha$ -mannoside, and a small amount of tightly bound glycopeptides by 1% sodium dodecyl sulphate (SDS) (Fig. 2 *a*, *b*). In contrast, we found that only 20% of the large glycopeptides from polyoma-transformed cells were bound to the column (Fig. 2*c*). This behaviour of the large glycopeptides did not change, even after neuraminidase digestion (Fig. 2*d*, dotted line), indicating that the enrichment of sialic acid is not responsible. A new structural difference between the large and the small glycopeptides was therefore shown.

We then compared core structures of the large glyco-

**Fig. 3** Sephadex G-25 column chromatography of glycopeptides treated with glycosidases. *a*, The large glycopeptides from polyoma-transformed BHK cells; *b*, the small glycopeptides from polyoma-transformed BHK cells; *c*, the small glycopeptides from normal BHK cells. Chromatography was performed on a column of Sephadex G-25, fine (1  $\times$  125 cm) equilibrated and eluted with 0.01 M Tris-HCl buffer, pH 7.5 containing 0.1 M NaCl. Fractions of 1 ml were collected. The standard substances, (Man)<sub>6</sub>(GlcNAc)<sub>2</sub>N-(<sup>14</sup>C)-acetyl-Asn (molecular weight 1,393) and GlcNAc-N-(<sup>14</sup>C)-acetyl-Asn (molecular weight 379) were eluted in fractions 47–48 and 60–61, respectively. ●, Glycopeptides treated with neuraminidase,  $\beta$ -galactosidase and  $\beta$ -N-acetylglucosaminidase. The condition of exoglycosidase digestion was the same as described in Fig. 2. ○, Glycopeptides treated with endo- $\beta$ -N-acetylglucosaminidase D in the presence of neuraminidase,  $\beta$ -galactosidase and  $\beta$ -N-acetylglucosaminidase. The glycopeptides were digested with the mixture of 10.4 milliunits of endo- $\beta$ -N-acetylglucosaminidase D (ref. 9), 5.8 mU of neuraminidase<sup>19</sup>, 14.2 mU  $\beta$ -galactosidase<sup>19</sup> and 46 mU  $\beta$ -N-acetylglucosaminidase<sup>20</sup>, all from *Diplococcus pneumoniae* in 0.06 ml of 0.05 M citrate-phosphate buffer, pH 6.6 at 37 °C for 16 h. The products of the endoglycosidase digestion were concluded to be glycopeptide fragments and not oligosaccharides, since they migrated identically with the glycopeptide fragments from IgG glycopeptides on paper chromatography in butanol-acetic acid–1 N NH<sub>4</sub>OH (2:3:1).

peptides and the small glycopeptides. The cores were prepared by enzymatic removal of sialic acid, galactose and *N*-acetylglucosamine. We found that 70% of the cores both from the large glycopeptides of transformed cells (Fig. 2d, solid line) and from the small glycopeptides of normal and transformed cells (data not shown) were bound to the column of con A-Sepharose. Molecular weights of the cores were estimated to be ~1,100 in all the cases (Fig. 3). Further similarity of core structures was indicated by digestion with endo- $\beta$ -*N*-acetylglucosaminidase D (ref. 9). Most of the large and the small glycopeptides were hydrolysed by endo- $\beta$ -*N*-acetylglucosaminidase D in the presence of neuraminidase,  $\beta$ -galactosidase and  $\beta$ -*N*-acetylglucosaminidase, yielding glycopeptide fragments of molecular weight ~450 (Fig. 3). Therefore, in both the large and the small glycopeptides, fucose residue was located in the vicinity of protein-carbohydrate linkage region as described previously in human diploid cells<sup>10</sup>. In addition to the linkage region, clusters of mannosyl residues must be present in the cores of most of the glycopeptides, since both susceptibility to endo- $\beta$ -*N*-acetylglucosaminidase D (ref. 11) and binding to con A-Sepharose<sup>8</sup> required their presence. The number of the mannosyl residues in the glycopeptides were estimated to be ~3 in all the cases, since the difference of molecular weights between the core and the glycopeptide fragments was ~650, and the value roughly corresponded to the molecular weight of Man<sub>3</sub>GlcNAc, the principal oligosaccharide released from cell-surface glycopeptides by endo- $\beta$ -*N*-acetylglucosaminidase D (ref. 12). Therefore, cores of the large and the small glycopeptides were very similar to each other and to those of non-membrane glycopeptides such as IgG glycopeptides<sup>13,14</sup> (Fig. 4).

Summarising the results, the large glycopeptides and the small glycopeptides were different in their behaviour towards con A-Sepharose in spite of the close identity of the core structures. We have previously indicated that the presence of two  $\alpha$ -mannosyl residues capable of interacting with con A is required for a glycopeptide to bind to the column<sup>8</sup>. The interacting  $\alpha$ -mannosyl residues are those with free hydroxyl groups on C3, C4 and C6 (ref. 15). Thus, the large glycopeptides may have more branches composed of sialic acids, galactose and *N*-acetylglucosamine (Fig. 4). These additional branches will take the place of the hydroxyl groups of  $\alpha$ -mannosyl residues, resulting in the reduction of the number of  $\alpha$ -mannosyl residues interacting with con A.

The above conjecture is also supported by molecular weight values of the two glycopeptides. Calibrating the Sephadex G-50 column with standard glycopeptides, we could estimate approximate molecular weights of the large and the small glycopeptides to be 4,000 and 2,500, respectively (Fig. 1). Thus, the molecular weight difference of the large and the small glycopeptides was 1,500, which might be too large to be explained by the addition of sialic acid itself, but can be easily explained by the addition of whole chains of sialyl-galactosyl-*N*-acetylglucosaminyl

branches (Fig. 4). If the above inference is correct, the key step leading to the large glycopeptides is not sialylation<sup>4</sup>, but the initial formation of additional branches, possibly *N*-acetylglucosaminylation.

We thank Dr A. Hakura, Osaka University for culturing normal and transformed BHK cells.

## Influenza A antigens on human lymphocytes *in vitro* and probably *in vivo*

INFLUENZA A viruses cause respiratory tract infections in man, associated with generalised symptoms of fever, headache and myalgia. Virus replication seems to be limited to the respiratory tract epithelium<sup>1</sup>, and attempts to demonstrate a viraemia have been largely unsuccessful<sup>2</sup>, although it is not unknown<sup>3</sup>. The mechanisms producing the generalised symptoms are not yet understood. In this paper we demonstrate the probable presence of viral antigens on peripheral blood lymphocytes from patients during peak infection with influenza. This could have important implications both for the pathogenesis of influenza and for early diagnosis.

The technique we used was the mixed antiglobulin rosette-forming reaction<sup>4</sup> (MAR), which involved two stages of lymphocyte sensitisation. The lymphocytes to be tested for adsorbed influenza antigens were first treated for 45 min at 4 °C with rabbit anti-influenza serum (R9 or R18; see footnote to Table 1), or with normal rabbit serum (NRS) or diluent as controls. All rabbit sera had been heat inactivated and absorbed  $\times 3$  with human erythrocytes and  $\times 3$  with human formalised leukaemic spleen cells to remove anti-species antibodies. The lymphocytes were washed twice after the first-stage sensitisation, and then exposed to a sheep (207, bleed 5) anti-rabbit globulin serum (45 min, 4 °C). They were washed twice more and centrifuged (350g, 2 min, 4 °C) for rosette formation with equal volumes (20-25  $\mu$ l) of 0.8% (v/v) sheep erythrocytes coated with immunoglobulin from a rabbit anti-sheep erythrocyte serum (R8104/II, dilution 1:10,000). The pelleted cells were gently resuspended and mixed with toluidine blue stain for microscopic examination.

Lymphocytes for examination were separated from

**Fig. 4** A structural model of the majority of the large glycopeptides from transformed cells. The number of branches was estimated to be ~4, since the molecular weight difference of the intact glycopeptides and the core was ~2,900. In the small glycopeptides, the core structure was probably identical, but the number of branches was considered to be smaller

heparinised blood by treating with carbonyl iron, followed by differential centrifugation on Ficoll-Hypaque<sup>5</sup>. The purified lymphocyte suspension was washed twice with phosphate-buffered saline (PBS) and treated with formaldehyde<sup>6</sup> to prevent the formation of Fc and E rosettes with the indicator cells used later in the MAR. The fixed cells were washed twice with PBS and stored in sterile bottles at 4 °C until tested, at which stage they were washed twice more and resuspended to approximately  $2.5 \times 10^6 \text{ cells ml}^{-1}$  in 0.2% bovine serum albumin in PBS (PBS/BSA).

Preliminary experiments were carried out on blood lymphocytes from healthy individuals and the results compared with those on normal lymphocytes which had been

agent in NRS is antibody immunoglobulin which is able to combine with one or more antigenic components of influenza A. This conclusion was supported by further experiments in which the reactivity of NRS was retained, and actually increased, after treatment to remove nonspecific haemagglutination inhibiting factors<sup>7</sup> by (1) heating to 65 °C for 30 min. (2) treating with potassium periodate, (3) heating as in (1) plus periodate treatment, or (4) trypsin digestion.

The patients providing lymphocytes to be tested for *in vivo* adsorbed virus were selected by medical general practitioners on a clinical diagnosis of influenza. Between 24 h and 5 d after onset of symptoms, blood was taken, heparinised for lymphocyte separation, and clotted for

exposed *in vitro* to either whole MRC11 strain (influenza recombinant  $\text{H}_3\text{N}_2$ ) virus suspension or ether-treated MRC11 split viral products (see footnote to Table 2). Lymphocytes from six normal individuals showed low percentages of reacting cells—usually 5% or fewer with either anti-influenza serum or NRS (Table 1). There were significant increases in percentages of rosetting lymphocytes, with up to 100% of cells reacting, when the lymphocytes were exposed to either whole MRC11 viruses or ether-treated split virus before formaldehyde fixation (Table 2). The reactivity, however, was also markedly increased, though to a somewhat lesser extent, in suspensions treated with NRS. A second pool of NRS and rabbit R9 pre-inoculation serum exhibited similar reactivity. When doubling dilutions of NRS (pool 23/4/70 and 30/6/70) and R18 anti-influenza serum were tested on lymphocytes coated with (1:100) split viral products, lower reactions were produced with the NRS, so that at 1:1,600 dilution R18 antiserum gave 92% rosettes while NRS gave only 31% weak rosettes. The reactive factor was also present in DEAE-cellulose purified rabbit IgG fraction, and  $\text{F(ab')}_2$  fragments of pepsin-digested rabbit IgG also reacted (Table 3). Since the uptake on to lymphocytes of rabbit serum proteins other than immunoglobulin would not be detected by the two-stage MAR, all the evidence suggests that the reactive

serum extraction. To confirm diagnosis, a throat swab was cultured and identification of the infecting agent attempted. A second serum sample was taken 10 d to 3 months after the onset, and both sera were tested by haemagglutination inhibition (HI) for any rise in anti-influenza A antibodies. The results of these tests are shown in Table 4.

Influenza A was grown from three of the ten patients and two more had serological evidence of infection. In four of the five positive patients the percentage of lymphocytes giving reactions for surface-bound influenza antigens

\* For each patient, the first figure is for serum collected at the same time as blood for lymphocytes, and the second for serum taken 10 d to 3 months later.

† These results were obtained 'blind', since the results of swab cultures and HI serum titres were unknown to the tester.

NT, Not tested.

was substantially greater than for the remainder of the group, in which the reactions were mainly similar to those of lymphocytes from normal, non-infected individuals. The highest proportion of reacting lymphocytes (45%) was found in a patient (A.N.) infected with influenza A Scotland 74 serotype, and he also showed the highest antibody titre (HI 1:1,280, 2 months after infection). Patient R. B., with 22% to 26% reacting lymphocytes, gave a negative culture, but the specific increase in serum HI titre (3 months postinfection) indicates that the infection was probably influenza.

The fifth influenza-positive patient (P.H.) gave a negative MAR test, although the virus had been grown and antibody production demonstrated. The lymphocytes from this person were obtained within 24 h of the onset of symptoms, whereas those from other positive patients were obtained 2–5 d after the onset. It is thus possible that there is a delay of at least 24 h between the onset of disease and the appearance of detectable viral antigen on circulating lymphocytes. It will be seen that, as with lymphocytes coated with viral antigens *in vitro*, lymphocytes from positive patients also reacted with NRS, although the numbers of rosetted cells found in three out of the four cases were lower than with anti-influenza serum.

The binding and subsequent inactivation of influenza and other myxoviruses by cultures of human and non-immunised, pathogen-free mouse lymphoid cells has previously been demonstrated<sup>8,9</sup>. Other viruses also known to adhere to the lymphocyte cell membrane are the Epstein-Barr virus, which attaches to B lymphocytes but not to T cells<sup>10</sup> and the measles virus, receptors for which are found only on T lymphocytes<sup>11</sup>. It would seem from the present work that influenza A will adhere *in vitro* to both T and B cells since < 100% of cells were positive in the MAR test. Fewer cells with attached virus were found in the peripheral blood of patients, however, and it is not yet known whether there is any bias in the *in vivo* adherence in favour of T or B cells.

Further investigations on influenza infection in ferrets have been initiated and it is hoped that these will provide information on the nature and spread of lymphocyte-adherent viral components in better controlled conditions than are possible in human infections.

We thank Mrs Z. Madden for technical assistance, Dr D. Rubenstein for organising the collection of specimens,

Dr G. Appleyard, Microbiological Research Establishment, Porton Down, for R18 anti-influenza serum, Dr J. Oxford, National Institute for Medical Research, London, for MRC11 strain influenza virus. D.N.P. was in receipt of a Leverhulme Fellowship and on leave of absence from Beecham Pharmaceuticals (Research Division).

## Dopamine-like renal and mesenteric vasodilation caused by apomorphine 6-propylnorapomorphine and 2-amino-6, 7-dihydroxy-1,2,3,4-tetrahydronaphthalene

DOPAMINE has several unique actions in the central nervous system (CNS)—particularly the striatum—and in blood vessels, which seem to be due to interactions with specific receptors<sup>1,2</sup>. It is not known whether the vascular and CNS effects are mediated by actions on the same or different receptors. To demonstrate receptor identity, classical receptor theory requires that tissues respond in the same

rank order to a series of agonists of varying potency<sup>3</sup>. Remarkable similarities have been revealed in the relative efficacy of dopamine agonists in dilating canine renal blood vessels<sup>4</sup> and in increasing dopamine-sensitive cyclic AMP accumulation in homogenates of rat striatum<sup>5</sup>. Further characterisation has been restricted for lack of additional agonists to extend the potency series. We describe here a comparison of the actions of two recently described dopamine agonists, 2-amino-6,7-dihydroxy-1,2,3,4-tetrahydronaphthalene (ADTN) and 6-propyl-norapomorphine (PNA) with dopamine and apomorphine in the canine renal and mesenteric vascular beds. Apomorphine, which has structural similarities to dopamine, causes dopamine-like vasodilation<sup>4</sup> and increases cyclic AMP accumulation in rat striatum<sup>5</sup> but is much less potent and efficacious than dopamine in both systems. Woodruff *et al.*<sup>6</sup> found that ADTN exerted dopamine-like actions in the CNS of mice and resembled dopamine in decreasing blood pressure in guinea pigs. ADTN is equipotent with dopamine in increasing cyclic AMP accumulation in rat striatal homogenates<sup>5</sup>, and intra-striatal injections of ADTN in rats and guinea pigs produce a dyskinetic phenomenon characteristic of dopamine-like agents<sup>7,8</sup>. Cannon<sup>9,10</sup> suggested that PNA was a dopamine agonist on the basis of its emetic potency in the anaesthetised dog.

ADTN and PNA were chosen after preliminary experiments suggested that they have dopamine-like vasodilating actions. Methods were similar to those described before<sup>11</sup>. Mongrel dogs were anaesthetised with pentobarbital (32 mg kg<sup>-1</sup>) given intravenously. Anaesthesia was maintained by injections of 32 or 64 mg of pentobarbital when required. Blood flows in the renal, mesenteric and femoral arteries were monitored continuously by a Statham electromagnetic flowmeter coupled to a Beckman Dynograph Vasodilating

**Fig. 1** Mean increments in renal blood flow produced by intra-arterial injection of several doses of: ○, ADTN; □, dopamine; ●, PNA, and △, apomorphine. ADTN was compared with dopamine in five experiments; PNA and apomorphine were compared with dopamine in six more experiments. The dopamine curve represents the mean values obtained in all eleven experiments. Phenoxybenzamine (5 or 10 mg kg<sup>-1</sup>) was administered in the renal artery before injection of the vasodilators. Vertical lines indicate the s.e.m. when this value was larger than the symbol.

**Fig. 2** Mean increments in mesenteric blood flow produced by intra-arterial injections of several doses of: ○, ADTN; □, dopamine; ●, PNA, and △, apomorphine in five experiments in anaesthetised dogs. Phenoxybenzamine (5 or 10 mg kg<sup>-1</sup>) was administered intra-arterially before injection of vasodilators. Vertical lines indicate the standard error of the mean when this value was greater than the symbol.

agents were administered after intra-arterial injection of 5 or 10 mg of phenoxybenzamine, which was sufficient to eliminate or reverse the vasoconstricting actions of noradrenaline. Injections were made in a volume which caused no injection artefacts (0.2–0.4 ml). Dopamine, ADTN, PNA and apomorphine were administered in a fourfold geometric dose progression in doses ranging from  $3 \times 10^{-9}$  to  $3 \times 10^{-6}$  mol. The effects of ADTN and dopamine were investigated in one group of five dogs; in a separate group of six dogs, the effects of PNA were compared with both dopamine and apomorphine. In mesenteric blood flow experiments all agents were investigated in the same five dogs. In femoral blood flow experiments ADTN, dopamine and bradykinin were compared in one group of five dogs and PNA, apomorphine, bradykinin and dopamine in a separate group of five dogs. When large doses of the compounds were injected intra-arterially, recirculation usually had a subsequent effect on blood pressure. Only those changes preceding the alteration in blood pressure were considered in the analysis of the results.

The effects of various antagonists were investigated in two experiments with the renal vascular bed. (1) In five dogs, haloperidol ( $1.4 \times 10^{-7}$  mol) was injected into the renal artery simultaneously with the putative agonists. This dose of haloperidol causes transient selective attenuation of the vasodilation produced by dopamine<sup>12</sup>. (2) The agonists were administered intra-arterially to four dogs before and after intra-arterial injection of a solution containing propranolol (2 mg kg<sup>-1</sup>) and atropine (1 mg kg<sup>-1</sup>); these doses were sufficient to attenuate markedly the vasodilation produced by acetylcholine and isoproterenol. ADTN was synthesised

Fig. 3 Effects of injections of dopamine ( $4.7 \times 10^{-8}$  mol), ADTN ( $4.7 \times 10^{-8}$  mol), PNA ( $7.5 \times 10^{-7}$  mol), and apomorphine ( $7.5 \times 10^{-8}$  mol) alone and combined with haloperidol ( $1.4 \times 10^{-7}$  mol). Phenoxybenzamine ( $5$  or  $10$  mg  $\text{kg}^{-1}$ ) was administered in the renal artery before injection of vasodilators. Dopamine and ADTN were administered in one experiment; PNA and apomorphine in a different experiment

by R.M.P., PNA by W.B.H. Sources of the other compounds were as follows: dopamine HCl (Calbiochem), noradrenaline bitartrate, isoproterenol hydrochloride, bradykinin and acetylcholine (Sigma), phenoxybenzamine (Smith, Kline and French), propranolol HCl (Ayerst). The paired *t* test was used for statistical analyses.

Dopamine and ADTN increased renal blood flow in a dose-related manner (Fig. 1). In most experiments, equimolar doses of ADTN produced greater vasodilation than dopamine (Fig. 3) and the differences were statistically significant ( $P < 0.05$ ) at three of the doses studied ( $3 \times 10^{-9}$  mol,  $1.2 \times 10^{-8}$  mol,  $9 \times 10^{-7}$  mol). PNA and apomorphine were much less potent and effective than ADTN and dopamine. In most experiments, PNA produced greater renal vasodilation than apomorphine and the differences in the mean values were statistically significant for doses of  $1.9 \times 10^{-7}$  mol,  $7.5 \times 10^{-7}$  mol and  $3 \times 10^{-6}$  mol.

Similar responses were produced in mesenteric blood flow (Fig. 2). As in previous studies with dopamine, the dose-response curves were steeper than those constructed from experiments in the renal artery<sup>12</sup>. Again, ADTN was more effective than dopamine in most experiments and the difference was statistically significant at two doses,  $1.2 \times 10^{-8}$  mol and  $1.9 \times 10^{-7}$  mol. PNA was a more effective vasodilator than apomorphine in all experiments. But unlike the situation in renal experiments, the mean differences were not statistically significant at any dose.

Arterial blood pressure was not changed appreciably with smaller doses of the vasodilators. But with the highest two doses profound hypotension frequently occurred, making it difficult to estimate the maximum increase in renal and mesenteric blood flow. The hypotension was more pro-

nounced in the mesenteric experiments and thus data from the highest dose are not included in Fig. 2.

In contrast to the vasodilation produced by ADTN, PNA, apomorphine and dopamine in the renal and mesenteric vascular beds, femoral blood flow was not altered by these agents. As in previous studies<sup>11</sup>, bradykinin in doses ranging from  $1 \times 10^{-11}$  mol to  $5 \times 10^{-11}$  mol increased femoral blood flow in every experiment.

Haloperidol ( $1.4 \times 10^{-7}$  mol) caused transient attenuation of the renal vasodilating effects of ADTN, PNA and apomorphine in all experiments and at every dose (Fig. 3).

Combined administration of propranolol and atropine did not affect the renal vasodilation produced by ADTN, PNA or apomorphine. These agents, however, virtually abolished the vasodilation produced by isoproterenol in the dose range  $3 \times 10^{-8}$  mol to  $3 \times 10^{-7}$  mol and acetylcholine in the dose range  $5 \times 10^{-7}$  mol to  $3 \times 10^{-6}$  mol.

These experiments have demonstrated that ADTN, PNA and apomorphine satisfy the criteria established for *in vivo* characterisation of dopamine-like vasodilators<sup>2,13</sup>. First, after administration of phenoxybenzamine, dose-related vasodilation occurred in the renal and mesenteric vascular beds, but not in the femoral vascular bed. Second, vasodilation was not antagonised by propranolol and atropine but was attenuated selectively by haloperidol. Accordingly, the series of dopamine-like vasodilators has been extended to include more rigid cyclic compounds. In a previous investigation, apomorphine seemed to be dopamine-like, but haloperidol attenuation was not demonstrated<sup>4</sup>.

The greater efficacy of ADTN compared with PNA or apomorphine indicates that the preferred conformation for dopamine-induced vasodilation is the fully extended transoid form. A similar conclusion was reached<sup>8-9</sup> for putative dopamine receptors in the CNS. Indeed, the almost identical potency series of agonists causing dopamine-like effects in the blood vessels and in the brain, and the observations that phenothiazines and butyrophenones antagonise both central and vasodilating effects of dopamine support the suggestion that dopamine receptors in the two regions are identical<sup>1,2,14</sup>.

## Possible involvement of central histamine H<sub>2</sub>-receptors in the hypotensive effect of clonidine

CLONIDINE and some other antihypertensive drugs exert their effect by acting on the central nervous system<sup>1-4</sup>. Some  $\alpha$ -adrenoceptor blocking drugs antagonise the centrally mediated hypotensive effect of clonidine<sup>5-7</sup>. It has therefore been suggested that clonidine acts by stimulating central  $\alpha$ -adrenoceptors, bringing about a depression of the cardiovascular system. The involvement of classical  $\alpha$ -adrenoceptors has, however, been challenged<sup>8,9</sup>. Moreover, in the brain tissue clonidine may even be a potent  $\alpha$ -adrenoceptor antagonist<sup>10</sup>.

We have previously reported that clonidine stimulates histamine H<sub>2</sub>-receptors in the gastric mucosa<sup>11</sup>, and recently it has been shown that clonidine also has the same effect in the heart<sup>12</sup>.

Histamine H<sub>2</sub>-receptors are present in the brain tissue<sup>13</sup>. Interestingly, alterations in the metabolism of brain histamine have been implicated in the pathogenesis of the spontaneous hypertension in rats<sup>14</sup>. We have now used the specific histamine H<sub>2</sub>-receptor antagonist, metiamide<sup>15</sup>, in order to study whether central histamine H<sub>2</sub>-receptors might be involved in the cardiovascular effects of clonidine.

Female Sprague-Dawley rats (200-250 g) were anaesthetised with urethane (1.5 g kg<sup>-1</sup> intraperitoneally). The trachea was cannulated with a polyethylene tube and the rats were allowed to breathe spontaneously. The mean blood pressure was measured directly from the left femoral artery by means of a pressure transducer (Harvard apparatus 377). The heart rate was calculated from the pulse waves. Since

**Fig. 1** Influence of metiamide on the hypotensive effect of clonidine in rats. Metiamide (1.5  $\mu$ mol per rat) or saline was administered intracerebroventricularly, 10-15 min later clonidine (30  $\mu$ g kg<sup>-1</sup>) was injected intravenously. Differences between the metiamide (●) and control (○) groups were significant to the  $P < 0.001$  level for all measurements except that made at 40 min ( $P < 0.02$ ). The time elapsed after the injection of clonidine is shown on the abscissa. Vertical bars indicate s.e.m. The number of rats was 18 in the control group and 10 in the metiamide group.

**Fig. 2** Reversal of the clonidine-induced hypotension by metiamide. Clonidine (30  $\mu$ g kg<sup>-1</sup> intravenously) induced hypotension as shown in Fig. 1. 30 min after the injection of clonidine, metiamide (1.5  $\mu$ mol per rat) or saline was administered intracerebroventricularly. The time elapsed thereafter is shown on the abscissa. The differences between the metiamide (●) and control (○) groups were statistically significant at the  $P < 0.005$  level after 20 min, and the  $P < 0.01$  level after 30 min. Vertical bars, s.e.m. The number of rats was 9 in the control group and 6 in the metiamide group.

metiamide does not penetrate the blood-brain barrier, it was administered intracerebroventricularly.

In the first series of experiments, metiamide (1.5  $\mu$ mol per rat) was infused during 15 min into the lateral cerebral ventricle in a volume of 45  $\mu$ l (pH 6). Ten to fifteen minutes after the completion of the metiamide infusion, 30  $\mu$ g kg<sup>-1</sup> of clonidine hydrochloride was injected into the left femoral vein. The control rats were treated in exactly the same manner but received saline (pH 6) instead of metiamide solution.

The blood pressure values before the clonidine injections were  $110 \pm 4$  (s.e.) mmHg in the control rats and  $109 \pm 5$  (s.e.) mmHg in the metiamide-pretreated rats.

In the control rats clonidine induced a marked hypotension which was obvious for at least 40 min (Fig. 1). The maximum fall of blood pressure (approximately 30% from the initial level) was reached within 20 min and the blood pressure remained nearly constant for at least another 20 min. Metiamide alone did not affect the blood pressure. In the metiamide-pretreated rats, however, the hypotensive response to clonidine was markedly attenuated (Fig. 1) and the blood pressure remained for the whole 40-min observation period significantly higher ( $P < 0.02$  to  $P < 0.001$ ) than in the control rats. The bradycardiac effect of clonidine was slightly but not significantly ( $P > 0.05$ ) antagonised by the metiamide pretreatment.

In another series of experiments the ability of intracerebroventricular metiamide to reverse the clonidine-induced hypotension was studied. Thirty minutes after the intravenous injection of clonidine (30  $\mu$ g kg<sup>-1</sup>), 1.5  $\mu$ mol of metiamide was injected intracerebroventricularly within 2 min in a volume of 15  $\mu$ l. The control rats received 15  $\mu$ l of saline. Metiamide caused a clear elevation of the blood pressure level within 5 min (Fig. 2). The metiamide-induced increase of the heart rate was not statistically significant ( $P > 0.05$ ).

In contrast to metiamide, the histamine H<sub>1</sub>-receptor

blocking agent diphenhydramine (0.03 to 1.5  $\mu$ mol per rat intracerebroventricularly) did not antagonise the hypotensive effect of clonidine. The highest dose (1.5  $\mu$ mol per rat) was lethal to most of the rats.

The present results indicate that clonidine also stimulates histamine  $H_2$ -receptors in the central nervous system as it does in peripheral tissues<sup>11,12</sup>. Moreover, the findings also suggest that a stimulation of central histamine  $H_2$ -receptors brings about a depression of the cardiovascular system which is manifested as the lowering of blood pressure.

This work was supported in part by grants from the P.I. Ahvenainen Foundation and the Ida Montin Foundation. We are grateful to the Smith, Kline and French Laboratories Ltd for the metiamide. Clonidine hydrochloride was supplied by Boehringer Ingelheim, and diphenhydramine hydrochloride by Parke-Davis & Co, Pontypool.

## Induction of ovalbumin and conalbumin synthesis in immature chick oviducts by ethionine

PROLONGED feeding of rats with ethionine results in a high frequency of hepatic carcinoma. Ethionine induces other pathological manifestations in other organs and tissues of experimental animals<sup>1</sup>, and some of its effects can be reversed rapidly by the administration of methionine. At the molecular level ethionine induces a rapid decrease in hepatic ATP concentration<sup>2-4</sup>, followed by inhibition of RNA<sup>5</sup> and protein synthesis<sup>6</sup>. The decrease in ATP concentration is due to formation of S-adenosyl-ethionine<sup>7</sup>, an inhibitor of tRNA methyltransferases<sup>8,9</sup>, and so tRNA isolated from the liver of rats injected with adenine and ethionine is hypomethylated<sup>10,11</sup>. It is well established that several eukaryotic mRNAs are methylated on the 5' terminus and that such modification is essential for translation<sup>12,13</sup>. To study the mechanism of methylation we attempted to produce a specific methyl-deficient mRNA by the administration of ethionine. To monitor the effectiveness of the deprivation of methyl groups the synthesis of hormone-induced ovalbumin in immature chick oviducts was followed. Administration of oestrogen to immature chicks causes cytodifferentiation and growth of the primitive oviduct<sup>14-17</sup>. The tubular gland cells synthesise ovalbumin, conalbumin, ovomucoid and lysozyme which comprise 85-90% of the egg-white proteins<sup>18</sup>. The con-

tinuous presence of oestrogen is required for sustained synthesis of these proteins in immature chicks; withdrawal of oestrogen is accompanied by a gradual decline in cell-specific protein synthesis as well as in the weight of the oviduct and the RNA content of the tissue<sup>17</sup>. But, the tubular gland cells in the oviduct magnum during withdrawal are retained although they do not synthesise cell-specific secretory proteins<sup>17,19</sup>. Readministration of hormone to chicks after withdrawal (secondary stimulation) results in restoration of cell-specific protein synthesis without concomitant need for DNA synthesis<sup>17</sup>. During these studies ethionine unexpectedly simulated the effects of the injection of oestrogen for secondary stimulation.

Four-day-old Calhoun chicks were injected with 1 mg of oestradiol benzoate in sesame oil for 10 d (ref 19). After a withdrawal period of 3-4 weeks the chicks were used in most of the experiments. The chicks were injected in groups of eight intraperitoneally with a 1-ml suspension in water of L-ethionine or methionine (0.25 mg per g body weight) and/or adenine (0.12 mg per g body weight) for 5-7 d. At the times specified the animals were killed and the capacity for ovalbumin synthesis of the magnum explants was determined. Oestradiol benzoate-17 $\beta$  was a product of Calbiochem, L-ethionine, adenine and methionine were from Sigma. <sup>14</sup>C-amino acid mixture (algal profile) was purchased from Schwarz/Mann. Medium 199 ( $\times 10$ ) and NaHCO<sub>3</sub>-free Hanks balanced salt solution ( $\times 10$ ) were from Grand Island Biological. Anti-ovalbumin and conalbumin sera were elicited in rabbits.

Chicks were decapitated and their oviducts were removed aseptically, the magnum portions of the oviduct were freed of adjoining tissue and were cut into small pieces. The magnum explants were incubated *in vitro* in antibiotic-free medium<sup>20-22</sup>. Tissue (100-200 mg) was incubated in 2 ml of medium in 25-ml, rubber stoppered Erlenmeyer flasks. Each flask contained tissue from at least three oviduct magna. The incubations were carried out at 37 °C for 3 h with constant shaking and the flasks were gassed with 95% O<sub>2</sub>-5% CO<sub>2</sub> at hourly intervals. At the end of the incubation the pieces of tissue were blotted on filter paper, homogenised in 2 ml of 15 mM NaCl-10 mM sodium phosphate, pH 7.5, and centrifuged at 100,000g for 1 h. The high speed supernatant was used for subsequent analyses<sup>20</sup>. Labelled ovalbumin was determined essentially according to Rhoads *et al.*<sup>23</sup>. The tubes were incubated at 37 °C for 1 h and then stored at 4 °C until they were filtered. The precipitates were collected on Millipore HAWP filters, 0.45  $\mu$ m (pre-wetted with the wash solution) and were washed three times

**Fig. 1** Time course of induction of ovalbumin synthesis in immature chick oviducts by oestradiol ( $\blacktriangle$ ), and ethionine and adenine ( $\bullet$ ). Chicks withdrawn from primary stimulation for 4 weeks were injected with oestradiol (1 mg) or ethionine and adenine as described in the text. At various times five chicks were killed and ovalbumin synthesis was determined in duplicate or triplicate samples. Details are the same as for Table 1.

**Fig. 2** SDS-acrylamide gel electrophoresis of high speed supernatants from incubations. Oviduct explants were incubated as described in the text. Samples of 50–100  $\mu$ l of the high speed supernatant were precipitated with trichloroacetic acid and electrophoresed on SDS-acrylamide gels<sup>20</sup>. The migration of conalbumin (CON) and ovalbumin (OV) is indicated. *a*, Chicks withdrawn for 28 d, after 10 d of primary oestrogen stimulation; *b*, withdrawn chicks injected with oestrogen for 24 h; *c*, withdrawn chicks injected with ethionine and adenine for 5 d.

with 1-ml samples of 10 mM sodium phosphate, pH 7.5 containing 150 mM NaCl, 1% deoxycholate and 1% Triton X-100. The filters were dried at 100 °C for 30 min and counted in a liquid scintillation counter. The reactions were performed so that at least three concentrations of ovalbumin precipitated in the linear range (antibody excess). A blank of bovine serum albumin (5  $\mu$ g) and rabbit anti-bovine serum albumin was used to correct for non-specific precipitation<sup>24</sup>.

When, 4 weeks after primary oestrogen stimulation—at which time oviducts do not synthesise ovalbumin—ethionine and adenine were injected for 3 d followed by secondary oestrogen stimulation with oestradiol for 18 h, the outcome was unexpected. Ovalbumin synthesis in these chicks was greater than in those which received oestradiol alone (data not shown). Therefore, the effect of the administration of ethionine without secondary oestrogen stimulation was studied in chicks 4 weeks after primary stimulation (Table 1).

Ethionine itself induced ovalbumin synthesis although a combination of ethionine and adenine was more effective. Adenine alone and in combination with methionine did not induce ovalbumin synthesis. The induction of ovalbumin synthesis by ethionine was slower than by oestrogen (Fig. 1). Ethionine is highly toxic to chicks and the animals died after 5–7 d. Conalbumin synthesis was also induced by ethionine as measured by precipitation with monospecific antiserum to conalbumin (data not shown). Induction of ovalbumin and conalbumin synthesis was confirmed by sodium dodecyl sulphate (SDS)-acrylamide gel electrophoresis (Fig. 2).

Electron microscopy of the oviduct revealed in the control tissues well developed tubular glands but the cytoplasm of the glandular cells was devoid of the organelles associated with specific intracellular synthesis (Fig. 3*a*). In the tissues of ethionine-treated chicks the nuclei of the glandular cells were located basally, the rough endoplasmic reticulum and the Golgi complex were well developed, electron-dense secretory granules were prominent and the

**Fig. 3** Electron micrographs of chick oviduct magna. The excised oviduct magnum tissue was minced into 1 mm cubes, fixed in buffered 4% glutaraldehyde for 1 h, postfixed in 1% osmium tetroxide, dehydrated in ethanol and embedded in Epon-Araldite via propylene oxide. Thin sections were stained with hot alcoholic uranyl acetate<sup>25</sup> and lead citrate<sup>26</sup>. *a*, Tubular gland from control chicks, the nuclei are randomly distributed and the cytoplasm has a minimal number of organelles ( $\times 6,250$ ). *b*, Tubular gland from ethionine-treated chicks; the nuclei are basal; the cytoplasm contains abundant rough endoplasmic reticulum, Golgi complex and apical-secretory granules ( $\times 6,500$ ). *c*, Tubular gland from oestradiol-treated chicks, the cytoplasmic organelles are even more prominent and there are abundant ribosomes ( $\times 6,750$ ).

Table 1 Induction of ovalbumin synthesis in immature chick oviducts by ethionine

Treatment	Oviduct magnum* weight per chick (mg)	<sup>14</sup> C-amino acids incorporated per mg of soluble protein (c.p.m. $\times 10^{-5}$ )	<sup>14</sup> C-amino acids incorporated into ovalbumin per mg of soluble protein (c.p.m. $\times 10^{-5}$ )	Ovalbumin synthesis, % of total protein synthesis
None	230 (4)	0.77 0.85	Not detected

Adenine+ methionine	230 (8)	0.77 0.85	Not detected	

After 10 d of primary oestrogen stimulation chicks were withdrawn for 28 d and in groups of eight were injected intraperitoneally for 5 d as described in the text. On day 6 the animals were killed and ovalbumin synthesis in the oviduct magnum explants was determined as described. The incubations were carried out in duplicate and the flasks contained tissue from at least two different chicks.

\*Average magnum weight, the number in parentheses refers to the number of chicks.

†Secondary oestrogen stimulation was by 1 mg of oestradiol for 24 h.

Fig. 4 Electron micrographs of epithelia of chick oviduct magna. Tissue processing was identical to that described for Fig. 3. Surface epithelium from control chicks (a), the epithelial cells contain sparse cytoplasmic organelles, few cilia are present in the surface ( $\times 5,000$ ). b, Surface epithelium from ethionine-treated chicks. The cells contain abundant cytoplasmic organelles and cilia are prominent in the oviduct cavity ( $\times 6,500$ ).

cells had membrane specialisation resembling tight junctions, desmosomes and microvilli (Fig. 3b). In the cells of oestradiol-treated oviduct, the nuclei were basal, and the rough endoplasmic reticulum and Golgi complexes were even better developed than in the tissue of ethionine-treated animals. The secretory granules were more prominent, membrane differentiation was obvious and the cytoplasm contained abundant ribosomes (Fig. 3c). A process similar to that in the glands, was obvious in the surface epithelium<sup>27,28</sup>. The surface cells in the controls had few organelles, only occasional cilia and sparse membrane specialisation. In the tissues of the animals exposed to oestradiol or ethionine, cell organelles, membrane specialisation and cilia became abundant (Fig. 4).

Induction of ovalbumin and conalbumin synthesis by ethionine was not observed in the "primitive oviduct" of chicks (5–6 weeks old) which had not received primary stimulation with oestrogen. This suggests that ethionine alone cannot cause cytodifferentiation and growth of the primitive oviduct, but that in tissues already differentiated by the action of oestradiol it can induce the further cellular differentiation needed for specific protein synthesis. The mechanism of induction of protein synthesis by ethionine remains obscure: it may or may not stem from interference with the methylation of either mRNA or tRNA or both. In view of the powerful oncogenicity of the agent the phenomenon is, however, worthy of study to delineate the mechanism of its induction.

## Regulation of degradation of thyrotropin releasing hormone by thyroid hormones

WHEN thyrotropin releasing hormone (TRH, pyroGlu-His-Pro-NH<sub>2</sub>) was isolated and its structure determined<sup>1,2</sup> the concept of neurohumoral regulation of hormone secretion by the anterior pituitary<sup>3</sup> was confirmed, but the mechanisms involved are not well understood. Enzymatic inactivation of TRH by blood and serum may regulate the hormone's activity by determining the number of molecules available to the thyrotroph<sup>4</sup>. With this physiological function, degradative enzyme(s) would itself need to be regulated and I report here that the activity of the TRH-degrading enzyme(s) is controlled by the thyroid hormones.

Rapid inactivation of TRH by serum was reported before its structure was elucidated<sup>5,6</sup>, but the mechanism of degradation remains to be elucidated. Based on the observation that the free amino acids are the main degradation products<sup>7</sup>, a quantitative test of TRH-degradation was developed. After incubation of TRH (labelled with <sup>3</sup>H in the histidine moiety) with serum, the labelled products

could be separated by ion exchange chromatography as described in the legend of Fig. 1. TRH migrated with an *R<sub>f</sub>* of 0.25 as identified by cochromatography of synthetic material which was visualised using Pauly reagent. All labelled degradation products remained absorbed near the origin, as shown by rechromatography of the material from the TRH zone with standard peptides. Thin-layer chromatography in several solvent systems and electrophoresis at pH 1.9 and 6.4, revealed one radioactive spot comigrating with the standard hormone while all the possible labelled cleavage products migrated separately (Table 1). Radioactivity in the TRH zone was determined by scintillation counting.

This test provided a simple and sensitive method for quantitative evaluation of TRH degradation by serum (see legend to Fig. 2). It is thus possible to follow the kinetics of TRH degradation by serum and to determine the initial rate as a measure of enzyme activity. In the conditions described (Fig. 2), the initial rate of degradation increased from 1.6% min<sup>-1</sup> for serum of untreated rats to 3.3% min<sup>-1</sup> for that of hyperthyroid animals (injected with triiodothyronine, T<sub>3</sub>). With serum from hypothyroid rats (treated with propylthiouracil, PTU) degradation was very slow (0.6% min<sup>-1</sup>) but restored to above normal (1.7% min<sup>-1</sup>) within 72 h by daily injection of 10 µg T<sub>3</sub>. This observation parallels the reported reduced TRH inactivation of plasma from hypophysectomised-thyroidectomised rats which was restored by treatment with T<sub>3</sub> (ref. 8). Because of the limitations of the biological assay, these studies could not be confirmed<sup>9</sup> and have not been extended.

With the demonstration of a single exponential relationship of TRH degradation with time (Fig. 2) and serum protein (our unpublished results) degradation activity could be determined by a four-point assay with four serum dilutions. When the degradation activity of serum from untreated control animals was compared with that from animals injected with T<sub>3</sub> or treated with PTU, the effect of the thyroid hormones could be demonstrated clearly (Fig. 3). As Fig. 3a shows, the activity of the serum enzyme(s) declined slowly when the formation of thyroid hormones

**Fig. 1** Separation of labelled split products from TRH-<sup>3</sup>H-histidine incubated with serum. Trunk blood from rats was collected in plastic tubes and allowed to clot for 3 h at 0 °C. Serum was obtained by centrifugation at 5,000 r.p.m. for 15 min. Serum (10 µl) diluted 1:3 with buffer A (100 mM Tris-HCl pH 7.6, 1 mM DTT), was incubated at 37 °C for 30 min with 1.0 µCi of purified TRH-<sup>3</sup>H-histidine (18 Ci mmol<sup>-1</sup>) in 20 µl buffer A. The reaction mixture and 10 µg synthetic TRH were applied to prewashed cellulose phosphate paper which was then developed with 1 N acetic acid. The labelled products were localised by scanning for radioactivity (Berthold Scanner, LB 2723) and the cochromatographed TRH was stained with the Pauly reagent.

**Table 1** Chromatographic separation of TRH from cleavage products

pH 6.4	20.5	6.4	6.5	32	21.5	25.5

The material from the TRH corresponding zone of Fig. 1 was eluted with 0.5 ml 1 N ammonia using extraction thimbles (Reeve Angel) and the standard material was applied to silica gel precoated plates (Merck No. 5721) for thin-layer chromatography or to paper (Whatman 3M) for electrophoresis. 1, TRH; 2, deamido-TRH; 3, pyroGlu-His; 4, His-Pro-NH<sub>2</sub>; 5, His-Pro; 6, His. The plates were developed in vapour-saturated tanks using the solvent systems: A, CHCl<sub>3</sub>-CH<sub>3</sub>OH-NH<sub>3</sub>aqueous (125:75:25); B, propanol-methyl-ethylketone-pyridine-acetic acid-water (40:40:40:20:40); C, phenol-water (150:50). Paper electrophoresis was carried out at 50 V cm<sup>-1</sup> using buffer pH 1.9 (HCOOH-CH<sub>3</sub>COOH-H<sub>2</sub>O 50:150:800) or buffer pH 6.4 (pyridine-acetic acid-water 100:10:890). The labelled material was localised by scanning for radioactivity and the cochromatographed standard material by staining with Pauly reagent or by the chlorine-iodide reaction for the phenol-containing solvent system.

**Fig. 2** Time course of degradation of TRH by serum. 0.5  $\mu$ Ci of TRH- $^3$ H-histidine in 40  $\mu$ l of buffer was incubated at 37°C with 20  $\mu$ l of serum (diluted 1:3 with buffer A). At various times 5  $\mu$ l of the reaction mixture was spotted on the ion exchange paper. After development in 1 N acetic acid the strips were segmented and the segments corresponding to the TRH zones were placed in scintillation vials. 500  $\mu$ l 2 N ammonia per segment (1.5  $\times$  2 cm) was added to each vial and after 10 min 10 ml of Bray solution was added before scintillation counting. The values are expressed as percentage of the total TRH added. The serum was obtained, as for Fig. 1, from one group of male rats, 6 months old.  $\circ$ , Untreated;  $\bullet$ , 10  $\mu$ g  $T_3$  per 100 g body weight given subcutaneously every 24 h, 72 h before decapitation;  $\nabla$ , PTU (200 mg  $l^{-1}$ ) was added to the drinking water for 4 months;  $\blacktriangledown$ , PTU-pretreated rats were injected with  $T_3$  as before.

was blocked by the goitrogenic agent PTU. In the conditions described (Fig. 3) peptidase activity was reduced by 50% after 40 d. Whether the slow decline reflects the long half life of the circulating enzyme(s) needs further investigation.

In contrast, a rapid increase of enzymatic activity became evident 24 h after injection of normal and hypothyroid animals with  $T_3$  (Fig. 3b): 72 h after injection there had been a 2.1-fold increase of enzymatic activity for euthyroid animals. The rate of increase was greater for euthyroid animals than for those pretreated with PTU. In parallel with biological activity, the stimulation of the enzyme activity was less pronounced when thyroxine ( $T_4$ , Sigma) was injected, but the onset of hormone expression was the same. The prolonged lag period and the preliminary observation that stimulation is inhibited by actinomycin D or puromycin indicate that the appearance of enzymatic activity is preceded by the induction of protein (enzyme) synthesis, as with the induction of hepatic cellular activities by thyroid hormones<sup>9</sup> or feedback control of pituitary thyroid stimulating hormone (TSH) secretion by  $T_3$  or  $T_4$  (refs 10–12).

As Fig. 3c shows, the effect of the thyroid hormones is strongly dose related. Even after subcutaneous injection of only 0.5  $\mu$ g  $T_3$  per 100 g body weight per day, there was strong stimulation of enzymatic activity. Euthyroid female rats showed only 85% of the enzymatic activity of euthyroid males. The origin of this sex difference is as obscure as the sex difference of plasma TSH and  $T_4$  in rats<sup>13</sup>. The response to  $T_3$  was less for female and PTU-treated rats than for control males.

These results show that the activity of the TRH-

degrading enzyme(s) is controlled by the thyroid hormones. Because there is evidence that blood collected from the hypothalamo-hypophyseal portal vessels inactivates TRH (ref. 6 and R. L. Eskay, personal communication), my results suggest that the regulation of the positive stimulus of TRH on the thyrotroph could be the physiological function of these enzyme(s). The enzymatic degradation would thus contribute to the balance of thyrotrophin secretion, which in turn is controlled by the thyroid hormone-induced negative feedback mechanism acting directly on the thyrotroph<sup>10–12</sup>. This sensitive and rapid assay provides a tool for further studies of the implication of the enzymatic degradation of TRH in the regulation of the hypothalamic-pituitary-thyroid axis, in clinical diagnosis (TRH-induced TSH-secretion tests) and in pathological disorders (enzyme defects) which might contribute to the "inappropriate secretion of TSH".

I thank Professor H. Kleinkauf for support and interest and P. Nowak for help and discussion. I thank Drs R. O. Studer and D. Gillessen, Hoffmann-La Roche AG, Basle,

**Fig. 3** Effect of thyroid hormones on the degradation of TRH activity of serum. Serum was obtained as for Fig. 1 and assayed at four dilutions (1:1, 1:2, 1:3 and 1:4) following a four-point kinetic (0, 7.5, 15 and 30 min), as described in Fig. 2. Degradation activity is expressed as percentage of the enzyme activity of serum from untreated male rats kept as control animals. **a** TRH degradation activity of serum from male rats after treatment with PTU (200 mg  $l^{-1}$  drinking water) for various times. **b**, At given times serum was obtained from 6-month-old male rats, injected subcutaneously with 10  $\mu$ g  $T_3$  or  $T_4$  per 100 g body weight every 24 h.  $\bullet$ , Untreated, injected with  $T_3$ ;  $\circ$ , untreated injected with  $T_4$ ;  $\blacktriangle$ , pretreated with PTU (200 mg  $l^{-1}$  drinking water) for 4 months, injected with  $T_3$ ;  $\triangle$ , PTU-pretreated, injected with  $T_4$ . **c**, TRH degradation activity of serum from 6-month-old rats injected subcutaneously every 24 h with the indicated dose of  $T_3$  per 100 g body weight 72 h before decapitation.  $\bullet$ , Males;  $\circ$ , females;  $\blacktriangle$ , males pretreated with PTU as before for 4 months.

for labelled hormone and peptide intermediates and the Deutsche Forschungsgemeinschaft for financial support.

## Primer-dependent copying of rabbit globin mRNA with Q<sub>β</sub> replicase

THE synthesis of complementary strands of heterologous RNAs has been achieved by incubating these RNAs with Q<sub>β</sub> replicase in the presence of Mn<sup>2+</sup> (refs 1, 2). Q<sub>β</sub> replicase has been used in this way for the *in vitro* copying of RNAs for which no replicating enzymes are available. A further extension of such synthesis is offered by the recently discovered primer-dependent RNA synthesis by Q<sub>β</sub> replicase<sup>3</sup>. This approach is specially suited for the copying of eukaryotic RNAs (mRNAs) with a 3'-terminating poly(A) sequence. The complementary RNA synthesis is started at these poly(A) sequences with oligo(rU)<sub>6</sub> as primer and continues into the heterologous part of the mRNAs. The particular advantages of this method are the independence of special structural features of the template RNA for the initiation of synthesis and the possibility to inhibit completely any disturbing 6S RNA synthesis which normally takes place in Q<sub>β</sub> replicase incubations. Because of its defined start of synthesis, the newly synthesised complementary RNA may be very useful for sequence determinations of the template RNAs. I describe here experiments using rabbit globin mRNA as an example of the primer-dependent copying of eukaryotic mRNAs.

The standard conditions for these replicase incubations were as follows: Q<sub>β</sub> replicase (preparation described in ref. 6) 80 U ml<sup>-1</sup>, 12 mM MgCl<sub>2</sub>, 80 mM Tris-HCl (pH 7.6), 0.8 mM ribonucleoside triphosphates, and rabbit globin mRNA (Searle) as well as oligo(rU)<sub>6</sub> (Boehringer) in concentrations as specified. Since endogeneous 6S RNA synthesis is a major problem in Q<sub>β</sub> replicase incubations with heterologous templates in the presence of the four common ribonucleoside triphosphates (ATP, UTP, CTP, GTP) (refs 4 and 5), conditions were sought which would inhibit this synthesis. 6S RNA synthesis is strictly dependent on the presence of GTP and it can be avoided completely if GTP is replaced by ITP in the incubation mixture (data not shown). This inhibition of 6S RNA seems to involve the initiation step, since the substitution of GTP by ITP does not interfere with the elongation steps of Q<sub>β</sub> replicase reactions<sup>3</sup>. As the primer-dependent start of RNA synthesis is independent of GTP, GTP was replaced by ITP in the following enzyme assays, thus inhibiting the concomitant 6S RNA synthesis.

The kinetic analysis depicted in Fig. 1 shows that in such enzyme incubations the incorporation of <sup>3</sup>H-CMP and <sup>3</sup>H-AMP in response to globin mRNA as template is greatly stimulated

Fig. 1 Kinetics of oligo(rU)<sub>6</sub>-dependent copying of rabbit globin RNA. Standard incubation mixtures (60 µl) containing <sup>3</sup>H-CTP (7 × 10<sup>4</sup> c.p.m. nmol<sup>-1</sup>) and <sup>3</sup>H-ATP (7 × 10<sup>4</sup> c.p.m. nmol<sup>-1</sup>), 40 µg ml<sup>-1</sup> rabbit globin RNA and no oligo(rU)<sub>6</sub> (Δ), 70 µg ml<sup>-1</sup> oligo(rU)<sub>6</sub> (△), 140 µg ml<sup>-1</sup> oligo(rU)<sub>6</sub> (●), or 250 µg ml<sup>-1</sup> oligo(rU)<sub>6</sub> (○) were incubated at 30 °C. At the times indicated samples were taken (4 µl) and analysed for 6% trichloroacetic acid-insoluble radioactivity as described previously<sup>6</sup>.

by high concentrations of oligo(rU)<sub>6</sub>. Incubations with <sup>3</sup>H-CTP as the only radioactive substrate give the same result. It should be stressed that in addition to the great molar excess of primer, the template-enzyme ratio is also important for a successful synthesis. Incubations without template resulted in less than 5% of the RNA synthesis obtained in assays with template.

To ascertain the amount of globin-specific RNA in the total reaction product, renaturation tests were carried out after denaturation of the product. Table 1 shows that in the case of the product from a 3-h incubation, 49% of the incorporated radioactivity can be renatured to a double-stranded structure as analysed by RNase digestion in standard conditions. Some experiments yielded up to 80% of this double-stranded RNA. Addition of an excess of globin mRNA to the renaturation

Table 1 Renaturation of product RNA with template RNA

Sample	Time of annealing (min)	Resistance to RNase (%)
1 Non-denatured	0	51
2 Denatured	0	4
3 Denatured	5	28
4 Denatured + 25 µg ml <sup>-1</sup> globin mRNA	5	42
5 Denatured + 125 µg ml <sup>-1</sup> globin mRNA	5	45
6 Denatured + 125 µg ml <sup>-1</sup> Q <sub>β</sub> RNA	5	22
7 Denatured	30	36
8 Denatured + 125 µg ml <sup>-1</sup> globin mRNA	30	49

A 100-µl standard incubation mixture containing <sup>3</sup>H-CTP (1 × 10<sup>5</sup> c.p.m. nmol<sup>-1</sup>) and <sup>3</sup>H-ATP (1 × 10<sup>5</sup> c.p.m. nmol<sup>-1</sup>), 40 µg ml<sup>-1</sup> globin RNA and 250 µg ml<sup>-1</sup> oligo(rU)<sub>6</sub> was incubated for 3 h at 32 °C, then brought to 1% SDS and 20 mM EDTA, phenolised, dialysed against 0.1 mM EDTA and concentrated to a small volume by desiccator evaporation. Aliquots containing 3,000 c.p.m. <sup>3</sup>H-product were supplemented with additional RNAs as shown and heated for 1.5 min at 100 °C. The samples were then adjusted to 0.75 M NaCl and 0.075 M Na-citrate in a total volume of 20 µl and annealed for the times indicated at 65 °C. After diluting the samples to 2 ml with 1 × SSC, the solutions were digested by RNase in standard conditions<sup>7</sup> and analysed for acid-precipitable radioactivity<sup>6</sup>.

**Fig. 2** Sedimentation analysis of the enzymatic product before and after denaturation. The SDS-treated and phenolised product of an incubation as described in Table 1 was adjusted to 0.5 M NaCl, heated for 5 min at 65 °C, diluted with and dialysed against the appropriate buffer for subsequent chromatography on a small cellulose column according to Franklin<sup>8</sup>, omitting the 30% ethanol step. The RNA-containing fractions eluted with TSE buffer<sup>8</sup> (analysed by trichloroacetic acid precipitation of aliquots) were pooled, dialysed against 0.1 mM EDTA and concentrated to a small volume by desiccator evaporation.  $^{32}\text{P}$ -labelled *E. coli* RNA was added and 20  $\mu\text{l}$  of this solution layered directly (a) on a 5–23% linear sucrose gradient (0.1 M NaCl, 0.005 M EDTA, 0.05 M Tris-HCl pH 7.6). In b 30  $\mu\text{l}$  of solution was diluted to 60  $\mu\text{l}$  with  $\text{H}_2\text{O}$ , heated first for 1 min at 100 °C and quickly cooled before layering on a gradient. After centrifugation for 4 h at 64,000 r.p.m. in the SW 65 rotor of the Beckman centrifuge, the  $^3\text{H}$ - and  $^{32}\text{P}$ -radioactivities of the fractions were counted after acid precipitation. One part of the fractions of b was treated with RNase in standard conditions before the acid precipitation and counting ( $\times$ ); the other part was analysed directly ( $\bullet$ ).

mixture speeded up the renaturation, but the presence of  $\text{Q}_\beta$  RNA had no effect on the reaction. These results suggest that part of the synthesised product is complementary to globin mRNA.

The unspecific RNA, synthesis of which increases with incubation time, is not identical with 6S RNA as judged from its sensitivity to RNase and from its S value of less than 4. The nature of this RNA was not investigated further, but it can easily be separated from the globin-specific RNA by chromatography on a cellulose column<sup>8</sup>. If an SDS-treated and phenolised reaction product is applied to such a column in the presence of 15% ethanol, the unspecific RNA does not absorb,

and the globin-specific RNA can be eluted only with buffer containing no ethanol. This latter RNA is RNase resistant and completely complementary to globin mRNA. It corresponds in quantity to the synthesised globin-specific RNA which was analysed directly in the enzymatic reaction product by renaturation. Therefore, cellulose column chromatography of the products of all primer-dependent reactions of  $\text{Q}_\beta$  replicase with heterologous RNAs as template, is recommended before further analysis.

The double-stranded material eluted from the cellulose column had an S value of about 7.5, as analysed by a sucrose gradient centrifugation in the presence of  $^{32}\text{P}$ -labelled *E. coli* RNA as internal marker (Fig. 2a). After denaturation the S value of most of the material shifted to 5.6 with some RNA sedimenting as a shoulder at 10S (Fig. 2b). The relatively small size of most of the single-stranded RNA product seems to result from premature termination of synthesis on the template RNA, thus leading to a double-stranded structure with a single-stranded tail. This argument is favoured by the comparatively large S value of the double-stranded structure which gets smaller on RNase treatment specific for single-stranded RNA (data not shown). The reason for the unfinished synthesis in the case of rabbit globin RNA as template is unknown but it should be noted that in the  $\text{Mn}^{2+}$ -type reaction of  $\text{Q}_\beta$  replicase with brome mosaic virus RNA as template, a smaller product of distinct size appeared in addition to the larger product<sup>1</sup>.

## Naturally occurring antibody against unusually high serum DNA polymerase activity

We have reported unusually high DNA polymerase activity in sera obtained from chimpanzees infected with the hepatitis B virus<sup>1</sup>, and Kaplan *et al.*<sup>2</sup> reported hepatitis B-specific DNA polymerase activity in sera of human patients during post-transfusion hepatitis. We and others<sup>3–5</sup> also found DNA polymerase activities associated with Dane particles, the putative hepatitis B virus, or their naked core components. Reports<sup>6,7</sup> of the specific association of an e antigen–e antibody system with carriage of HB<sub>Ag</sub> prompted us to examine HB<sub>Ag</sub> positive sera containing unusually high levels of DNA polymerase activity for the presence of e antigen or e antibody. Subsequently, we studied the effects of sera containing e antibody on high DNA polymerase activity in sera from individuals with acute hepatitis B, chronic asymptomatic hepatitis B, chronic aggressive hepatitis B or chronic non-B hepatitis.

We have screened several hundred sera for high DNA polymerase activity using a standard radioisotope method<sup>8</sup>. Sera from normal healthy controls were found to contain low levels of polymerase activity, usually about 400 c.p.m.

DNA polymerase activity in serum was determined by a radioisotope method that measures the incorporation of <sup>3</sup>H-dTTP into an acid-insoluble product. The polymerase assay contained in a volume of 0.370 ml: 50 µl of serum and 260 µl 0.01 M Tris buffer, pH 7.8, containing 30 mM MgCl<sub>2</sub>·6H<sub>2</sub>O, 60 mM KCl, and 1.5% Triton X-100; the balance of the reaction mixture contained (final assay concentrations) mercapto-ethanol (2.5 mM), dATP, dCTP, dGTP (0.25 mM each), 50 µg carrier chicken cell DNA and <sup>3</sup>H-dTTP (0.90 µM, specific activity 54 Ci mmol<sup>-1</sup>). All reaction mixtures were incubated for 3 h at 37 °C; two 100-µl samples per assay were pipetted on to Whatman 3MM filter paper disks, which were then transferred to a solution of ice-cold 5% trichloroacetic acid (TCA) plus 2% pyrophosphate. The disks were washed four times with this solution, once with a 5% TCA solution, twice with 95% ethanol and then air dried. Each disk was counted in 10 ml of a toluene PPO (PPO = 2,5-diphenyloxazole)-POPOP (POPOP = 1,4-di-[2-(5-phenyloxazolyl)]-benzene) cocktail. Zero-time (T = 0 min) c.p.m. were typically 100 and were subtracted from the gross sample c.p.m. to yield the tabulated c.p.m. HB<sub>s</sub>Ag and anti-HB<sub>s</sub> content of sera were determined by solid phase radioimmunoassay techniques, using commercial reagents (Abbott). Measurement of e antigen and antibody was performed using rheophoresis plates (Abbott) with incubation at 27 °C in humidified Petri dishes. The standard e antigen and e antibody reagents used were obtained from HB<sub>s</sub>Ag positive blood donors. All adsorptions were carried out at 37 °C for 1 h, followed by overnight incubation at 5 °C (16 h). Test sera (50 µl each) were adsorbed with 50 µl normal human serum and centrifuged the following day at 5,000g for 30 min to pellet out immune aggregates; the supernatants were used as the control sera in these experiments. Adsorptions of test sera with anti-e and anti-HB<sub>s</sub> antisera were carried out in a similar manner. Anti-e antiserum (100 µl) was preadsorbed with 10 µl of either goat anti-human immunoglobulin A, G and M antiserum (or with horse antihuman IgG antiserum) before use as an adsorbant of the test serum. Conditions for preadsorption of the anti-e antiserum were as described above, except that overnight incubation was omitted. Preadsorption of normal human serum with either goat or horse antiserum before use as an adsorbant of test sera did not alter control sera DNA polymerase activity. NT, not tested.

above background, whereas sera from acute or chronic cases of hepatitis B ranged in activity from 450 to 1,500 c.p.m. Several sera, however, had unusually high levels of DNA polymerase, ranging in activity from 4,000 to 173,000 c.p.m. All the sera used in our study were selected initially on the basis of very high DNA polymerase activity, without previous regard to the presence of e antigen or e antibody (Table 1). With these sera we found no correlation between this high DNA polymerase activity and the presence or absence of HB<sub>s</sub>Ag, e antigen or e antibody. It is interesting that high DNA polymerase activity was found in sera from individuals with chronic non-B hepatitis as well as in two individuals who had e antibody.

The inhibitory effect of serum containing e antibody on the DNA polymerase activity found in the above sera was unexpected. This inhibitory effect was not confined to serum samples from hepatitis B patients, since high DNA polymerase activity in sera from chronic non-B hepatitis patients was similarly suppressed by addition of e antiserum (for example, serum containing e antibody). Briefly, sera containing high DNA polymerase activity were mixed with either normal human serum (the control) or human serum containing e antibody or anti-HB<sub>s</sub> and incubated for 1 h at 37 °C and overnight at 5 °C; the mixtures were then centrifuged at 5,000g for 30 min. The supernatants were assayed for residual DNA polymerase activity. Substantial reductions in polymerase activity (up to 84%) were found in serum samples incubated with e antiserum in contrast to samples reacted with normal human serum or anti-HB<sub>s</sub>. For example, when two serum samples with control DNA polymerase activities of 9,300 and 26,500 c.p.m. were adsorbed with e antiserum, their polymerase activities were reduced to 3,150 and 4,140 c.p.m. respectively. This phenomenon was confirmed by repeating the assays using two other sera containing e antibody for the pre-incubation step. Sera containing anti-HB<sub>s</sub> antibody did not affect substantially any of the high DNA polymerase activities, indicating that the activity was not associated with HB<sub>s</sub>Ag. These findings strongly suggested the presence of a specific factor in serum containing e antibody that can inhibit DNA polymerase activity. Adsorption of e antiserum with goat anti-human IgG antiserum inactivated this factor, indicating that it was an antibody.

Statistical analysis of the effects of e antiserum, adsorbed e antiserum, and anti-HB<sub>s</sub> antiserum on test serum DNA polymerase activity was performed by first ranking the percentage effects (calculated as percentage depression or increase over control activity) of the antisera on the test serum activity and then inspecting the resulting array for possible separation points. Such a point occurred at 35% depression. Seventeen of the twenty-one test sera contained DNA polymerase activity which could be depressed by 36–84%. Only one of seven test sera examined contained DNA polymerase activity which could be depressed more than 36% (40%) by the e antiserum which had been pre-adsorbed with goat anti-human IgG. None of the ten anti-HB<sub>s</sub> adsorbed test sera had depressions (or increases) in polymerase activity  $\geq 36\%$  of the matching control activity. Student's *t* test was applied to the difference between proportions exceeding 35% depression (or increase) in activity to determine the statistical significance of the findings. For the e antiserum proportion (17/21) compared with adsorbed e antiserum proportion (1/7), the probability of e antiserum producing an excess of depressions on the basis of chance alone is  $P \leq 0.001$  ( $t_{26}=3.85$ ), strongly suggesting the involvement of an antibody (IgG) in the suppression of DNA polymerase activity. Similarly, the probability of producing an excess of depressions compared with anti-HB<sub>s</sub> (0/10) is  $P < 0.001$  ( $t_{29}=6.31$ ), indicating the absence (in the two different anti-HB<sub>s</sub> antisera used) of a naturally occurring antibody against DNA polymerase activity in the test sera. The significance of these findings was basically unchanged

when the effects of the antisera on high polymerase activity were analysed statistically using results from individual patient's sera instead of test sera. In this case, 14 of 16 patients' sera contained DNA polymerase activity which could be depressed 36–84% by adsorption with e antiserum.

As far as we know, this is the first report of a naturally occurring antibody which specifically inhibits high DNA polymerase activity in human serum. In addition, the inhibitory effect of e antiserum was not confined to DNA polymerase activity associated with HB<sub>s</sub>Ag positive sera, suggesting a more general role of the inhibitory factor (now believed to be an antibody) in suppressing unusually high DNA polymerase activity. These data do not show whether or not the inhibitory effect of e antiserum directly involves the DNA polymerase enzyme or its template. Furthermore, the polymerase activities reported here have not been characterised as specific to either host or virus; however, it is tempting to speculate on the existence of naturally acquired (occurring) anti-viral DNA polymerase antibodies which can either abort or modify the course of a viral infection or virus-induced disease.

## Safer derivatives of bacteriophage $\lambda$ gt $\lambda$ C for use in cloning of recombinant DNA molecules

THOMAS *et al.*<sup>1</sup> have constructed a mutant strain of bacteriophage  $\lambda$  ( $\lambda$ gt $\lambda$ C) which is especially well suited to studies involving the cloning of recombinant DNA molecules. Specifically, this bacteriophage, deleted of 15% of its genome, has only two *EcoRI* restriction endonuclease sites which, when cleaved, reduce the phage chromosome to three DNA fragments. The larger of these, the right- and left-hand arms of the chromosome, encode all functions necessary for lytic infection. The smaller, central fragment consisting of approximately 5,000 base pairs encodes the  $\lambda$  attachment site, the *Int* and *Xis* functions and a necessary part of the  $\lambda$ -generalised recombination system, but no genes necessary for phage propagation. Although left- and right-hand restriction fragments have all necessary  $\lambda$  genes, they seem to lack sufficient length of DNA for packaging into a viable phage particle<sup>1</sup>. This provides a powerful positive selection for recombinant DNA molecules consisting of isolated and rejoined right and left restriction fragments

**Fig. 1** Characteristics of wild-type  $\lambda$  and  $\lambda$ gt- $\lambda$ C. *Eco*RI target sites given below line as %  $\lambda$  unit length<sup>12</sup>. *Eco*RI fragments are lettered *a* to *f* below line,  $\lambda$  genes above line. For  $\lambda$ gt- $\lambda$ C note that *b* fragment is removed and a hybrid RI target at 54.3% is regenerated<sup>1</sup>. Amber mutations in gene *S* were isolated by modifying the procedure of Goldberg and Howe<sup>7</sup> as follows.  $\lambda$ gt- $\lambda$ C lysogens of *E. coli* mutD<sup>3</sup> were obtained by isolating colonies from the centre of a phage plaque.  $\lambda$ -resistant clones of these lysogens were made by plating on EMBO plates seeded with *λvir* (ref. 8); 10-ml cultures of these  $\lambda$ -resistant,  $\lambda$ gt- $\lambda$ C lysogens were grown at 32 °C in tryptone broth to about  $2 \times 10^8$  cells ml<sup>-1</sup>. Cultures were induced by growing at 42 °C for 20 min and then at 37 °C for 3 h. Lysis was virtually complete by 60 min. After 3 h at 37 °C, culture was centrifuged for 10 min at 4,000 r.p.m. in a Sorval GLC-2. Pellet containing unlysed cells and debris was washed once with tryptone broth and centrifuged again. Pellet was resuspended in 0.5 ml tryptone broth containing enough  $\lambda$  antiserum to give a *K* value of 1. This mixture was incubated at 32 °C for 5 min and then diluted 100-fold in 0.01 M Tris, 0.01 M MgSO<sub>4</sub>, 0.1% gelatin (TMG). After centrifugation at 4,000 r.p.m. for 15 min, the pellet was washed with 45 ml TMG and recentrifuged. This pellet was resuspended in 1 ml TMG and incubated with several drops of chloroform at 37 °C for 5 min. The chloroform-treated mixture was plated on a mixed indicator of *supO* (N99) and *supF* (*Ymel*) bacteria at 37 °C. Turbid plaques, indicating growth on one indicator but not the other, appeared at a frequency of  $10^{-3}$ – $10^{-4}$ . Two isolates were characterised by growth on suppressor strains and by complementation as described by Shimada *et al.*<sup>8</sup>. Both mutants formed plaques on *supF* bacteria but plated at less than  $10^{-6}$  efficiency on *supO* hosts. In addition, both mutants plated well on *supC* (CA169) but grew poorly on *supE* (C600). Both isolates complemented all tested  $\lambda$  mutants except *Sam7*. The mutants were therefore designated *Sam100* and *Sam101*.  $\lambda$ Sam100 lysogens of *supO* hosts do not lyse after induction until chloroform is added.  $\lambda$ Sam101 lysogens of *supE* hosts behave similarly but 2 h after induction, some spontaneous lysis can be observed. Optimal phage yields (about 200–500 phage per induced cell) from induced *supE* lysogens are obtained by collecting phage 2 h after induction.

which have also incorporated a fragment of foreign DNA restoring the  $\lambda$  chromosome to viable size.

Although the  $\lambda$ gt- $\lambda$ C-*Escherichia coli* K12 host-vector system offers rather special advantages as a system in which to clone DNA fragments that might contain potentially biohazardous segments, the need for further modification to make this and other vectors even safer was made clear during the Asilomar Conference on Recombinant DNA Molecules<sup>2</sup>. Accordingly, we have introduced three muta-

tions into the original  $\lambda$ gt- $\lambda$ C phage which reduce the possibility of its encountering a host in nature by at least a factor of  $10^6$  and which make it especially amenable to high titre growth in small and therefore more manageable volumes of medium. These modifications should make this phage suitable for use in experiments which require moderate biological containment barriers<sup>2</sup>.

Here we describe the construction of derivatives of  $\lambda$ gt- $\lambda$ C containing three amber mutations, *Sam100* *Eam1100* and

**Fig. 2** Construction of  $\lambda$ gt- $\lambda$ C *Wam403 Eam1100 Sam100*. Phage parent I (*a*) was  $\lambda$ gt- $\lambda$ C *Sam100* obtained as described previously. Phage parent II (*b*) (obtained as G96 from NIH stock collection) was  $\lambda$  *Wam403 Eam1100 gal8 bio256 imm434 cts1*. Strain *Ymel* was infected with both parents at a multiplicity of five of each phage. After 15 min adsorption at 32 °C, the infected cells were treated with ultraviolet light at a dose of 300 erg mm<sup>-2</sup>, diluted 1,000-fold in tryptone broth containing  $10^{-2}$  M MgSO<sub>4</sub>, and incubated at 40 °C for 70 min. Chloroform was added to complete lysis. Incubation at 40 °C insured a low level of *Int*-promoted recombination<sup>9</sup>. Dilutions of the lysate were plated on *Ymel recA56*. Parent I, but not parent II, will make plaques on this host because *bio256* deletes the *red* and *gam* genes<sup>10</sup>. These plaques were tested on *Ymel groE*<sup>11</sup>. Only parent II and recombinants carrying the *Eam1100* mutation will plate on this host. The presence of the *Wam403* mutation does not influence this test. Several isolates that made plaques on *Ymel recA56* and on *Ymel groE* were tested for their immunity by ability to grow on  $\lambda$  and phage 434 lysogens of *Ymel*. Because both *Eam1100* and *Wam403* are suppressed well on *supE* hosts but *Sam100* is not, the presence of *Sam100* was inferred by poor growth on C600. The presence of the *gal8* substitution was determined by measuring transduction to *gal*<sup>+</sup> of a *Ymel gal* deletion (SA825). Stocks with  $\lambda$  immunity also made clear plaques above 37 °C and turbid plaques at 32 °C indicating the presence of the *CI857* mutation. Complementation tests<sup>8</sup> were carried out to confirm that the phage contained *E*, *W* and *S* mutations. Finally, the presence of *nin5* was determined by plating on *E. coli* 'super nus' (M. Baumann and D. I. Friedman; N. S., unpublished). Two isolates were chosen for further study. One transduced SA825 to *gal*<sup>+</sup> and the other did not. Both were immunity  $\lambda$ , *E*<sup>-</sup>, *W*<sup>-</sup> and *S*<sup>-</sup>. The *gal*<sup>-</sup> recombinant presumably resulted from an event depicted by crossover I, the *gal*<sup>+</sup> recombinant from crossover II.

**Fig. 3** Electrophoretic separation of *Eco*RI fragments of DNA from wild-type  $\lambda$  and the  $\lambda$ gt- $\lambda$ C derivatives. *a*,  $\lambda$ c1857*Sam*7; *b*,  $\lambda$ gt- $\lambda$ C; *c*,  $\lambda$ gt- $\lambda$ C *Sam*100; *d*,  $\lambda$ gt- $\lambda$ C *Wam*403 *Eam*1100 *Sam*100; *e*,  $\lambda$ gt- $\lambda$ C *Wam*403 *Eam*1100 *Sam*100 *gal*8. Phage were prepared from induced lysogens or plate stocks<sup>5</sup>. Phage suspensions of  $1-20 \times 10^{10}$  phage ml<sup>-1</sup> were adjusted to a density of 1.35 g cm<sup>-3</sup> by addition of 0.5 g CsCl per 1.0 ml suspension and concentrated by centrifugation on a layer of CsCl at 1.70 g cm<sup>-3</sup> in 20 mM Tris-HCl, pH 7.8, and 10 mM MgCl<sub>2</sub> in an SW41 rotor for 1.0 h at 30,000 r.p.m. at 4 °C. The interface bands were pooled and banded to equilibrium by centrifugation in an SW56 rotor for 18 h at 35,000 r.p.m. at 4 °C. The suspensions were stored in CsCl at 0–5 °C. Phage suspensions ( $1-50 \times 10^{11}$  phage ml<sup>-1</sup>) in CsCl were brought to 1.0 mg ml<sup>-1</sup> Pronase (Calbiochem, nuclease-free) and dialysed at 37 °C for 90 min against 100 volumes buffer A (20 mM Tris-HCl, pH 7.8; 1.0 mM EDTA, 0.1 M NaCl) plus 0.002% Triton X-100. After gentle extraction with an equal volume of buffer A-saturated phenol, DNA was dialysed for 2–3 h against 100 volumes buffer A plus 0.002% Triton X-100, and then overnight against 100 volumes buffer A. The resulting DNA (0.010–1.2 mg ml<sup>-1</sup>) is stored at 0–5 °C. *Eco*RI was purified from the strain *E. coli* BRY 13.3/1100.5 (described elsewhere). The standard *Eco*RI reaction contained 0.1 M Tris-HCl, pH 7.9, 50 mM NaCl, 0.1 mM EDTA, 12 mM MgCl<sub>2</sub>, 10–50  $\mu$ g ml<sup>-1</sup> DNA, and enough *Eco*RI to completely digest 30–150  $\mu$ g  $\lambda$  DNA. The reaction was incubated for 30 min at 37 °C and stopped by addition of EDTA to 25 mM. After incubation for 5 min at 75 °C, the reactions were electrophoresed through 0.7% Agarose slab gels as described previously<sup>6</sup>. The DNA was stained by immersion of the gel in 0.0025% ethidium bromide for 3 min and visualised under an ultraviolet lamp.

*Wam*403. The *S* mutation, which prevents host lysis, was isolated by mutagenesis because the location of an RI cleavage site very close to or within the *S* gene makes it difficult to cross an *Sam* mutation into  $\lambda$ gt- $\lambda$ C without introducing unwanted RI sites (Fig. 1).  $\lambda$ Sam100 is not efficiently suppressed in conditions that suppress both *E* and *W* amber mutations. This produces an additional advantage in that one can obtain large phage concentrations in small, easily manipulated volumes of media. *Eam*1100 and *Wam*403 were crossed into  $\lambda$ gt- $\lambda$ C. The *E* gene product is the major head protein of the phage. The *W* gene product enables addition of tails to heads. Thus,  $\lambda$  carrying *Eam*1100 cannot make phage heads, whereas  $\lambda$  carrying *Wam*403 in the presence of a functional *E* gene, makes heads and tails but does not assemble these components. An additional effect of the *Eam*1100 mutation is that oligomeric  $\lambda$  DNA, the product of intracellular phage replication, is not cut into monomeric DNA with normal cohesive ends. We have tested the reversion frequency of each of these amber

mutations separately and found them to be of the order of  $10^{-6}$ . The *W* and *E* mutations therefore have an expected joint reversion frequency to *am*<sup>+</sup> of approximately  $10^{-12}$ . The probability of a host amber suppressor mutation arising spontaneously is approximately  $10^{-7}$ – $10^{-10}$  (ref. 4).

Two phage derivatives obtained from the cross shown in Fig. 2 have been characterised genetically by complementation tests and biochemically by *Eco*RI fragment patterns. The first,  $\lambda$ gt- $\lambda$ C *Wam*403 *Eam*1100 *Sam*100, has the restriction pattern characteristic of the parent phage,  $\lambda$ gt- $\lambda$ C (Fig. 3). The second,  $\lambda$ gt- $\lambda$ C *Wam*403 *Eam*1100 *Sam*100 *gal*8, has a larger left-arm fragment following *Eco*RI restriction and a smaller central fragment. In a separate mixing experiment with  $\lambda$ c1857, this latter fragment's molecular weight was found to be  $3.2 \times 10^6$ . We conclude that there is a single RI cleavage site within the *gal*8 substitution.

The presence of the *gal*8 substitution in the second phage enables establishment of lysogeny by recombination with the host genome and facilitates recognition of such lysogens. Although this is not desirable in recombination experiments with an uncharacterised constellation of DNA sequences, it may prove useful in the handling of a homogeneous, well-characterised fragment.

We thank Dr R. W. Davis for  $\lambda$ gt- $\lambda$ C phage; Dr J. Davies for *E. coli* BRY 13.3/1100.5; Dr M. Howe for advice in isolating *S* mutants; and Ms C. Kunkle for assistance.

## Construction of infectious polyoma hybrid genomes *in vitro*

WITH recent advances in nucleic acid biochemistry, it has become possible to recombine different animal viral DNAs at specific sites *in vitro*<sup>1,2</sup>. Specific hybrid viral genomes can be used in the genetic analysis of animal tumour viruses. With this aim in mind, we have made hybrids of two strains of polyoma (A-3 and P16). A-3 and P16 were developed from independent isolates and have been characterised both phenotypically and genotypically<sup>3,4</sup>. Using the hybrids it has been possible to begin to locate the DNA regions coding for phenotypic differences in the parent strains.

The two viruses differ phenotypically in their plaque morphology and haemagglutination (HA) properties; P16 produces small plaques and agglutinates guinea pig red blood cells at 20 °C as well as 4 °C whereas A-3 produces large plaques and agglutinates guinea pig red blood cells at 4 °C but not at 20 °C. The P16 and A-3 strains also differ genotypically. Three genotypic differences are readily dis-

**Fig. 1** Construction of DNA hybrids *in vitro*. The A-3 and P16 strains of polyoma virus vary genotypically in at least three different sites denoted by (x) for A-3 and (o) for P16 on the circular genomes where (o) marks the origin and (-) marks the *HindIII* restriction endonuclease cleavage sites. The two strains also differ phenotypically; A-3 has a large plaque (LP) morphology whereas P16 has a small plaque (SP) morphology. Purified supercoiled (FI) DNA of A-3 and P16 viruses were digested with *HindIII* to yield two fragments approximately 44% and 56% of the genomes. The *HindIII* fragments from each viral DNA were separated by electrophoresis through 1.4% Agarose gels<sup>11</sup>, visualised by ethidium bromide staining<sup>11,12</sup>, individually sliced from the gels, eluted by gel electrophoresis and concentrated by ethanol precipitation. The A-3 *HindIII*-56% fragment was combined in a test tube with the P16 *HindIII*-44% fragment while the P16 *HindIII*-56% fragment was combined in another test tube with the A-3 *HindIII*-44% fragment. The fragments were covalently joined with *T*<sub>4</sub> DNA ligase in a reaction mixture containing 67 mM Tris (pH 7.6), 6.7 mM MgCl<sub>2</sub>, 0.67 mM dithiothreitol, 0.067 mM rATP, 300 µg per ml of each DNA fragment and  $2 \times 10^{-3}$  units *T*<sub>4</sub> DNA ligase by incubation at 5 °C for 16 h. Subsequent infection of mouse embryo cells with the hybrid DNAs for plaque assay facilitated the determination of the plaque morphology characteristics of the hybrid strains (LP and SP as indicated).

cerned in the *Haemophilus parainfluenzae* restriction endonuclease (*HpaII*) cutting patterns of their DNA (Fig. 2a and ref. 3). The most obvious difference between the P16 and A-3 *HpaII* cleavage patterns is that P16 is cleaved nine times by *HpaII* whereas A-3 is cleaved only eight times. The additional cleavage site of P16 is located within the largest *HpaII* fragment of A-3 (designated A-3 *HpaII*-1) and generates two new fragments (designated as P16 *HpaII*-1a and P16 *HpaII*-1b) which migrate in 3.3% polyacrylamide-0.5% Agarose gels on either side of the A-3

*HpaII*-fragment-4 (*HpaII*-4). In addition, the *HpaII*-3 and *HpaII*-5 fragments of A-3 are slightly smaller (migrate faster) than the equivalent P16 fragments (designated P16 *HpaII*-3 and P16 *HpaII*-5). Hybrids constructed from these two polyoma strains can therefore be studied both at the genotypic level and at the phenotypic level; hybrid formation can be confirmed by the *HpaII* cleavage patterns of the hybrid viral DNAs and the phenotypic differences of plaque size and HA ability can potentially be correlated with a specific region of the viral genome.

The construction of A-3 and P16 hybrid viruses is schematically shown in Fig. 1. Both A-3 and P16 are cleaved twice by the *HindIII* restriction endonuclease yielding two fragments of approximately 44% and 56% (designated *HindIII*-44% and *HindIII*-56% respectively) of the genome<sup>3</sup>. These fragments were purified by gel electrophoresis through 1.4% Agarose gels. The *HindIII*-44% of A-3 was combined with the *HindIII*-56% of P16 and, vice versa, the P16 *HindIII*-44% was combined with the A-3 *HindIII*-56%. To encourage intermolecular rather than

**Fig. 2** *a*, An autoradiograph showing the restriction nuclease cleavage patterns of (1) <sup>32</sup>P-labelled P16 DNA and (2) <sup>32</sup>P-labelled A-3 DNA (modified from Fried *et al.*<sup>3</sup>). The numbers at the side of the gel designate the nomenclature of the bands. The gels (20 × 20 cm) were composed of 3.3% acrylamide-0.17% bis-acrylamide-0.5% Agarose and run as described previously<sup>7</sup>. In P16, *HpaII*-1 is absent and two new fragments (1a and 1b) are present. The sizes of *HpaII*-3 and *HpaII*-5 can be seen to vary between the A-3 and P16 strains. *b*, Secondary whole mouse embryo cells (WME) were infected with each A-3/P16 hybrid DNA, overlaid with agar and stained with neutral red after 9 d incubation at 37 °C. Plaques of each hybrid were picked, virus stocks of each plaque were produced at low multiplicity<sup>10</sup> and <sup>32</sup>P-labelled form I DNA was prepared as previously described<sup>3,7</sup>. The labelled DNAs were digested with *HpaII* and the resulting fragments were electrophoresed through a 3.3% acrylamide-0.17% bis-acrylamide-0.5% Agarose slab gel. The autoradiograph shows the representative *HpaII* cutting pattern of (3) the small plaque hybrid P16 *HindIII*-44% + A-3 *HindIII*-56%, (4) the large plaque hybrid A-3 *HindIII*-44% + P16 *HindIII*-56%, and (5) small plaque P16 control. For both the hybrids, five plaques were picked and tested. Five out of five plaques in each case showed the expected cutting patterns. In the gels in *a* and *b* *HpaII*-8 has been run off the gel. There was no difference in the electrophoretic mobility of *HpaII*-8 between the A-3 and P16 strains or any of the plaque isolates.

Table 1 Analysis of the phenotypic properties of A-3/P16 hybrids

DNA	Plaque size*	HA at 20 °C†	HA at 4 °C
A-3 Form I DNA	LP	—	+
P16 Form I DNA	SP	+	+
A-3 <i>Hind</i> III-44% + P16 <i>Hind</i> III-56%	LP	—	+
P16 <i>Hind</i> III-44% + A-3 <i>Hind</i> III-56%	SP	+	+

\*LP, large plaque morphology; SP, small plaque morphology<sup>4</sup>.

†Ability of virus stocks derived from picked plaques to haemagglutinate guinea pig red blood cells at 20 °C.

(—) indicates less than 10 HA were detectable; (+) indicates HA titres between 160 and 1280. There was no difference in the HA titres of the P16 type at 4 and 20 °C.

intramolecular joining of fragments, each DNA was present at a concentration of 300 µg ml<sup>-1</sup>. The combined fragments were first heated to 50 °C to ensure complete denaturation of the four-base overlap at the restriction nuclease cutting site<sup>5</sup> and then cooled slowly to 5 °C and allowed to re-anneal at 5 °C for 30 min. The resulting hybrid DNAs were covalently closed by T<sub>4</sub> DNA ligase (a gift from Dr Ian Molineux). In the conditions used, approximately 90% of the DNA molecules were judged to have been ligated. This was determined by observing the disappearance of molecules with the electrophoretic mobility of the 44% and 56% fragments and the appearance of DNA with an electrophoretic mobility for molecules 88–112% the size of polyoma. Low levels of unligated *Hind*III-44% and 56% fragments and intramolecularly ligated *Hind*III-44% and 56% fragments were observed in gels but accounted for less than 10% of the ligation products. The remaining 90% of the DNA products migrated in 1.4% Agarose gels with a mobility equivalent to linear and circular forms of molecules 88%, 100% and 112% the length of polyoma DNA. Random intermolecular associations account for the size distribution of products.

Secondary whole mouse embryo cells (WME) were infected with the hybrid DNA products using the DEAE-dextran technique as described by Thorne *et al.*<sup>6</sup> for polyoma DNA. The results of the plaque assays with DNA are presented in Table 1. The *Hind*III-44% and *Hind*III-56% fragments alone had negligible contaminating infectivity (less than 1 × 10<sup>2</sup> PFU per µg DNA). The combined *Hind*III-44% and -56% fragments without ligation had a specific infectivity of 3 × 10<sup>3</sup> PFU per µg DNA; thus the cell is capable of ligating the two *Hind*III fragments at a low level. The *in vitro* ligated P16 *Hind*III-44%/A-3 *Hind*III-56% and A-3 *Hind*III-44%/P16 *Hind*III-56% ligated hybrid DNAs had a specific infectivity of 1 × 10<sup>3</sup> PFU per µg DNA. In control experiments, A-3 *Hind*III-44%/A-3 *Hind*III-56% ligated DNA also had a specific infectivity of 1 × 10<sup>3</sup> PFU per µg DNA indicating that the hybrid viral DNAs are as efficient in plaque formation as *in vitro* constructed parental DNA. Untreated supercoiled FI polyoma DNA or singly-nicked FII DNA had a specific infectivity of 1 × 10<sup>6</sup> PFU per µg DNA. Analysis of the plaque size produced by the A-3/P16 hybrid DNA molecules revealed that the plaque morphology depended on the source of the *Hind*III-44% fragment; the small plaque morphology of P16 was observed for the P16 *Hind*III-44%/A-3 *Hind*III-56% hybrid while the large plaque morphology of A-3 was observed for the A-3 *Hind*III-44%/P16 *Hind*III-56% hybrid. The haemagglutination characteristics also segregate with the *Hind*III-44% fragment (Table 1) in a manner similar to plaque morphology.

To confirm that the hybrid DNAs actually contained the genetic information of the two different parental DNAs, plaques of the hybrid viruses were picked and virus stocks produced. The viral DNA derived from <sup>32</sup>P-labelled infected cells was digested with *Hpa*II restriction endonuclease. Analysis of the fragments by gel electrophoresis (Fig. 2b) showed that the hybrid viruses constructed from the P16 and A-3 *Hind*III fragments exhibit *Hpa*II cutting patterns expected for such hybrids. From the physical order

of polyoma restriction nuclease fragments<sup>7</sup>, it is known that the *Hpa*II-3 and *Hpa*II-5 are located in the *Hind*III-56% fragments whereas the portion of the *Hpa*II-1 fragment containing the new *Hpa*II cutting site of P16 is located in the *Hind*III-44% fragment. The small plaque hybrid virus constructed from the P16 *Hind*III-44% and A-3 *Hind*III-56% fragments contains *Hpa*II-5 fragments which are smaller (migrate faster) than the equivalent P16 fragments and yet the hybrid contains the additional *Hpa*II cutting site characteristic of P16. The large plaque hybrid virus constructed from the A-3 *Hind*III-44% and P16 *Hind*III-56% fragments contain *Hpa*II-3 and *Hpa*II-5 fragments which comigrate with the corresponding P16 *Hpa*II fragments yet the hybrid does not contain the additional cutting site in *Hpa*II-1 fragment which is characteristic of the P16 type.

Thus, the *Hpa*II fragment patterns of the viruses confirm that hybrids between A-3 and P16 strains have been constructed and that they contain the sequences expected by our experimental approach. Furthermore, it is clear that the phenotypic difference between the P16 and A-3 strains of polyoma are not related to the genotypic differences located in the *Hind*III-56% fragment (that is the *Hpa*II-3 and *Hpa*II-5 fragment size differences). The genotypic difference which accounts for the phenotypic differences of the two strains must reside in the *Hind*III-44% fragment. Another plaque morphology variant and several late mutants have been mapped by a maker rescue technique in the *Hpa*II-1 sequences contained in the *Hind*III-44% fragment (L.K.M. and M.F., manuscript in preparation). This region also contains the additional *Hpa*II cutting site found in the P16 strain.

More exact determination of the locations of mutations affecting phenotype can be made by forming hybrid DNAs using different restriction nuclease fragments. Recently we have been able to construct hybrid molecules by ligation of restriction nuclease fragments produced by an enzyme from *H. haemolyticus* (*Hha*I). This enzyme produces fragments which contain a two-base overlap at their termini (Roberts and Myers, personal communication).

It has been possible to take advantage of the difference in restriction enzyme cleavage sites to analyse *in vivo* recombinants between adenovirus-2 ND<sub>1</sub> and adenovirus-5 (refs 8 and 9). We have used this type of genotypic analysis to characterise *in vitro* recombinants of polyoma. Construction of hybrid viruses *in vitro* provides a rapid and direct method for introducing genotypic markers into different virus strains.

We thank Beverley E. Cooke for technical assistance. This investigation was supported in part by a US Public Health Service Grant from the National Cancer Institute.

## Measurement of forces between lecithin bilayers

CELL fusion<sup>1</sup> and vesicle-membrane<sup>2</sup> or vesicle-synapse<sup>3</sup> fusion are currently thought to involve distance-dependent interactions between membranes. We have devised a general method for measuring such forces between planar phospholipid membranes, and report here results for the specific case of egg lecithin (phosphatidyl choline) bilayers in water.

When immersed in an excess amount of water, bilayers of zwitterionic lecithin form a lamellar lattice where the equilibrium bilayer separation is 27.5 Å (refs 4-7). We found that below this equilibrium spacing there is an apparent repulsion between bilayers, a repulsion that falls off exponentially with bilayer separation, with a decay distance of ~1.9 Å. The repulsive force for a separation < 22 Å is of the order of atmospheres, and reaches 10 atm by 17.5 Å. Our results indicate further that at the equilibrium spacing in pure water, repulsion is balanced by an attractive force between bilayers of ~6.5 × 10<sup>4</sup> dyne cm<sup>-2</sup>, or 0.065 atm.

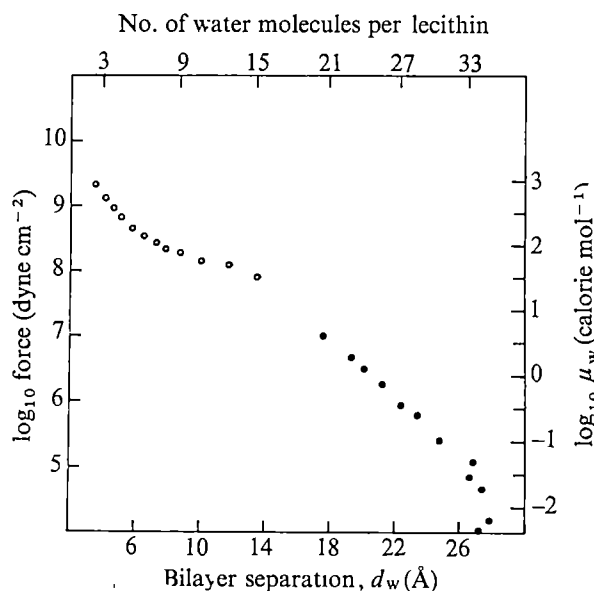

To measure the net repulsion or 'disjoining pressure'<sup>8</sup> we immerse pure egg lecithin into solutions of very high molecular weight dextran, rather than into pure water. The branched dextran molecules, having radii of gyration of the order of hundreds of Angstroms<sup>9,10</sup>, apparently cannot enter the well defined lamellar structure which still forms. (Enclosing the lipid in dialysis membranes before exposure to dextran solutions has no observable effect on the lamellar phase.) At each higher dextran concentration, the lamellar phase must come to

**Fig. 1** Lamellar repeat distance  $d$  as a function of dextran concentration. Chromatographically pure samples of egg lecithin (~30 mg) prepared by the method of Singleton *et al.*<sup>20</sup> were dispersed in 10 ml (10 g) of water or dextran (BDH: molecular weight 200,000-275,000) solution with the aid of sonication (30 s at half power on a Biosonic III). The lamellar lecithin phase was separated by ultracentrifugation. Scatter of points near 0% dextran is not systematic, but apparently arises from manipulation of the lipid. Repeat distances determined by X-ray diffraction are accurate to 0.1 Å.

equilibrium with water of lower chemical activity. Mechanically, the dextran solution exerts an osmotic pressure on the lamellar phase preventing full swelling of the lattice. At the new equilibrium, and for each dextran concentration, repulsion between bilayers is equal to the osmotic pressure of the dextran solution. The osmotic pressure is measured directly with a mercury manometer, or with pressure gauges. The resulting lattice spacings are measured by X-ray diffraction<sup>4-7</sup>. These spacings are shown in Fig. 1, where we plot the lattice repeat distance against dextran concentration.

To obtain a force-separation curve, we must calculate the spacing between leaflets at each dextran concentration. The total lattice repeat distance  $d$  is pictured as the sum of a biomolecular lipid layer of thickness  $d_l$  and a water layer of thickness  $d_w$ . To find  $d_l$  and  $d_w$  from  $d$  in Fig. 1, we use our X-ray diffraction data<sup>7</sup> for repeat spacings  $d$  in the one phase lamellar lattice formed in ~50% water. The state of the one-phase system is defined by mixing set amounts of water and lipid (of volume fraction  $\phi$ ). When  $\phi$  is set, one can say  $d_l = \phi d$  and  $d_w = (1 - \phi)d$ . The lamellar repeat  $d$  increases monotonically with added water (until the limit of swelling where the second, pure water, phase begins to form). The same set of limited-water states may be reached by removing water osmotically from the fully swelled system. Specifically, one is observing the same thermodynamic state for lattices of a given  $d$  whether the lipid-water ratio has been determined by gravimetric means or osmotically. Then the  $d$  spacings of Fig. 1 can be converted to  $d_w$  and  $d_l$  thicknesses as described in the table. The data are shown as a force against separation curve in Fig. 2.

**Fig. 2** Curve of force as a function of separation. Chemical potentials of water in the dextran solution (●) are found from  $\mu_w = \text{osmotic force} \times \text{specific volume of water}$  (using present data for the osmotic force). Those from Elworthy's vapour pressure (○) are derived from  $\mu_w = -RT \ln(p_w/p_w^{\text{sat}})$ , assuming water density is not noticeably changed, and are measured in calorie mol<sup>-1</sup>. Separation and water content per lecithin are as in Table 1. The relationship for pressure,  $P_0 \exp(-d_w/\lambda)$ , is convenient for discussing the osmotic data. Curve fitting to our osmotic pressure data (●) for 17.5 <  $d_w$  < 26.6 Å gives  $P_0 = 1.0 \times 10^{11}$  dyne cm<sup>-2</sup>,  $\lambda = 1.93$  Å.

The influence on  $d_l$  of any mono- or disaccharide breakdown products of dextran intercalated between bilayers is probably small. Besides the observed irrelevance of a dialysis membrane between dextran solution and lipid, we know that the replacement of water by glucose or sucrose solutions (of concentrations up to 40% by weight) has negligible effect on  $d$ ,  $d_l$  and  $d_w$  when used in the one-phase lamellar system<sup>7</sup>.

The lipid thickness  $d_l$  increases with decreasing water content (Table 1). This increase in thickness itself indicates the repulsion

Table 1 Analysis of osmotic stress data

Osmotic pressures of the dextran solutions were made directly using a mercury manometer or pressure gauge. Solutions connected to the manometer were in contact with distilled water by way of a dialysis membrane. Putative volume fractions of lipid,  $\phi$ , in the lamellar phase were found by matching against separations seen in the single phase formed at low total water content<sup>7</sup>. Separation  $d_w$  is then  $(1-\phi)d$ , where the lamellar repeat distance  $d$  is measured by X-ray diffraction. Values in parentheses are interpolated between adjacent measured values. The definition of  $d$  as a separate layer containing only water is arbitrary. The aqueous region could also be defined to include the lipid polar moiety<sup>6</sup>. In that case the apparent thickness  $d$  will be greater than the values derived here. It is also a matter of convenience to picture the lipid-water interface as a sharp step where it is actually an interface of thickness comparable to the dimensions of the polar groups

between bilayers<sup>11</sup>, which is being quantitatively measured here.

At a separation of  $27.5 \pm 0.5$  Å, the lamellar lattice is in thermodynamic equilibrium with pure water. Because of its rapid exponential variation, the repulsive component apparently dominates the net interaction for separations only a fraction of an Angstrom less than the equilibrium separation in water. By taking the repulsion curve  $P_0 \exp(-d_w/1.9 \text{ Å})$  derived from fitting the experimental points of Fig. 2 that lie in the range  $17.5 < d_w < 26.6$  Å, and by extrapolating to the equilibrium separation of 27.5 Å in pure water, we estimate the repulsive part of the force between bilayers at equilibrium in water. Since this repulsion is equal and opposite to bilayer attraction, this method provides a first estimate of the interlamellar attraction force,  $5 \times 10^4$ – $8.5 \times 10^4$  dyne cm<sup>-2</sup>. The error, which appears among different lipid preparations, and probably results from handling the lipid, here assumes an ambiguity of 0.5 Å in the determination of the 27.5 Å equilibrium spacing.

Our results using osmotic stress on the lamellar lattice are supplemented by those of Elworthy<sup>12</sup> (supplied to us in tabular form) who determined the amount of water imbibed by egg lecithin as a function of aqueous vapour pressure,  $p_w$ . The chemical potential,  $\mu_w = -RT \ln(p_w/p_w^{\text{sat}})$ , measures the work of transferring water from the lamellar lattice vapour pressure  $p_w$  to bulk water (vapour pressure  $p_w^{\text{sat}}$ ). By dividing the work per mol by the molar volume (the value for pure bulk water is used here), the force per area between the bilayers from which water is removed is obtained. Lamellar repeat distances and bilayer separations are known from X-ray diffraction on lecithin<sup>7</sup> at these limited amounts of water. These vapour pressure measurements are plotted as the open circles in Fig. 2. (The strict similarity of the egg lecithin used in the imbibing and X-ray experiments is not established. The temperature in both studies was 25 °C, but was not strictly controlled in our case.)

The curve of force as a function of separation in Fig. 2 suggests that the vapour pressure and osmotic pressure experiments are consistent. But comparison is difficult because there is a 4 Å gap in data (between 13.5 and 17.5 Å separation). To this extent there does not seem to be a sharp jump in the work of removal of water at any point in the curve from 3 to 33 molecules of water per lecithin; within the limits of these measurements, there is a smooth change in the work of removing water near the lecithin polar groups. It is clear that the simple exponential law (solid points, osmotic data) is not maintained

when more than two-thirds of the original water is removed from the lamellar lattice.

Analyses of the amount of water near lecithins using thermal<sup>13</sup> and resonant<sup>14</sup> probes reveal 10–12 'hydrating' or 'bound' water molecules per lecithin molecule, with another 11 waters 'trapped' by each lecithin<sup>14</sup>. These probes would suggest that the remaining water is bound loosely enough to be considered bulk water. But the finite work of removal,  $\mu_w$ , which we measure osmotically shows this is not so.

The repulsion between lecithin bilayers probably arises both from electrostatic interaction between charged groups and from energy of hydration of all polar groups on the molecule. In the presence of solvent boundaries, as occur here between lipid and water, the change in hydration might be visualised in terms of electrostatic image forces. Between molecules without charged groups, repulsion would occur because of hydration energies alone. The exponential force measured here (Fig. 2) does not fit a model<sup>17</sup> where the lecithin polar group is thought to form an internal double layer.

The attractive force is of the order of magnitude expected for van der Waals' forces in lipid-water multilayers<sup>18</sup>. Its identity with these forces remains to be established by determination of the attractive force as a function of separation. This we are doing by applying osmotic stress to lamellae containing varied fractions of charged lipids in salt water media. We measure double-layer repulsions which will increase the equilibrium separation<sup>7,19</sup>. From each lamellar repulsion curve we may infer an attractive force at each equilibrium separation.

The work of pushing together two electrically neutral zwitterionic phospholipid bilayers can be significant compared with energies available from thermal motion in collision. To bring two faces of area  $100 \text{ Å}^2$  to even 15 Å separation would require about  $8 \times 10^{-13}$  erg or 20  $kT$  units. Alternatively, using the Derjaguin step approximation<sup>15,16</sup> to convert the interaction of two parallel planes to one between a planar bilayer and a spherical bilayer vesicle, a sphere of outermost radius 300 Å coming within 14 Å of contact also feels a barrier of about 20  $kT$ . Such large energies suggest that when fusion of two pure lipid vesicles is in fact observed experimentally, there might be some destabilisation or transient rearrangement of the phospholipid molecules to push apart the polar head groups. This would allow the hydrocarbon moieties to merge without requiring a large amount of work to remove water from the polar groups as observed here for uniform planar bilayers.

We hope that coupled energetic and structural measurements,

such as we report here, will lead to more precise analyses of the forces responsible for lamellar stability.

We thank Professor P. H. Elworthy for his prompt and generous response to our request for data used in Fig. 2. We appreciate the assistance given to us by Mrs Nola Fuller. R. P. R. acknowledges research support from the National Research Council of Canada.

## Stimulation and suppression of response of mouse T cells to the schistosomules of *Schistosoma mansoni* during infection

INFECTION of mice with cercariae of *Schistosoma mansoni* produces a disease with immunopathology similar to human bilharziasis<sup>1</sup>, the chronic hepatosplenomegaly being probably secondary to granulomatous reactions to eggs deposited in the tissues<sup>2</sup>. It has been shown that thymus-derived lymphocytes have a major role in the granulomatous reaction<sup>3,4</sup>, but the reaction of the T cells to earlier stages of the parasite has not hitherto been studied. We have investigated one such reaction—the helper T-cell response to the schistosomule—by using schistosomules as carriers for a hapten and measuring the anti-hapten response in normal and infected mice. In analogous experiments using protein carriers, the anti-hapten response has been shown to be due to cooperation between T cells and B cells<sup>5</sup>. We have found evidence for a specific T-dependent helper response which is greatly increased during the first 2 weeks after infection and subsequently diminishes, and we suggest that the diminution may partly represent a specific suppression of helper T-cell function.

(C57BL×BALB/c)F<sub>1</sub> mice and *nu/nu* (athymic) mice of various genotypes were infected with 40 cercariae of *S. mansoni* on the shaved abdomen<sup>6</sup>. Schistosomules were prepared *in vitro* by mechanical agitation to cercariae in a Vortex mixer<sup>7</sup>, isolation of the cercarial bodies by layering the mixture of bodies and tails on to the Hanks' buffered salts solution (HBSS) in a test tube, where the bodies sink to the bottom in 10 min, and incubation of this pellet for 24 h at 37 °C in RPMI-1640 with 20 mM HEPES in atmosphere of 5% CO<sub>2</sub> in air. The resulting schistosomule preparations were con-

**Table 1** Carrier effect of schistosomules in the antibody response of normal mice to TNP

Mice	No. of schistosomules injected intravenously	TNBS used for coating (mg/ml)	No. of mice	4 d anti-TNP PFC per spleen (geometric mean ± s.e.)
Normal	—	—	6	116(92–147)

	2000	5.0	5	4,755(3,750–6,748)

taminated with less than 5% cercarial tails. For vaccination, schistosomules were fixed in 0.06% formaldehyde for 5 min, followed by three washings in HBSS. For use as carriers for the hapten, schistosomules were coated with trinitrophenol (TNP) by a modification of the method of Rittenberg and Pratt<sup>8</sup>: 5,000–10,000 schistosomules were incubated in a 0.5% solution of trinitrobenzene-sulphonic acid (TNBS) in 0.28 M cacodylate buffer (pH 6.9), for 30 min, at 37 °C, then washed with modified barbital buffer (pH 7.1), followed by three washes in HBSS. TNP-coated schistosomules were injected into mice and the direct anti-TNP plaque forming cell (PFC) responses in their spleens were measured at various intervals thereafter, using lightly TNP-coated sheep erythrocytes<sup>9</sup>, by the slide method<sup>10</sup>. Preliminary experiments showed that intravenous injection produced a better response than intraperitoneal and that the response was maximal if assayed 4 d after infection. This procedure was adopted accordingly for experiments on groups of normal, nude, infected or vaccinated mice. For specificity controls, other groups of infected mice were injected intravenously with TNP-coated horse erythrocytes and the TNP response measured as above.

In normal mice, schistosomules showed a weak carrier effect, at least 900 TNP-schistosomules being needed to give a substantial anti-TNP response. The use of higher or lower TNBS concentrations for coating schistosomules did not greatly affect the result. Nude mice responded very much less well suggesting that the carrier effect was largely T-cell mediated (Table 1).

In mice infected with 40 cercariae, as little as 100 TNP-schistosomules produced a massive anti-TNP response, greatest when the TNP-schistosomules were injected 10 d after the

**Table 2** Failure of carrier effect to increase following a second infection with *S. mansoni* cercariae

	Anti-TNP PFCs per spleen (geometric mean ± s.e.)		
	0	7	10
First infection (40 cercariae)	1,765 (1,505–2,070)	88,495 (80,433–97,366)	233,675 (218,488–249,917)
Second infection at 5 weeks (40 cercariae)	25,098 (20,651–30,503)	20,973 (14,760–29,801)	38,193 (33,650–43,348)
Second infection at 10 weeks (40 cercariae)	4,971 (3,522–7,016)	5,783 (5,389–6,205)	11,181 (9,400–13,300)

(C57BL×BALB/c)F<sub>1</sub> mice were infected with 40 cercariae either once or twice at 5- or 10-week intervals, and injected with 100 TNP-schistosomules 7 or 10 d later.

infection, and thereafter declining, but only falling to the level of response in non-infected mice at about week 12, or 13 when the mice were beginning to die. This increased response to TNP-schistosomules was significantly lower in nude mice, showing that the increase predominantly represents a response of T-helper cells. Mice at all but the latest stages of infection responded normally to TNP-horse red blood cells, showing that the increased T-cell response was immunologically specific (Fig. 1). Similar results have been obtained in CBA mice. In mice infected with *S. mansoni* but not injected with TNP-schistosomules, we noted that the background PFC against both TNP and SRBC began to rise from 4 weeks, possibly an indication of nonspecific B-cell activation.

In mice vaccinated with 40 formalin-fixed schistosomules a substantial but smaller helper T-cell response was seen, which was maintained for at least 13 weeks after vaccination. This suggests that both the early increase and the subsequent decline may be partly due to the living infection (Fig. 2).

In view of the fall in the helper T-cell response in the later stages of the infection (see Fig. 1), mice that had been infected 5 or 10 weeks earlier were reinfected with 40 cercariae and tested with TNP-schistosomules 7 or 10 d later. At no stage was there a significant increase in the TNP-response (Table 2). In other words, the helper T-cell response to the second infection was significantly lower than that to the first, indicating that the decline in helper T-cell activity was not due merely to the disappearance of antigens restricted to the schistosomule. We hope to establish by serum and cell-transfer experiments whether this decline in the T-cell response is caused by antibody and/or antigen, as has been shown in tumour-bearing animals<sup>11</sup> or perhaps by specific suppressor cells. One possibility is that this T-cell tolerance is associated with the deposition of eggs,

**Fig. 1** Increased carrier effect of schistosomules following infection with *S. mansoni* cercariae. The anti-TNP PFC response was measured in the spleens of mice infected with 40 *S. mansoni* cercariae and subsequently injected with 100 TNP-schistosomules or  $2 \times 10^8$  TNP-horse RBCs. The responses were assayed 4 d later, but are plotted against the day of infection. ●, (C57BL  $\times$  BALB/c)F<sub>1</sub> mice injected with 100 TNP-schistosomules; \* nude mice injected with 100 TNP-schistosomules; ○ (C57BL  $\times$  BALB/c)F<sub>1</sub> mice injected with  $2 \times 10^8$  TNP-horse RBCs. The zero time point represents the response to 100 TNP-schistosomules in non-infected mice.

**Fig. 2** Increased carrier effect of schistosomules following vaccination with dead schistosomules. The anti-TNP PFC response was measured in the spleens of (C57BL  $\times$  BALB/c)F<sub>1</sub> mice vaccinated with 40 formalin-fixed schistosomules and subsequently injected with 100 TNP-schistosomules. The broken line indicates the response of infected mice (see Fig. 1).

which release antigens known to strongly stimulate T cells<sup>3</sup>. Egg-laying does not however begin until about 5-6 weeks after cercarial penetration, whereas the reduction in helper T-cell responsiveness is already apparent by 4 weeks (Fig. 1). On the other hand, the granulomatous response to eggs in the tissues, which is also a T-cell mediated response<sup>2,3</sup>, also decreases in the course of time<sup>1,13</sup>, and it is tempting to speculate that the underlying mechanisms may be similar: in the case of our helper T cells, circulating antigens derived from the adult worm but shared with the schistosomule may be responsible for the reduced T-cell help late in the infection.

It is interesting that protective immunity in mice infected with *S. mansoni* reaches a peak relatively late (approximately 12 weeks) after infection<sup>14</sup>, at a time when the helper T-cell response has declined to the level in uninfected mice (Fig. 1). Protection seems to be at least partly dependent on antibody<sup>15</sup>, which suggests that other factors than T-cell reactivity may be responsible for its unexpectedly late development. It would clearly be of great value to be able to follow the response of the antibody-forming (B) cells during infection, with the same degree of precision as is now available for the T cells.

This work was supported by Conselho Nacional de Desenvolvimento Científico e Tecnológico (Brazil) and the Medical Research Council. We thank Dr S. R. Smithers for the supply of cercariae and Miss Elaine Holder for assistance.

## Similarities between "cholinergic proteolipid" and detergent-extracted cholinergic proteins

A REPORT from Changeux's group<sup>1</sup> concludes that the cholinergic receptor proteolipid<sup>2</sup> is different from the detergent-extracted cholinergic protein<sup>3</sup>. This conclusion is based on the observation that there is no immunological cross reactivity between the proteins and their respective antisera. Furthermore, confirming some earlier observations of Karlin<sup>4</sup>, they found that after affinity labelling of the receptor *in situ* with <sup>3</sup>H-MPTA, the radioactive ligand is not extracted by chloroform-methanol. They failed, however, to establish whether the cholinergic receptor proteolipid is still extractable after the affinity labelling and thus committed the same error as did Karlin previously.

In an attempt to clarify the problem we have repeated the experiments (Table 1). In membranes from *Electrophorus* we found that treatment with dithiothreitol (the preliminary step in the affinity labelling) followed by mercaptoethanol, produces a drastic reduction (61%) in the receptor proteolipid that can be extracted. By affinity labelling *Torpedo* membranes with <sup>3</sup>H-MPTA we confirmed the findings of Karlin<sup>4</sup> and Changeux<sup>1</sup> in the sense that only 6% and 14% of the radioactivity was extracted with chloroform-methanol; however in the same experiments there was a reduction of 70% and 80% in the cholinergic receptor proteolipid (Table 1). Thus an alternative and more valid conclusion to draw from the experiments of both Changeux<sup>1</sup> and Karlin<sup>4</sup> may be that the cholinergic receptor proteolipid is labelled in the membrane but is no longer extractable by the organic

solvents, although it can still be solubilised with strong detergents in aqueous solutions.

With respect to the immunological work, we can offer no explanation at present for the apparently negative results. The isolation procedure used by Changeux's group, however, is not that used by our group<sup>2</sup>. Thus the diethyl ether precipitate used by them contains only 10% of the total proteolipids and practically no cholinergic receptor proteolipid. Clearly therefore the question of the immunological comparison of the proteins must be investigated further before definite conclusions can be drawn.

It is convenient to summarise the many similarities between these two proteins. Both extraction procedures are designed to solubilise hydrophobic intrinsic membrane proteins and both proteins have been purified by affinity chromatography either in aqueous solutions<sup>4</sup> or in organic solvents<sup>5</sup>.

The number of receptor sites that can be labelled with  $\alpha$ -toxin in *Electrophorus*<sup>1</sup> and *Torpedo* corresponds closely to the amount of cholinergic receptor proteolipid that we extract<sup>2</sup>. Both isolated proteins show high affinity binding for a range of cholinergic nicotinic ligands, including acetylcholine, decamethonium, *d*-tubocurarine and  $\alpha$ -bungarotoxin. We can transfer our proteolipid to aqueous solutions using Triton X-100 and in these conditions the binding of <sup>3</sup>H- $\alpha$ -bungarotoxin can be demonstrated. Incorporation of the proteolipid into lecithin liposomes has also been achieved and the binding of  $\alpha$ -toxin in the aqueous solution has been observed. From this evidence we conclude that the cholinergic proteolipid of the electrophorus is probably identical with the binding subunit of the detergent-extracted protein.

We thank Dr J. P. Changeux for <sup>3</sup>H-MPTA and *Torpedo* tissue and Dr G. G. Lunt for helpful discussion.

BARRANTES ET AL. REPLY—As De Robertis *et al.* point out<sup>1</sup>, the extent to which chloroform-methanol (2:1) (C:M) extracts proteolipids after treatment of the receptor-rich membranes with dithiothreitol (DDT) and reaction with <sup>3</sup>H-MPTA was not mentioned in our report in *Nature*<sup>2</sup>. It was, however, a daily experience in the laboratory that such treatments did not modify, in any respect, the dissolution of the receptor protein by detergents such as Triton X-100 or sodium cholate; but as De Robertis claims, this might no longer be true in the case of the extraction of the proteolipids by chloroform-methanol.

To our surprise, when De Robertis carries out this control he assays the proteolipid by measuring <sup>14</sup>C-acetylcholine binding after affinity labelling with <sup>3</sup>H-MPTA. From Karlin's work and from our own experience it is well established that <sup>3</sup>H-MPTA attaches covalently to the cholinergic receptor site and therefore blocks cholinergic ligand binding. On the other hand, the fact that acetylcholine binds to the proteolipid after reaction with <sup>3</sup>H-MPTA suggests that, in the presence of organic solvents, <sup>14</sup>C-acetylcholine binding is largely nonspecific (and this might equally be true for  $\alpha$ -bungarotoxin binding in such drastic conditions). Also C:M extracts about the same fraction (0.5-1%) of the total proteins from both fresh

**Table 1** Percentage reduction in the extraction of the cholinergic proteolipid from membranes of *Electrophorus* and *Torpedo* electrophorus, after affinity labelling with <sup>3</sup>H-MPTA

	$\mu$ g Receptor proteolipid per g fresh tissue		Reduction (%)
	Control	Treated	
<i>Electrophorus</i> *	5.2	2.0	61
<i>Torpedo</i> †	23.0	7.0	70
<i>Torpedo</i> †	24.9	5.0	80

The experiments were carried out as described in ref. 1. The amount of receptor proteolipid was determined after chromatography of the extract on Sephadex LH-20 in the presence of  $10^{-6}$  M <sup>14</sup>C-acetylcholine<sup>3</sup>.

\*Treated with dithiothreitol and mercaptoethanol.

†Affinity labelled with <sup>3</sup>H-MPTA (4-(*N*-maleimido)-phenyltri-<sup>3</sup>H-methylammonium).

*Torpedo* electric tissue and purified membrane fragments enriched 50–100 times in  $\alpha$ -toxin sites and containing the cholinergic receptor as 10–30% of their protein.

Nevertheless, we were able to repeat the observation made by De Robertis when the proteolipid was measured by the method of Lowry as modified by Hess and Lewin. Starting from 1 ml of a suspension of membrane fragments of specific activity 890 nmol of toxin sites per g of protein (6.6 mg protein per ml) the C:M extract contained 17  $\mu$ g protein after MPTA labelling as compared with 76  $\mu$ g protein in the absence of DTT and MPTA.

If after  $^3\text{H}$ -MPTA labelling, however, the membrane fragments are exposed to an oxidising reagent such as 1 mM 5,5'-diithiobis-(2-nitrobenzoic acid) (DTNB) C:M extracts 46  $\mu$ g of protein from 1 ml of membrane suspension, a value closer to that found before DTT treatment. In both conditions, that is after  $^3\text{H}$ -MPTA labelling and with or without DTNB treatment less than 2% of  $^3\text{H}$ -MPTA (and not 6% and 14% as mentioned by De Robertis) is extracted into the C:M. Therefore, -SH reagents markedly modify the extractability of the proteolipids by C:M but show no effect on that of the radioactively labelled receptor.

During these control experiments, we noticed that DTT added to the C:M extract of proteolipid considerably enhances its transfer into an aqueous 1% Triton X-100 phase (the ratio of aqueous to organic phase of 2.6:13.0 becomes 16.0:1.6  $\mu$ g protein per ml in the presence of 1 mM DTT). Nevertheless, the DTT-solubilised proteolipids extracted by Triton X-100 still do not bind  $^3\text{H}$ -toxin from *N. nigricollis* in the presence of physiological Ringer solution in the conditions routinely used for receptor assay.

Finally, a comparison has been made between native receptor-rich membrane fragments and membranes which have been extracted with C:M. SDS-polyacrylamide electrophoretograms of both preparations reveal the presence of the 39,000–41,000 daltons band characteristic of the cholinergic receptor protein. Electrophoretograms of membranes labelled with  $^3\text{H}$ -MPTA show this to be the only band to be radioactively labelled and confirm its identity as the receptor.

These observations give additional support to one of our initial conclusions; that the C:M-extracted cholinergic proteolipid shows little if any relationship to the now well identified cholinergic receptor protein in its detergent-extracted form.

## Climate in the 1970s

A FEW words near the end of our letter<sup>1</sup> headed "Climatic reversal in northern North Atlantic", seem to have resulted in our diagnosis of recent climatic shifts being so widely misrepresented elsewhere that some further statement is necessary.

Our letter gave a diagnosis of what had been happening in the North Atlantic-European sector between 1971 and 1975, and was explicitly not a forecast. That diagnosis was, and is, valid, though it was probably not advisable to use the words "little ice age" to describe two decades of colder climate, and it was certainly not advisable to suggest that that episode was over just because of a run of four or five mild winters in Europe, when the other seasons (in spite of August 1975!) continue mainly cold, and the generally lower level of temperatures over the Arctic above 70°N, which set in about 1961, persists.

What has happened since 1971 may be largely attributed to a change of the prevailing wave positions in the circumpolar vortex, even though we do not yet know what causes such shifts involving the centre of the polar cap itself. In 1971 the Canadian Arctic became, for the first time, involved in the cooling that set in sharply in other sectors of the far north in 1961, and, just as sharply, the coldest centre was transferred to the Canadian sector. This meant that, there was a great increase in the south to north thermal gradient between the western Atlantic and northern Canada, particularly in the winter months, resulting in a great increase in the energy of the atmospheric circulation over the North Atlantic, driving mild air towards Europe and more saline water to Iceland—as M. Rodewald (unpublished) has pointed out. But these conditions do not seem to have penetrated as far into the Arctic as during the general Arctic warming in the 1920s and 1930s, and it is not yet clear whether the mechanism described since 1971 is capable of restoring conditions there to what they were before 1960. Doubts on this are strengthened by observation that the centre of the polar cold regime and the waves in the circumpolar vortex returned to their 1960s' positions for about six months around late 1973 and again in 1975. The ice then again increased in the sector east of Greenland, and once more approached the coasts of Iceland in July and August 1975, perhaps for the first time this century in those months.

S.-A. Malmberg informs me that in June 1975 off north Iceland the salinity anomaly was slight, only  $-0.03\text{‰}$ , though the temperature anomaly was  $-1.60^\circ\text{C}$ . No influx of the Atlantic watermass into northeast Icelandic waters was observed in June 1975. The ice conditions were "relatively unfavourable", and by July 1975 there was ice in the East Iceland Current. In June 1975 both the polar and

Atlantic currents were weak in the north Iceland region. Sometimes both these currents are strong (as in 1964 and 1968), and sometimes one is strong and the other weak: no relationship has been found between them.

Recent investigations<sup>2–4</sup> imply that the great variations to which the volume of polar water transported by the East Greenland Current and the southward penetration of this water in the East Iceland Current are prone, may be one of the most interesting and important aspects of climatic change, affecting alike the development of major ice ages, the little ice age of recent centuries, and the cooling since the 1950s.

## Lattice absorption in small particles

LUKES<sup>1</sup> has suggested that the width of the lattice absorption peak for small particles of ionic solids at very low temperatures would be dominated by collisions of phonons with the surfaces. The estimate given for the phonon collision time,  $\tau \sim R/v$ , where  $R$  is the particle radius and  $v$  is the velocity of sound in the bulk, is, however, applicable to acoustic phonons only. This collision time is not relevant to the phenomenon of lattice absorption, which is due to the long-wave optical phonons. The collision time  $\tau$  enters the calculations of lattice thermal conductivities at very low temperatures, when all other possible scattering mechanisms become ineffective. This is a well known boundary effect which has been investigated extensively<sup>2,3</sup>.

As regards lattice absorption by small particles, many experiments have shown the absorption peak to be considerably broader than that calculated by using the bulk value of the damping constant  $\gamma$  appearing in the expression for the dielectric constant<sup>4,5</sup>. For small NaCl and MgO crystallites ( $R \lesssim 1\mu\text{m}$ ) it has been estimated<sup>6</sup> that the damping parameter increases beyond its bulk value by a factor of  $\sim 2.5$ . No fundamental calculations of  $\gamma$  in small particles, analogous to those which exist for bulk crystals<sup>7</sup>, have so far been performed.

# Landmarks in North Sea geology

There is a comparable breadth of technical information. This ranges from the trans-European stratigraphic syntheses presented in papers by the Ziegler brothers, through the many field case histories (documented by

# Europe in the Sixteenth century by A. Ortelius

Courtesy The Mansell Collection London

There is no doubt that the discovery of North Sea oil has been the biggest stimulus to British geologists since the advent of William Smith. This volume provides a landmark in the history of North Sea geological studies and may be the definitive text and sourcebook for more than a decade. It provides an excellent insight into the thought processes and extent of technical knowledge required by a practising petroleum geologist. This book may demonstrate to many geologists outside oil companies that the search for petro-

At £16 for 501 pages, this book is worth every penny. **R. C. Selley**

The papers explaining how oil wells are drilled and fields developed and produced will, I fear, make heavy reading for the non-specialist to whom they should have been addressed. An overall impression of complex problems solved with sophisticated equipment and with considerable attention to preventing oil spillage is conveyed. Reading these papers, however, the non-specialist would have to be very persevering to understand what a blow-out is, how it occurs, who can prevent it and with what equipment.

The papers on oil pollution will be of much greater value to the non-specialist. They are no less technical than the oil industry papers but are neatly divided into the effects on Fisheries, Shore Life, Birds and Long Term Low Level Exposure in all areas.

The problems associated with analysing the effect of one pollutant, oil, in the marine environment are expressed in all papers, and admirably summarised in one, as follows: "Chronic pollution of marine waters by oil from numerous sources is widespread but hard to quantify. It is also difficult to specify its biological effects, since these can often be deduced only from laboratory experiments in conditions which are far from natural. In the field, it is rarely possible to exclude the effects of other pollutants or adverse natural conditions."

Two papers provide valuable data on the role of Government and the oil industry in oil spill clean up.

This volume will be a valuable reference to those interested in the problem of oil and its effects on the marine environment. **P. Selwood**

*Geology of the North-West European Continental Shelf.* Volume 1. By D. Naylor and S. N. Mounteney. Pp. 162. (Graham Trotman Dudley; London, 1975.) £6.50. Volume 2. By R. M. Pegrum, G. Rees and D. Naylor. Pp. 225. (Graham Trotman Dudley; London, 1975.) £8.50.

WITH the increasing level of effort now being put into the exploration and exploitation of the Continental Shelf surrounding the British Isles, a large number of non-petroleum specialists have become involved in the work. Bankers, lawyers, accountants, economists, and professionals in many disciplines are finding that an elementary understanding of the geology of the various areas in which their companies are working is a distinct advantage. And it is for such professionals that these books were essentially compiled.

It is not quite clear why the book is in two volumes particularly as both contain together only 380 pages. Nevertheless the division between the books is clear enough—the first dealing with relatively unexplored western basins of the Shelf, the second being confined to the North Sea area. If a division has to be made then this at least is a logical approach.

Assuming their intended market, both volumes tend to assume very little geological knowledge, but there are times when without it the layman will be stretching a little. Volume 1 begins by introducing the concept of plate tectonics in an attempt to place the

## Biochemistry of hormone action

*Biochemical Actions of Hormones.* Volume 3. Edited by Gerald Litwak. Pp. xvi+415. (Academic; New York and London, August 1975.) \$36; £18.

READING this book straight through it becomes increasingly obvious that the real breakthroughs in the understanding of hormone action will only come when the tools provided by molecular biology and genetics are brought to bear on the problems. Unfortunately, not all the hormone-responsive systems currently under study are amenable to

British Isles in a regional framework. To a geologist the way in which this is done may seem a little glib but the message may get across nonetheless. By reference to geophysical and bottom sampling data acquired in each of the western basins together with a resumé of the inferred stratigraphy, a generalised picture is built up of the basins stretching from the Channel to the west of Shetland. The amount of information in each chapter varies with the amount of information published, but nevertheless for the audience intended there is sufficient data to give a reasonable idea of the variations in structure and rock type between each of the basins considered.

A more systematic treatment, however, with maps, cross sections and stratigraphic tables, would have enabled comparisons to be made rapidly, as would mention of the relationships between onshore and offshore geology, even in diagrammatic form. The account of the palaeogeography and the evolution of western Britain, brief though it is, seems somewhat misplaced. Indeed it might be said that the book tends on occasion to forget its audience. What will be useful to the layman, however, are the brief notes on how oil is trapped, and explanation of how a seismic survey is conducted and how a well is drilled. These are partially repeated in the second volume together with a glossary, but they perhaps bear re-enforcement.

The second volume is concerned mainly with the North Sea and the information it contains is based on factual material, much of it released for the first time at the Conference in London last November, and which is drawn on freely. The stratigraphy is described systematically from the basement to the Tertiary system, and sadly the procedure of describing Basins is not adopted in this volume as it was in

these approaches and very often when these tools would prove useful they are not applied. The articles in this book serve to illustrate this point.

Molecular and genetic studies are obviously much easier where the gene product affected by the hormone can be identified; the chapter by Schimke *et al.* provides an elegant example of molecular biology being used to study ovalbumin induction in the chick oviduct. This chapter appears next to another (on the same topic) by Rosen and O'Malley which has an annoying amount of overlap. Indeed this is a general fault with the book: half of it is concerned with steroid hormones, and the central dogma of steroid action is repeated several times. But some of

the first. In many ways this method is a much more convenient one of describing an area which geologically has a very complex history.

The "field data sheets", which is effectively what they are, will be appreciated, however, by the layman as they condense a considerable amount of information very concisely. Each field is presented in a similar manner each having a map and cross section together with pertinent information on the field. The stratigraphic information which has been derived from studies of the fields is incorporated into the accounts of various geological systems and thus the fields are placed in their geological perspective. Because the book does not use the Basin approach of the first volume, however, the significance of the various discoveries (for example, the predominance of gas fields in the southern North Sea Basin) might go unnoticed.

It may be that it is too early in the history of the exploration of the Continental Shelf to attempt the synthesis which is presented in the second volume. There is still a great deal of information that remains confidential, and authors are unable to construct the geological cross sections and maps which would make all the difference to unravelling the history of these areas and which are so essential to an elementary understanding of the geology.

In many respects the two volumes are complementary, one deals with essentially untried areas the other with proven and established Basins. They both contain a considerable amount of compiled information—albeit very generalised. It is a matter of choice and of the reader's expertise as to whether one goes to the original text (the proceedings) or to this concordance. **J. R. V. Brooks**

these articles are good. There is an excellent review of the action of oestrogens by Katzenellenbogen and Gorski, although it is somewhat marred by the primitive techniques used to analyse oestrogen-induced RNA synthesis.

There are three chapters dealing mainly with hormone receptors; that by Hollenberg and Cuatrecasas is a particularly useful introduction to peptide and catecholamine receptorology. One other chapter deals exhaustively with the glucocorticoid receptor and another discusses the evidence for a specific nuclear receptor for thyroid hormones.

Any genetic approach to the problem of hormone action presupposes that hormone-mediated events can be studied in cultured cells. The problems of establishing hormone responsive cells in culture is discussed in two chapters,

one by Armelin (which mentions some of the pitfalls) and a disappointingly brief chapter by Sato. In it he discusses the role of serum in cell cultures and comes to the conclusion that a whole new series of peptide hormones are about to be discovered.

The hardest task in reviewing this book is trying to decide who it was aimed at. Although some of the topics treated have not been reviewed previously, libraries are becoming full of books which serve as a vehicle for yet more reviews on the same topics. It might be more useful to have more shorter reviews with good references so that the reader has enough information to go to the relevant literature if he wishes. This book is, however, good of its genre and provides a relatively painless entry into some of the biochemistry of hormone action.

Robert Shields

differ according to the broadscale environment and to the geographical zone, season of the year, synoptic weather situation and so on. The subject is at the same time eminently practical and useful but unfortunately general principles do not get us very far and empirical studies for local application need to be made in every part of the world; the literature becomes ever more voluminous as many hundreds of worthwhile studies are published every year. How does one set about reducing such material to a textbook for a university course. Professor Yoshino is one of the few who have tried.

A short opening chapter on terminology is followed by 25 pages of 'History of Research', just enough to remind students that the subject is not a new one. In chapter 3 of 142 pages, climate is related to the surface, flat land, city, forest, seashore, lakeshore, riverbank, including some fundamental boundary layer theory which seems either too much or too little. A chapter of similar length concerns 'topography', here implying mountains, hills and valleys, and its relationship to climatic elements; the next is entitled 'Local Airstreams and Weather' and relates the weather (rather than the climate) with synoptic pattern, local fronts, and local winds, fohn, bora, and the like. The sixth and last shorter chapter is headed 'Local and Microclimate and Nature' which could mean anything but turns out to be just a taste of applied climatology, with geomorphology and plant ecology, and provides a place for a pet subject of the author, wind shaped trees.

A broad qualitative knowledge of meteorology and its basic principles is assumed and just occasionally mathematics finds a place. The Japanese book production is excellent and would do credit to the best English academic publishers although with sufficient minor misprints and infelicities in English to call for a little indulgence. It is a book to be acquired by every specialist library although the inevitable bias towards Japanese climate and Japanese literature makes it unsuitable as a coursebook outside Japan.

I have never taken readily to the textbook, however, which in its anxiety to acknowledge its sources reads at times more like an annotated bibliography. Nearly 1,000 different authors earn some 1,200 references and yet the selection from the much vaster world literature still seems almost arbitrary. A text for students which digests the material and is sparing with the 'credits' can be briefer and cheaper, more cogent, more instructive and certainly not so soon dated, although the scholarship may be less obvious.

R. C. Sutcliffe

## Analysing sediments

*Archaeological Sediments: a Survey of Analytical Methods.* By Myra L. Shackley. Pp. 159. (Butterworths: London and Boston, Massachusetts, June 1975.) £7.00.

THIS book is a compendium of methods for the description and analysis of inorganic sediments laid down by wind and water, and for the handling of field and laboratory data. A large part of the book deals with particle size analysis and is a thorough and reliable guide to techniques in this field, but there is very little discussion of experimental errors, and a spurious precision of measurement is recommended, given the sampling strategy proposed. Interpretation of field observations and experimental results receives very little attention, and examples of the use of the methods are presented with uncritical acceptance of their suitability to the problems in hand and of the value of the results. Outside the field of traditional sedimentology, selection of sources and coverage of techniques is erratic, and misleading advice and information appears. In the confused discussion of the relationship between soils and sediments no mention is made of mineral alteration and secondary mineral formation; organic components of sediments, although their study is a separate field, surely require discussion as participants in the processes of sedimentation and postdepositional alteration. Most archaeological sediments are complex mixtures of mineral and organic materials of

diverse origin and history, laid down in intricate interstratification by people and animals as well as by the inanimate agencies, and their study demands a synthesis of methodology derived from many branches of field and laboratory investigation. This book understates the limitations of the contribution its methods can make in deriving information about human environment and behaviour from the deposits left by or related to human activity. It provides a useful short cut to the standard literature of sedimentology, but fails to provide the archaeologist or the scientist working with him with the help in formulation of questions, selection of appropriate techniques and interpretation of results which he badly needs.

Susan Limbrey

## Small-scale meteorology

*Climate in a Small Area: An Introduction to Local Meteorology.* By Masatoshi M. Yoshino. Pp. xvi+549. (University of Tokyo: Tokyo; International Book Distributors: Hemel Hempstead, Herts, April 1975.) £16.

PROFESSOR YOSHINO has provided a successful textbook on small-scale climatology, an area which does not lend itself readily to systematic presentation. It is a multidimensional subject in which the range of physical variables—pressure, temperature, humidity, cloudiness, sunshine, rainfall, wind and others—are related to a comparable variety of physical features—hills and valleys, land and sea, rivers and lakes, trees and forests, towns and cities—all of which have effects which

## Developmental controversy

*Cell Cycle and Cell Differentiation.*

(Results and Problems in Cell Differentiation: a Series of Topical Volumes in Developmental Biology, Volume 7.)

Edited by J. Reinert and H. Holtzer.

Pp. xiii+331. (Springer: Berlin and New York, 1975.) DM69; \$29.50.

As editors of *Cell Cycle and Cell Differentiation* Reinert and Holtzer have put together chapters on some of the currently most interesting topics in developmental biology. This monograph can be roughly divided into two parts: the first four chapters deal with different cell types whose differentiation depends on a critical stage in the cell cycle, the remaining chapters either equivocally touch on the dependence of differentiation on the cell cycle itself, or argue that it may be irrelevant to differentiation.

The book begins with a chapter on myogenesis by S. R. Dienstman and H. Holtzer, the latter being currently one of the most prominent protagonists of the idea of the 'quantal cell cycle' as a key to understanding cellular differentiation. The next three chapters also echo the same theme of coupling of cell division or cell cycle to the differentiation of erythroid cells (H. Weintraub), of neuronal specificity (R. K. Hunt) and neurogenesis (C. H. Phelps and E. Pfeiffer). Those authors by and large agree with Holtzer's concepts but also urge caution before all the conclusions regarding lineage-dependence of differentiation are definitively accepted. The question of the mechanism of quantal cell cycle is however left unanswered, nor is it clear if such a cycle plays a 'causal' or a 'permissive' role in the expression of a developmental programme.

R. C. King gives a good account of the exploitation of genetics and hormones (particularly ecdysone) in evaluating the role of cell division during oogenesis in *Drosophila*, but avoids a clearcut conclusion about the causal role for the cell cycle or cell division. The book then takes a major turn with two short chapters by P. Lawrence and J. B. Gurdon who come out against quantal mitosis as essential for differentiation. Lawrence uses his work on pattern formation in larval and adult cuticle development in the insect, *Oncopeltus*, a process regulated by juvenile hormone, to argue that whereas asymmetric cell divisions may generate diversity it is not certain that symmetric mitosis leads to differentiation of daughter cells. Gurdon turns to his group's work on nuclear transplantation to argue that cell division

is not essential for all differentiative processes. He proposes that what may be important is cyclic condensation and swelling of chromosomes; the latter would pick-up a new set of cytoplasmic regulatory proteins during their postmitotic decondensation. It seems to me that there is room for Holtzer's quantal cell cycle idea as well as those of Lawrence's and Gurdon's and that these need not be mutually exclusive.

Four chapters depict the importance of studying differentiation in simpler organisms before attempting to interpret the more complex phenomena of animal cells. These include morphogenesis in the prokaryote, *Caulobacter* (N. B. Wood and L. Shapiro), plants in general (F. Meins, Jr), plant tumour formation as a differentiative process (A. C. Braun) and cell differentiation in *Neurospora* (R. E. Nelson, C. P. Selitrennikoff and R. W. Siegel). None of the authors of these chapters provide strong evidence for or against the idea of a quantal cell cycle as the basis of cell differentiation and hint that many morphogenetic changes can be dissociated from growth and cell division. Meins, after discussing mathematical analysis of several well known plant differentiative kinetic models, emphasises the well-known totipotency of differentiated plant cells which strongly suggests that cytodifferentiation results from epigenetic rather than permanent genetic modifications. Tsanev takes the reader back to animal cells with a detailed and fresh analysis of the very complex changes associated with hepatic regeneration, a very popular model for temporal analysis of functional changes and DNA synthesis but one which does not clarify the role of the cell cycle in differentiation and goes on to suggest that one should separately consider the activities of 'tissue-specific' and 'mitotic' genes. Th. W. Borun makes a plea for considering histones as important for early cell differentiation and not to regard them merely as 'glue' for keeping inactive genes repressed. He distinguishes the simple multiplicity of histones from the microheterogeneity generated by their phosphorylation, acetylation and methylation particularly of histones.

For students of developmental biology, *Cell Cycle and Cell Differentiation* will be most valuable for bringing together views of some of the most original workers in this field, but the controversy it generates about the essential role of quantal cell division may be more apparent than real. The monograph once again shows how far we still are from, or even how futile it may be to search for, a unified hypothesis for the oldest unsolved problem of biology.

**J. R. Tata**

# obituary

**Kasimir Fajans** was born in Warsaw, Poland, May 27, 1887, and died in Ann Arbor, May 18, 1975. He went to school in Warsaw, to university in Leipzig, and then to Heidelberg where he did his Ph.D. work, and also won the Victor Meyer Prize (1909). He spent the next two years as a postdoctoral student at the Technische Hochschule in Zurich, where he became acquainted with Albert Einstein, and at the University of Manchester, where he worked with Lord Ernest Rutherford. After six years at the Technische Hochschule at Karlsruhe, he moved to Munich, and became the director of the Institute for Physical Chemistry in 1932. He first visited the United States in 1930 as the Baker Lecturer at Cornell University, and returned in 1936 as Professor of General and Physical Chemistry at the University of Michigan, where he remained for the rest of his career.

His major work was on radioisotopes, where he discovered the branching of radium transformation series in 1911, established the radioactive displacement laws in 1913, found the first isotope of the 91st element in the Periodic Table and discovered the precipitation rule of radio elements. Less well known, but equally fruitful, was his prolific research on other topics in chemistry. A partial list would have to include: the heat of hydration of gaseous ions, thermo-chemistry, chemical binding, volumetric analysis by adsorption indicators, theory of glasses, and the partial separation of D- and L-stereo-chemical isomers by asymmetrical catalysts. He was the author of five scientific books; and remained active long after his formal retirement, the last of many awards given to him, the Gold Award for 1975 of the Affiliate Council of the Engineering Society of Detroit, was bestowed only a few months before his death.

Professor Fajans married Salomea Kaplan, in 1910. She survives him together with their two sons Edgar W. and Stefan S., four grandchildren and two great grandchildren.

Thomas M. Dunn

Like many men of modest physical stature, **Hamilton Hartridge** who died on January 13, 1976, at the age of 89, was a dynamo. He used to produce

ideas at the rate of a normal person's heart-beat, a faculty which dove-tailed with his nineteenth century many-sidedness, but ultimately led to his professional evaporation.

After completing his medical studies he stayed at King's College Cambridge till 1926. It was there that he did his best scientific work. He collaborated with Roughton in the classical analysis of the composition of blood in relation to various levels of oxygenation the study was furthered by Hartridge's ingenious invention of the reversion spectroscope, suitable for an estimation of the movement of haemoglobin bands. He suspended silk threads from the ceiling of his room at distances just greater than a bat's wing-span, and showed that, though the bats flew around, not a single thread was torn. He provided an optical system enabling Rutherford and Geiger to get on with their experiments counting  $\alpha$ -particles. Later he buttressed Helmholtz' theory of hearing. He applied physical principles to the theory of visual resolution in the early twenties, was elected to the Royal Society and appointed subsequently—if not consequently—to the chair in physiology at Barts in 1927. This he occupied till 1947.

Paradoxically, his name is best known in the world of vision undoubtedly because of his literary rather than his scientific output. His crucial experiment on accommodation in the cat is forgotten. But his quixotic attacks on the validity of Young's trichromatic theory of colour vision raised enough dust for even some present-day authors deeming it necessary to flick a duster. Hartridge's lively brushes at the Physiological Society and the Colour Group of the Physical Society (as it then was) intrigued even laypersons.

Explicitly presented in a volume of Transactions of the Royal Society, affectionately known as the Yellow Peril, his polychromatic theory is alien to British sensory physiology in being unquantified and therefore untestable. The Medical Research Council set up a Vision Research Unit in 1947 under Hartridge's direction so that he might have a chance to prove his ideas. He failed. Yet he managed to attract a handful of people who have directly and indirectly stimulated vision research in the last thirty years both in this country and abroad. This should not be forgotten even though it is unlikely to be engraved on any stone.

R. A. Weale

**Dr R. W. B. Nurse**, a former Head of the Materials Division at the Building Research Station and a world authority on cement chemistry, died on November 13, 1975, aged 62. He received his degree in Physics from London University in 1934 and began at the BRS, which he joined in 1932, his fundamental work on inorganic building materials including the thermodynamics of multicomponent systems. Early in his career he invented with F. M. Lea (later Sir Frederick Lea) the Lea-Nurse apparatus for determining the specific surface of powders by an air-permeability method. He made major contributions to Portland and slag cement chemistry, for which he was awarded the D.Sc., London, in 1954, and contributed principal papers to the 4th, 5th and 6th International Symposia on the Chemistry of Cement. He was probably best known for his work on the manufacture of cement from impure limestone which led to the setting up of a thriving cement industry in Uganda, the first anywhere in the world to use phosphatic limestone. His work was recognised in 1963 by the award of the Sir George Beilby Medal. He also initiated at BRS studies of fibrous composites and crystallised glasses. In 1965, in recognition of his outstanding research abilities he was awarded special merit promotion to Deputy Chief Scientific Officer, which enabled him to reduce his administrative responsibilities and to concentrate on research. Between 1965 and his retirement in 1973, he continued his work on fibrous composite materials, contributing to the understanding of the properties and fracture mechanics of glass fibre cement composites in particular. He had been President of the Mineralogical Society and was an honorary member of the Permanent Committee of RILEM (Réunion Internationale des Laboratoires d'Essais et de Recherches sur les Matériaux).

Ron Nurse was a man of very wide-ranging interests and talents: he took a particular interest in the training of young people, for instance as a member of the Board of Governors in local schools and colleges. Among his many qualities his generosity of mind, modesty and his willingness to help others were outstanding. He leaves a wife, a son and a daughter by whom, as well as by his colleagues and friends, he will be greatly missed.

Witold Gutt

# announcements

## Appointments

**Sir Denys Wilkinson**, Professor of Experimental Physics at the University of Oxford, has been appointed Vice-Chancellor of Sussex University.

**Professor John B. Goodenough**, Leader of the electronic materials group at M.I.T., has been appointed Professor of Inorganic Chemistry at the University of Oxford.

## Awards

The Geological Society of London has announced the following awards for 1976:

The **Wollaston Medal** to **Sir Kingsley Dunham**, Foreign Secretary of the Royal Society, an authority on mineral occurrences in Northern England.

The **Murchison Medal** to **Professor R. A. Howie**, King's College, London, for his research on pyroxenes and other minerals and his contribution to teaching.

The **Lyell Medal** to **Mr W. B. Harland**, University of Cambridge, for work in Spitsbergen, contributions to stratigraphy and the geology of tillites and work on orogenesis.

The **Prestwich Medal** to **Professor W. W. Bishop**, Queen Mary College, London, for his studies of mammalian palaeontology and the stratigraphy and geomorphology of Miocene-Pleistocene deposits in East Africa.

## International meetings

March 1, Deadline for **Experimental Use of Algal Cultures in Limnology** to take place on October 26-28, in Sandefjord, Norway (Norwegian Institute for Water Research, P.O. Box 333, Blindern, N-0slo 3, Norway)

March 25-26, A symposium on **The Zoological Society of London 1826-1976 and Beyond**, to be held at the Meeting room of the Zoological Society (Assistant director of Science (UM), Zoological Society of London, Regent's Park, London NW1 4RY, UK)

March 30-April 2, **Sixth Conference on Molecular Spectroscopy**, University of Durham (Institute of Petroleum, 61 New Cavendish Street, London W1M BR, UK).

March 30-April 2, **The Synapse**, St Andrews, Scotland (Dr G Cottrell, The Wellcome Laboratories, The Gatty Marine Laboratory, St Andrews, Fife, UK).

## Person to Person

**Joseph Lister**, a new biography. I wish to consult letters, diaries, related materials held by friends, former patients, family, especially descendants of Lister's sisters, Isabella Sophie Pim and Jane Harrison, and of James Syme, the Scottish surgeon, Richard B. Fisher, 26 St Paul's Road, London, N1. 01-226 2765.

There will be no charge for this service. Send items (not more than 60 words) to Martin Goldman at the London office. The section will include exchanges of accommodation, personal announcements and scientific queries. We reserve the right to decline material submitted. No commercial transactions.

March 31, Deadline for attendance at an **International Symposium on Migraine**, London (The Director, The Migraine Trust, 23 Queen Square, London WC1N 3AY, UK).

March 31-April 2, **Intraocular Foreign Body and Metallosis**, organised by the German Ophthalmological Society, Cologne (Professor Dr H. Neubauer, Universitäts-Augenklinik D 5 Cologne 41, Joseph-Stelzmann-Strasse 9).

April 1-2, **A Symposium on Diabetes and Other Endocrine Disorders During Pregnancy and in the Newborn Infant**, New York City (Professor Maria I. New, Cornell University Medical Center, 525 East 68th Street, New York, N.Y. 10021).

April 5-8, **mRNA: The Relation of Structure to Function**, Gatlinburg, Tennessee (Elliot Volkin, Chairman, Organising Committee, 1976 Biology Research Conference, P.O. Box Y, Oak Ridge, Tennessee 37830).

April 5-6, **Microscopy of Organic Sediments**, Oxford (The Administrator, Royal Microscopical Society, 37/38 St Clements, Oxford OX4 1AJ, UK).

April 5-8, **Anglo-Dutch Wood Anatomy Meeting**, Oxford University (The Administrator, Royal Microscopical Society, 37/38 St Clements, Oxford OX4 1AJ, UK).

April 5-9, **Fifth European Ophthalmology Congress**, Hamburg (The Congress Secretariat, c/o Holland Organising Centre, 16 Lange Voorhout, The Hague, The Netherlands).

April 5-9, **EMBO Workshop on Thermodynamics and Calorimetric Studies on Biological Systems**, Santa Mar-

gherita Ligure, Genoa (Dr Giovanni Rialdi, c/o Centro Chimica Fisica di Macromolecole Sintetiche e Naturali, Consiglio Nazionale delle Ricerche, Istituto di Chimica Industriale, Via Pastore, 3-16132 Genova, Italy).

April 5-9, **The Annual Chemical Congress of the Chemical Society and the Royal Institute of Chemistry**, Glasgow (Dr John F. Gibson, The Chemical Society, Burlington House, London W1V 0BN, UK).

April 6-8, **Components of Protein Synthesis**, Cambridge (Dr A. R. Fersht, M.R.C. Laboratory of Molecular Biology, University Postgraduate Medical School, Hills Road, Cambridge CB2 2QR, UK).

April 6-8, **Advances in Mechanisms of Drug Metabolism and Species Differences in Drug Metabolism—from Microbe to Man**, Guildford (Dr L. J. King, Department of Biochemistry, University of Surrey, Guildford, Surrey GU2 5XH, UK).

April 6-9, **Biology and Systematics of Colonial Organisms**, Durham (Dr B. Rosen, Department of Palaeontology, British Museum (Nat. Hist.), London SW7 SBD, UK).

April 7-9, **A Symposium on Endocytosis and Intracellular Digestion**, organised by the British Society for Cell Biology/Lysosome Club, Nottingham (Dr T. R. Ricketts, Department of Botany, School of Biological Sciences, University of Nottingham, Nottingham NG7 2RD, UK).

April 8-9, The British Institute of Radiology announces its **34th Annual Congress and Scientific Exhibition**, London (The General Secretary, The British Institute of Radiology, 32 Welbeck Street, London W1M 7PG, UK).

April 8-9, **Moisture in Solid Materials in the Process Industries**, jointly organised by SIRA and The Koninklijk Instituut van Ingenieurs (Netherlands), Delft (Mrs R. G. Keiller, SIRA Institute Ltd, South Hill, Chislehurst, Kent BR7 5EH, UK).

April 8-9, **The Ordinary Meeting of the Royal Astronomical Society**, Manchester (The General Secretary of the Royal Astronomical Society, Burlington House, London W1V 0NL, UK).

April 30, Deadline for abstracts, **The Stratosphere and Related Problems**, Logan, Utah, on September 15-17 (Dr Wesley T. Huntress, Jr, Executive Secretary, Jet Propulsion Laboratory, M/S 183-401, 4800 Oak Grove Drive, Pasadena, California 91103).

## Your man in Whitehall

TWICE in the past three months the absence of a Chief Scientific Adviser to the government has been pointedly remarked on. Sir Alan Hodgkin, retiring President of the Royal Society, drew attention to the vacant post in his farewell address in November. Now the Commons Select Committee on Science and Technology, in an exchange of letters with the Prime Minister, brings the issue to the surface again. But are those who ask for one person to head government's central machinery for co-ordination of policymaking really clear that the system would thereby work any better than it does at present?

The post of Chief Scientific Adviser based in the Cabinet Office has been vacant for almost two years. Sir Alan Cottrell, having served for his five-year term, returned to academic life. His deputy, Dr Robert Press, a career civil servant with a background in nuclear matters, took over responsibility for science and technology without being named as chief adviser. Dr Press retires this summer; hence the rumblings.

The Select Committee says that in the past its suggestion of a ministry for research and development was brushed aside because the Chief Scientific Adviser was already said to be responsible for ensuring adequate co-operation and co-ordination between departments. In the absence of such an adviser, the committee says, "[we] wonder whether assurances given by successive governments about the co-ordination of research and development continue to represent government policy . . . failure to fill the vacancy has caused considerable dismay in the scientific community, and has raised doubts about the sincerity of the government's commitment to the importance of an independent scientific voice in the formulation of policies at the highest level."

In reply, the Prime Minister emphasises that Dr Press's appointment was intended as transitional, but that he has in mind stronger central co-ordination—though the appointment of Chief Scientists in many ministries "emphasised the increasing importance attached to scientific advice and underlined the impracticability of providing this from one central point. The creation of the Central Policy Review Staff as a multidisciplinary body of advice to the Cabinet also added a new dimension." Mr Wilson missed an excellent opportunity very recently of further sounding out views on science in government by devoting most of a speech to the Parliamentary and Scientific Committee to fulsome praise for the National Research Development Corporation (repeated almost verbatim from the Blackett Memorial Lecture of three months earlier), and by relegating questions of science in government to a few sentences on the

difficulty of pleasing everyone all the time. The question of advisers in general was passed off with a joke about an advisory bull belonging to FAO.

The real trouble with the post of Chief Scientific Adviser is that he is placed in such an ambiguous position. The Select Committee's letter refers to at least four functions:

- responsibility for interdepartmental coordination and co-operation
- co-ordination of research and development
- an independent scientific voice in policy formulation
- articulation of scientific advice to the Cabinet.

The academic community would undoubtedly add a fifth—provision of a direct channel for academic scientists to have access to government particularly when they held views which diverged from those expressed by civil service scientists. Industrial scientists might add further functions. The job begins to look attractive only to a megalomaniac or a superman.

Further, neither of the last two advisers exactly raved about the job after their departure; they certainly gave the impression that they found it rather frustrating. If famous names were now to be canvassed for the post, the government would have a lot of arm-twisting to do. And if the scientific community has been expressing dismay at the lack of a Chief Scientific Adviser, it has been doing so in a most *sotto voce* way.

Mr Wilson declares that he wants stronger central co-ordination but can do without the centralised advice, so he will probably look for a sound scientific administrator from within the civil service rather than a famous name from without. If he views the civil service as the sole source of scientific input to the government, this makes sense. But hundreds of millions of pounds are spent each year on nurturing science and technology both in academe and industry. Much of this expenditure will not result in anything that the government desperately needs to know about, but the existence within the Cabinet Office of some sort of external liaison office accessible to research councils, industrial organisations and individual scientists might well ensure that when matters of importance do turn up, they do not get tangled up in Whitehall bureaucracy and interdepartmental rivalry.

The post of Chief Scientific Adviser should no longer be retained. But when Mr Wilson recruits his top co-ordinator for departmental science he should also hire a good scientist from outside the civil service as liaison officer with the outside world.

## Change and consequence

In a second concluding article, **Peter Pockley** looks at Australian science and the recent election.

SCIENCE was not a starter in the public campaigning for the December election although there was plenty of activity behind the scenes. The Liberal Party did, however, make three mentions of science which were important in the light of subsequent events. This made the score Liberals 3, Labour 0, for the Labour campaign concentrated on dramatising the constitutional issue of the powers of the Senate and the essentially political actions of the Governor General in bringing down the popularly elected government.

The first mention came in Mr Fraser's policy speech, in which, as an item of evidence for ineptness in the Labour administration, he took a passing swipe at the research grants controversy. The second item was the Liberal Party's issuing of a statement on science policy in which the Department of Science retained a central role. Mr Fraser's acceptance of any science policy is a political turn-around. In 1968, as Minister for Education and Science, he had argued in a major speech before an Academy of Science meeting that attempts to define a science policy were futile. This *volte face* paled into insignificance, though, before some others which Mr Fraser underwent but which he successfully played down during the campaign: he had, for instance, been one of the strongest advocates and administrators of compulsory military service and of the ultimately futile expedition by Australian forces, including conscripts, to the Vietnam war, policies which he could not afford to embrace in 1975.

Mr Fraser got away with such inconsistencies by developing a form of non-speak which he used successfully to deflect all specific questions with varying combinations of a few generalised, qualified or conditional phrases. This technique, which tied him down to almost no action of detail or permanent substance, was aggravating in the extreme to working journalists and political opponents alike, but such was the strength of feeling he generated against Labour that he had no cause for deigning to answer questions with facts or commitments. An example of this approach was provided by the third mention of science in the campaign.

Only five days before the election, Mr Fraser personally issued a statement designed to quell speculation that the Australian Science and Technology Council (ASTEC) would be abandoned or greatly modified by a Liberal government which had arisen from some

remarks on a radio programme by the then Liberal spokesman on science, Mr Eric Robinson. The statement largely affirmed the objectives defined for ASTEC by Labour (although not by name, of course) and went on to say that it will report directly to the Prime Minister. This plan was welcomed by many scientists who had not been happy with Labour's arrangement in which ASTEC reported to the Minister for Science and Consumer Affairs. This much, at least, of Mr Fraser's statement calmed troubled spirits who felt even more secure from the statement that ASTEC "will be a body of the highest status and greatest independence".

It seems to have been only after the election that observers realised that the statement quoted gave no guarantee of independence, except in the way that that term may be defined by a conservative government. Labour was guaranteeing independence for ASTEC by making it a statutory corporation operating under its own Act of Parliament and requiring it to publish its findings. The necessary legislation was, however, one of many important Labour Bills already under debate but which were nullified by the proroguing of Parliament. ASTEC has, in fact, been operating only on an officially "interim" basis.

What happens to ASTEC now is a matter of guesswork. The small organisation has been transferred to the responsibility of the Prime Minister. The Chairman of the Interim body, Dr J. A. L. Matheson, has left his job as Vice-Chancellor of Monash University in anticipation of early confirmation as full-time Chairman. At the time of writing, if the government is acting on the matter at all, it is doing so with sealed lips. The longer the delay, the greater the speculation that "greatest independence" may mean becoming a box in the organisational chart of the Prime Minister's Department or the Department of Science and being treated as a kind of bureau.

### Science department curtailed

No group in the public service would probably be happier with a diminution of ASTEC's independence than the Department of Science, which had never been enthusiastic about ASTEC as a rival in the advisory stakes to government. The department, however, lost much and gained nothing in terms of responsibilities after the election. For a few brief months of potential glory in 1975, the department had

Photos: AIS

James Webster (top) and Clyde Cameron

taken on an extra function of considerable political importance. For some time previously, Mr William Morrison had paved the way for his department to fly the popular flag of consumerism. On taking over Mr Morrison's portfolio, Mr Clyde Cameron was presented with the grander title of Minister for Science and Consumer Affairs. Mr Cameron made a rather ungainly start; his set-piece speeches cast grapes at many targets and displayed little sympathy with his new responsibilities. But, to his credit, he soon settled down to becoming a convinced champion of science *per se*, which Mr Morrison had never done.

In the consumer field, he secured a promise of services from Mr Ralph Nader. Substantial legislative powers were being developed by the new Consumer Protection Division of the department which had been given responsibility of the consumer sections of the forceful Trade Practices Act. In a trade-off with the Attorney General's Department which had thereby lost part of the administration of this Act, the Science Department handed over its Patents operations. Earlier in 1975, the Science Department had established a Consumer Standards Branch. In Mr Cameron's short reign, then, his department enjoyed both a monitoring and prosecuting function in the interests of consumers. This useful union

of powers never enjoyed active consummation; if it had, there is little doubt that it was a potential vote-winner for Labour.

In the December shuffle of responsibilities by Mr Fraser, all consumer activities were removed from Science and split between Attorney General's (consumer protection) and a new Department of Business and Consumer Affairs (consumer standards) where it will require devilish determination to prevent a conflict of interest between business and consumers, to the likely detriment of the latter. Patents, incidentally, continue to bounce around; their administration has now gone from Attorney General's to Business and Consumer Affairs. The fate of consumerism under the Liberals mirrors that of environmentalism which has similarly been buried within a large department of diverse interests, namely Environment, Housing and Community Affairs.

Also after the election, the Department of Minerals and Energy was renamed National Resources under the National Country Party Leader and Deputy Prime Minister, Mr Doug Anthony, as Minister. Professor Messel and Sir Lenox Hewitt retain influence in the department's area of responsibility through the Australian Atomic Energy Commission (AAEC), of which Sir Lenox is Vice-Chairman. Two of the five places on the AAEC have been vacant for some time. Mr Connor was probably keeping his empire-building options open; one of these options was thought to be the creation of a new multi-energy research and development authority which would have incorporated the AAEC, the Bureau of Mineral Resources and the Mineral Research Laboratories of CSIRO, all of which were then under Mr Connor's control. Mr Anthony has not held on to the CSIRO bit, and has shown no indication of how he will treat the AAEC.

The disciplined control on information within the Fraser ministry meant that it was not until some time after the election that the most senior people in CSIRO could obtain clarification of the line of responsibility of their organisation. The new Science Minister, Senator Webster, is now solely responsible for the Science and Industry Act which gives CSIRO its statutory independence. The Minister-CSIRO line is direct and separate from the Minister-Department line. In the face of diminished duties, the Science Department is not out of the woods yet; it will have to work hard to maintain its position which could be called into question whenever Mr Fraser reshuffles his Cabinet or when its Secretary reaches retiring age within a couple of years.

Senator Webster himself is somewhat of an unknown quantity. Before his elevation to the ministry, he was known only to the public through having survived a legal challenge to his eligibility to sit in Parliament on grounds of alleged improprieties in dealings between a family company and the government. Since coming to office, Senator Webster has made only the odd routine announcement on behalf of the organisations under him. He is not yet known for having a personal interest in science. However green a minister he may appear at the moment to senior Australian scientists, he is no different in pre-knowledge of scientific affairs from either of his Labour predecessors, and given his parliamentary reputation as a diligent worker on committees, Senator Webster should make something of his job in a stable political environment.

#### Labour's heritage

If nothing else, the political awakening

of Australia under Labour has produced a quality of information and debate about science policy which is likely to work to the benefit of Australian science in the long run. On a more universal plane, the thoughtful, informed and voluminous reports issued recently, and the subsequent arguments about the very necessity for a Department of Science in any national government, are worthy of separate analysis outside the election context, for the factors involved for science planning may well prove to have global validity.

On the Australian scene, after five years of almost stand-still operations while awaiting times of enlightenment in science policy, it is sad to reflect that the arrival of these very times has coincided with a period of tight-fisted, inflation-dominated management of the economy. Australian scientists had deserved a better deal from both parties; but perhaps they were simply too nice and soft for too long. □

### Ring the changes

Australian science did not escape the impact of the country's political hiatus, as shown by this summary, covering in order the changes over the period beginning a few days before the election:

- The Science Task Force of the Royal Commission on Australian Government Administration recommended abolition of the Department of Science, and redistribution of its functions among other departments.
- Mr Fraser, the second former Minister for Education and Science in a Liberal Government to become Prime Minister (the first was Mr John Gorton), won an outstanding victory, helped by a long-standing imbalance in size of electorates in favour of the conservative parties—Labour received 43% of votes but gained only 25% of seats.
- The first Labour Minister for Science, Mr Bill Morrison (later Minister for Defence) lost his seat by a handful of votes. The second, and last Labour Minister for Science (and Consumer Affairs), Mr Clyde Cameron, retained his seat and immediately lambasted Mr Whitlam for his leadership (which had led to the demotion of Mr Cameron to the Science portfolio).
- Mr Fraser appointed Senator James Webster, of the National Country Party, as Minister for Science, the portfolio which has the lowest seniority. The Department of Science remained in existence, but without consumer affairs.
- The Department of the Environment, another Labour-initiated de-

partment, was abolished and its staff absorbed and reorganised under the umbrella of the new Department of Environment, Housing and Community Development. This department also embraced the Labour-established Department of Urban and Regional Development. Its Minister is Senator Ivor Greenwood, a hard-line conservative.

- The Secretary of the Department of Science, Sir Hugh Ennor, publicly castigated the Task Force's recommendation that his department be abolished, saying it "lacked credibility" and "questionable logic".
- The Australian Academy of Science was publicly drawn into the debate about the usefulness of the Department of Science through the release of its submission to the Task Force. In appealing with feeling for stability in organisation and financing of science, the Academy concentrated on strengthening the advisory roles to government of the Academy itself and the Australian Science and Technology Council (ASTEC); the Academy mentioned the Department only in passing.
- The CSIRO was returned from a dual responsibility to Labour's Minister for Science and Consumer Affairs and Minister for Minerals and Energy to a single Minister for Science under the Liberals.
- The election by staff of a member of the CSIRO Executive, a mild attempt by Labour at worker participation, was stopped in mid-flight just before nominations closed. Official reason—to give time for re-examination of the implications.

## BRITAIN

# 'Cuts' both ways

*The UK Government last week unveiled its White Paper on Public Expenditure and dismayed practically everyone. Colin Norman looks at the implications for British science*

GRADUAL erosion of government support for so-called big science, such as high energy physics and astronomy, little real growth in other areas of basic research, and a virtual freeze on university appointments. Those gloomy prospects are held out in the White Paper which sets out tentative plans for public expenditure for the next five years, and it represents a painful re-ordering of some of the Labour government's most cherished domestic priorities; it has provoked howls of protest from various sources, including the resignation of a junior minister.

The basic strategy is a desperate attempt to curb the inexorable growth in public expenditure by cutting back heavily in such sensitive areas as education and social services as well as defence. The 'cuts' themselves, which are only being made in the expenditure planned for the next few years and thus aim to prevent the growth in spending which would otherwise have occurred, are designed to have their greatest impact in a couple of year's time: the hope is that their effect on unemployment will be mitigated by the fact that worldwide economic recovery should have filtered through to Britain by then. The proposals should not be taken as Gospel, since they will be reviewed each year and they are unlikely to be put into effect if economic recovery doesn't materialise. But the trends are important, and the dismal state of Britain's economy now seems to make it imperative that some blood will be spilled by the Treasury's knife. For the past couple of years, the government has tried to stave off unemployment by spending heavily on public programmes, with the result that with inflation it has run up a massive national debt, for which it is now forced to make staggering interest payments that could outweigh the savings themselves. Unless the debt and the interest payments can be reduced, politically unacceptable tax increases will be inevitable.

## Science and technology

As far as science and technology are concerned, the government is proposing to hold support for basic research constant until the end of the decade. The amount of money flowing to the research councils would increase mar-

ginally this year and next, and thereafter it would decline slightly. Within those totals, however, there is a very deliberate trend away from support of large, capital-intensive programmes, which means that the Science Research Council (SRC) is in for a lean time.

The White Paper itself states that the government intends "to reduce expenditure in the areas of 'big science' (high energy physics, astronomy and space science) supported by the Science Research Council, in order to sustain the other sciences (including applied science) supported by that council, and to enable the Agricultural, Medical, Natural Environment, and Social Science Research Councils to continue to develop programmes based on social need as well as scientific opportunity."

That policy was laid down about a year ago, when the Advisory Board for the Research Councils, an advisory body which recommends how the science pie should be divided among the research councils, suggested that Britain's limited scientific resources should be used to support more people by giving priority to less capital intensive efforts. The result was that SRC's budget was cut by about 2% in 1975, and a similar reduction is expected for each year until 1980.

The axe will fall most heavily on high energy physics, with two accelerators in jeopardy. The first will be the 5 GeV accelerator, known as NINA, which is located at Daresbury, near Manchester. It is due to cease operation at the end of 1977. The other is NIMROD, located at the Rutherford Laboratory, support for which, according to SRC sources, is likely to be reduced although no execution date has been settled.

As for space science, officials in the SRC suggest that British contributions to the European Space Agency will be reduced in the next few years, but the details have yet to be worked out. And the prospect for astronomy is that

there will be no large new capital projects in the next five years.

The other research councils are likely to fare rather better than SRC. The Medical Research Council's funds will grow this year by about 1.7%, those for the Agricultural Research Council are expected to grow by about 2%, and the others are likely to expand in similar fashion.

## Additional impact

But there are other proposals in the White Paper which could affect the science budget. Proposed support for higher education has been greatly reduced from previous plans. The target now is for a total student population of some 600,000 in institutions of higher education by 1981; until last week, the target was 640,000. One impact of the reduction, according to the White Paper, will be that "there will be little, if any, scope for increasing total staff numbers after 1976-77." That stagnation in university hiring would follow on equally tight period in academic appointments.

Another dismal aspect of the proposals for education is that "capital expenditure on new buildings, . . . will continue to be severely restricted and more intensive use of available premises will accordingly be required". Failure to commit adequate funds to university facilities is indirectly likely to hurt the research councils. There is some fear that the research councils will find themselves paying for equipment and facilities which would normally come from general higher education support funds. Again, the SRC would suffer most.

In another area earmarked for the Treasury's knife, defence research and development, few details have yet been released. But last week Defence Secretary Mr Roy Mason announced that "we are reviewing the future levels of research and development on defence against chemical and biological warfare carried out at the Porton research establishments, with the object of making significant economies". □

Science Budget expenditure analysed by main forms of research and training support (in £ million)

	ARC	MRC	NERC	SRC	SSRC	Total
Research grants and contracts	1.1	8.3	2.2	19.7	3.0	34.3
Research units	1.2	10.6	0.0	0.0	0.5	12.3
Research Council Establishments	3.5	5.9	12.3	34.7	0.0	56.4
Research Council grant-aided institutes	6.7	0.0	1.3	0.0	0.0	8.0
Postgraduate Awards	0.1	1.9	1.5	10.1	3.9	17.5
International subscriptions	0.0	0.6	0.0	24.7	0.2	25.5
Centrally supported schemes and administration	0.5	1.6	1.9	7.2	1.1	12.3
	13.1	28.9	19.2	96.4	8.7	166.3

Expenditure based on 1975-76 figures, excluding expenditure by the Natural History Museum and the Royal Society (£4.6 million).

## EMBO

## Transatlantic translation

*A unique proposal for regulating genetic research in Europe has been developed. Colin Norman reports*

A MECHANISM for controlling potentially hazardous genetic manipulation experiments in Europe will soon be proposed by the European Molecular Biology Organisation (EMBO). A special EMBO committee, consisting of 10 leading European biologists, agreed at a meeting last week that regulations already drafted to control such research in the United States are more than strict enough to protect public health, and a statement expected next week will recommend that they should be implemented in Europe.

Although EMBO is purely an advisory body, with no authority to regulate research, its recommendations will probably carry considerable weight. Its proposals are especially relevant for smaller countries which are unlikely to establish their own mechanisms for controlling genetic manipulation experiments, and, if implemented, they would set up a unique arrangement for regulating scientific research on an international basis.

The experiments involve the use of

newly discovered enzymes to transplant genes from virtually any living organism into viruses or bacteria, and the proposed US regulations, drafted last December but not yet finalised, would outlaw some of the more hazardous experiments and require that others be performed under special safety conditions. In particular, they specify that several types of experiments should only be carried out by transplanting genes into bacteria or viruses which have been genetically crippled to render them incapable of surviving outside an artificial laboratory environment.

Some members of the EMBO committee considered those regulations stricter than necessary to protect public health, but agreed that not all European countries should repeat the tortuous process of drafting their own regulations. So, with the proviso that the US controls are not made yet more stringent, the committee recommends that each country should establish its own national committee to vet applications for research grants involving gene transplant experiments and decide whether they conform to the US regulations. EMBO also suggests that an international committee, possibly under the auspices of the European

Science Foundation, should deal with problem cases.

One possible problem area involves the certification of crippled strains of bacteria or viruses. The US regulations detail the criteria by which modified microorganisms should be judged sufficiently crippled for use in gene transplant experiments, and one strain of bacterium recently produced at the University of Alabama is expected to meet the criteria. Although strains produced in the USA will be made available throughout the world, other modified strains may be produced in Europe.

National committees would be responsible for certifying whether or not such strains meet the criteria, but the EMBO committee is willing to offer its advice in specific instances. It has also offered to advise European governments and individual scientists about technical aspects of genetic manipulation research and safety precautions, a service that could be particularly useful for countries with small numbers of researchers.

While some European countries, including Britain, are already developing their own regulations and are unlikely to adopt the US version lock, stock and barrel, the idea of an international committee to discuss problem cases is likely to have considerable support throughout Europe. □

## SOVIET JEWRY

## Tailoring tactics to suit

*Vera Rich reports from Brussels, where the Second World Conference of Jewish Communities on Soviet Jewry was held last week.*

THE problem of Jewish scientists and other academics wishing to emigrate from the USSR to Israel continues to arouse debate. So too does the degree to which scientists should commit themselves to helping and campaigning for their disadvantaged colleagues. At the conference on World Jewry, a Special Commission on Science and the Humanities, chaired by Professor Yuval Neeman of the Israel Committee for Soviet Jewry, resolved to set up an International Federation of Concerned Scientists. Professor Denis Schiame of Oxford explained that its purpose would be to gather and disseminate information and to coordinate the activities of its affiliates from all countries where committees already exist or are being formed.

But the precise policy to be followed provoked lively discussion. A large

contingent, headed by the Nobel Prize-winner for Physics Dr Polykarp Kusch, stressed the importance of using international scientific cooperation agreements, which at present tend to favour the USSR, to exert pressure on behalf of disadvantaged scientists. The case of *refusnik* Aleksandr Lerner and the Fourth International Conference on Artificial Intelligence was cited: his attendance and active participation was secured after pressure was applied that threatened to change the venue from Tbilisi to a location outside the Soviet Union. But Dr Gabor Dessau of Pisa stressed the beneficial effect which foreign contacts could have on Soviet scientists who, he said, are often themselves secretly in favour of a greater freedom of movement. The idea of a total boycott of Soviet science was ultimately firmly rejected. It was agreed that the tactics to be used should rather be tailored to each specific problem as it arose.

Golda Meir referred to the "education tax" on Soviet academics, and cast doubt on the possibility of a mass

emigration of scientists seriously depleting the Soviet Union: dismissal was the immediate consequence of a visa application, she argued, so that "their brains are drained already". Aleksandr and Evgenii Levich, referring to the problem of classified information, recalled that their father, Academician Venyamin Levich, had been promised an exit visa at the end of 1975, when his knowledge would no longer be "classified", this promise was later withdrawn.

Mention was also made of Soviet delegations to international conferences which regularly consisted of "representatives" chosen for their standing with the authorities and not their scientific knowledge or relevance.

The absorption of scientists from the Soviet Union into the Israeli economy, although not a direct concern of the conference, was discussed in various formal and informal gatherings. The current policy, said Dr. Eliezer Rafaeli, Rector of the University of Haifa, is to absorb them into existing institutions, establishing new departments or laboratories if necessary, but not setting up new universities. □

## MEDITERRANEAN

## Treaty in store

*Sixteen Mediterranean states meeting in Barcelona earlier this month adopted a treaty on the protection of the Mediterranean against pollution which augurs well for a future "action plan". Robert Allen reports*

AN interval of only two years separates discussion of the first principles of the Mediterranean anti-pollution treaty and its signature. There are two main secrets of this success, which comes despite the sharp political differences of the participants (Spain, France, Monaco, Italy, Malta, Yugoslavia, Greece, Turkey, Cyprus, Syria, Lebanon, Israel, Egypt, Libya, Tunisia and Morocco).

One reason is the existence of a regional scientific and resource management body, the FAO's General Fisheries Council for the Mediterranean (GFCM). Arabs and Israelis, Greeks and Turks, have worked together on the Council for some years now, and are used to each other at the scientific and technical levels of government. Secondly, there is the United Nations Environment Programme (UNEP), which can not only bring governments together, but can locate, harness and coordinate legal, scientific and planning expertise scattered amongst numerous research institutes throughout the Mediterranean area and within the UN's many (often competing) specialised agencies. It is this capability which is the key to an ambitious "action plan" being developed by UNEP and the Mediterranean coastal states and involving co-operative action on four related fronts: scientific, legislative, institutional, and planning.

UNEP has set up seven research projects\*, to run initially for two years, in order to establish a basic pollution profile of the Mediterranean. Each project will employ a network of laboratories, coordinated by UNEP, appropriate specialised agencies and a designated national research centre. So far, eight countries (Algeria, Cyprus, Israel, Italy, Lebanon, Malta, Spain and Yugoslavia) have nominated a total of 19 laboratories. Other countries are expected to nominate laboratories soon.

Where necessary, UNEP will provide

analytical equipment and training in its use. It will also fund a common maintenance service to avoid long gaps in coordinated data collection. The International Atomic Energy Agency's Marine Radiation Laboratory in Monaco will help ensure compatibility of results by setting monitoring standards and providing intercalibration services.

The entire scientific programme is expected to cost some \$10 million (almost \$2 million from UNEP, and about \$8 million from participating governments). For this, the coastal states of the Mediterranean will obtain a reliable pollution profile of the marine environment, derived from simultaneous measurements of pollutant levels in the same taxa, at a large number of sampling points, with the same instrumentation. There will be a comprehensive range of strictly comparable national data from the entire region instead of the present hodgepodge of hard facts, circumstantial evidence and anecdote. Without this data, planning the rational exploitation of the Mediterranean commons would be virtually impossible. It would also be extremely difficult to maintain the present rapid legislative progress when more contentious issues are tackled.

The treaty consists of a convention supported by two protocols (one on dumping, the other on cooperation in the event of pollution emergencies, such as oil spills), but the next one to come, controlling pollution from land-based sources like rivers and coastal outfalls, is the one most likely to founder if the data base is insecure. Mediterranean nations will be confronted with the substantial economic differences between north and south and difficult trade-offs between one sector of a national economy and another. With non-Mediterranean up-river states also involved, a reliable pollution profile will be essential.

Much of the additional promise of the action plan lies in its integrated planning effort, which aims to help governments develop the shared resources of the Mediterranean in a sustainable fashion. Permanent channels for co-operative planning are being set up, based on a conception of the Mediterranean Sea area as an ecological unit. It sounds slightly over ambitious, but as Peter Thatcher, Director of UNEP's Geneva office, remarked, the adoption of the treaty demonstrates that the "political leaders of the Mediterranean have overcome the divisive issues of today in order collectively to preserve their common heritage and discharge their responsibilities to future generations". □

## CANADA

## New breed

*Canada's space programme was back on the nation's front page and television screens again briefly last month when the United States launched her neighbour's latest satellite, the CTS (communications technology satellite). David Spurgeon reports from Ottawa*

CANADA'S space programme has been one of her most successful scientific and technological ventures. Alouette I, the first satellite designed and built by a nation other than the United States or the Soviet Union, was still sending back useful ionospheric data 10 years after its launch in 1962. Three other Canadian made scientific satellites successfully followed that (Alouette II, ISIS-I, ISIS-II), and two domestic communications satellites (Anik-I and Anik-II) both continue to serve the country's communications needs, the former being the first such satellite to be used in a geostationary orbit.

Canada's vast distances, severe climate and scattered population have all meant that its space program has been oriented toward electronic methods of communication. The new CTS satellite follows this pattern. It is considered the forerunner of a new breed of high-powered communications satellites that will be able to transmit directly to small, low-cost earth stations sometimes in remote and otherwise inaccessible locations.

The CTS is in fact the most powerful communications satellite now operating, by virtue of three major subsystems. One of these is the travelling wave tube amplifier: its power output of 200 watts operating at an efficiency of 50% compares with the six watts at 30% efficiency of the current generation of tubes used in communications satellites. A pair of lightweight, extendable antenna arrays carries enough solar cells to provide one kilowatt of power to the satellite; and a three-axis stabilization system, employing a fixed momentum wheel and hydrazine gas thrusters, maintains the aiming accuracy of the antenna and keeps the spacecraft oriented toward the sun (rather than letting the spacecraft spin as is usual) to ensure full use of solar power.

The CTS satellite is able to employ high power transmitters because it operates in a new frequency band of 12-14 gigahertz allocated for broadcast satellites. Current systems operate in the 4-6 gigahertz band, which is shared by other types of system on the ground. For this reason, satellite power levels must be limited to prevent interference

\*The 7 projects include: (1) baseline studies and monitoring of oil and petroleum hydrocarbons in marine waters (coordinated by UNEP and the Intergovernmental Oceanographic Commission, IOC, of UNESCO), (2) baseline studies and monitoring of metals, particularly mercury and cadmium, in marine organisms, and (3) of DDT and other chlorinated hydrocarbons in marine organisms—both coordinated by UNEP and the GFCM.

## USA

with ground systems: previously this was a major factor dictating the use of large and expensive ground antennas.

Antenna diameters for the CTS range from 32 inches to 30 feet. The only other satellite designed to transmit high-quality colour television to small, simple ground stations is the ATS-6 (applications technology satellite), which was launched in 1974 and is now being used by the government of India to relay educational programs to isolated villages. The ATS-6 must use a 30-foot antenna, and its effective radiated power is 53 DBW (decibel watts), whereas CTS's is 59 DBW.

Canadian groups have designed 26 experiments for the CTS, to begin in May. They include:

- One-way video and two-way audio transmission to provide continuing medical education for doctors in remote areas.
- High-quality telephone links to and from remote camp-sites in the James Bay area, where a power dam is being built.
- Curriculum-sharing between Carleton University, Ottawa, and Stanford University, California, using a digital video compression technique.
- Provision of computer-communications networks for native peoples in Canada's isolated northern regions, and evaluation of the potential.
- Linking of two francophone communities in different parts of Canada—Zenon Park, in Northern Saskatchewan, and a community in Quebec—for interchange of cultural and educational programs via two-way audio and video links. Other projects involve propagation measurements, a system for sharing telephone channels, and a fast frequency-shift keying system for high-speed digital data transmission.

The Canadian Broadcasting Corporation will try to demonstrate direct television reception from the satellite using simple, domestic-type equipment from laboratories in Japan and perhaps Europe. The satellite is also to be used for remote coverage of the 1976 Olympic Games equestrian competition at Bromont, Quebec. The signals would help in assessment of portable ground stations and reception and transmission from large, populated areas.

The United States and Canada will share equally in experiment time during the satellite's lifetime, using it on alternate days. If the experiments go as planned, the remote areas of many parts of the world—as well as Canada and the United States—may soon benefit from a multitude of communications services presently not economically feasible using conventional ground-based methods. □

With only one dissenting voice—that of Senator John V. Tunney of California—a subcommittee of the Joint Committee on Atomic Energy has produced a report giving full support to the liquid metal fast breeder reactor (LMFBR) programme and suggesting that “the time has come to end the discussion over whether or not [the United States] should have a breeder research and development program. Rather, national attention should be turned toward solving the outstanding problems associated with the program and its eventual commercialisation.”

Senator Tunney identifies what he describes as a failure to deal adequately with many fundamental issues and questions surrounding the breeder programme, and in particular he objects to the subcommittee's attempts to see discussion of the programme stifled. That would be an abdication of responsibility, he says, as well as inconsistent with the subcommittee's conclusion that the building of the Clinch River Breeder Reactor in Tennessee would not represent “an irreversible commitment to commercialisation.” (The Clinch River reactor, a 350-MW demonstration plant, is at present expected to be completed in 1983, at a cost of about \$2,000 million.)

The subcommittee, chaired by Congressman Mike McCormack of Washington, heard four main objections from opponents of the breeder reactor programme. It was argued that development costs would turn out to be prohibitive, that estimates by the Energy Research and Development Administration (ERDA) of indigenous uranium resources were too conservative, that energy demand would not grow as fast as projected, and that problems like plutonium toxicity and waste management would prove to be insoluble.

The subcommittee brushes those objections aside. One of its chief arguments in support of the LMFBR programme, for example, hinges on the suggestion that conventional reactors could start to run out of domestic supplies of uranium early in the twenty-first century, and unless the plutonium-producing capability of the breeder reactor is developed, the nuclear industry could grind to a halt. ERDA estimates, in fact, that there are about 3.6 million tons of uranium, available at a cost of less than \$30 per pound, in the United States. That is sufficient to guarantee a lifetime's fuel only to those reactors expected to be built before the mid-1990s.

● After 18 months of uncertainty, the future of Sacramento Peak Solar Observatory in New Mexico seems assured now that the National Science

Foundation (NSF) has agreed to provide \$1.45 million “to maintain the observatory at a productive level”. The US Air Force, which has operated the observatory since 1952, will, however, still maintain a presence, and provide some of that money—\$700,000 in the first year of the new arrangements, and \$450,000 in the second. After that it is not clear what, if any, contribution it will make, or how the NSF will make up the shortfall.

Even with the Air Force chipping in a further \$250,000 for the salaries of those remaining and \$250,000 in grants, the observatory will, according to its acting Director, Dr Richard Dunn, have to sustain cuts of 15% in its present budget of \$2.2 million and 27% in its staff of 63, as from June 30.

The new funding scheme was hammered out by a committee chaired by Professor Martin Schwarzschild of Princeton University, and the NSF has now formally accepted it. Agencies such as NASA and ERDA were also involved in the discussions: NASA already has a group working at Sacramento Peak, and the observatory's research programme contains sufficient plasma physics, hydrodynamics and so on for ERDA to find it relevant to its own fusion research activities. (In fact at one time it seemed as if ERDA might pick up the tab for the observatory itself.) As the Air Force's contribution diminishes, the NSF will undoubtedly be looking to other agencies to stump up some of the extra money needed. The matter awaiting resolution now is precisely how the observatory will be managed once the Air Force relinquishes its overall responsibility.

● The fifth annual report to Congress on marijuana and health shows that more than half of those between 18 and 25 have used the drug at some time, and that “what was once clearly statistically deviant behaviour has become the norm for this age group.” The report also says that the correlation with level of education has now all but disappeared. The authors of the report, produced by the Department of Health, Education and Welfare, say, however, that the drug's long term effects are not yet properly understood. Another aspect of the drug's use seems to have altered: whereas users of marijuana were once less likely than non-users to consume alcohol, they now seem more likely to do so. “Frequently the two drugs are used simultaneously,” says the report, “a combination that may be more hazardous than either used alone”.

## IN BRIEF

**Soviet treaty call**

The Soviet Union called for an early treaty covering the development of weapons "still more pernicious" than nuclear arms when the 15th session of the Committee on Disarmament opened in Geneva last week. Delegates from 30 nations, urged to adopt a Soviet draft agreement on the issue, remained in the dark about the precise nature of the doomsday weaponry hinted at, but the Soviet delegate stressed that the reference was not to environmental or weather modification techniques, on which the USSR and USA are expected to approve a draft ban treaty by the end of the 1976 conference. The USSR also renewed its call for a committee of nuclear and non-nuclear states to discuss a comprehensive test ban treaty.

**Nuclear safety**

Three nuclear scientists who recently quit responsible positions with General Electric in a stand against the US nuclear programme last week told a

Joint Congressional Committee that many US nuclear installations should close because they are below Federal safety standards. In Europe, the Nuclear Energy Agency of the Organisation for Economic Cooperation and Development has meanwhile calculated that ambient radiation levels would increase by about 6% if electricity production needs were met entirely by fission reactors—an increase reckoned to pose less overall risk than hazards associated with existing methods of production. News has also come of a similar assessment attempted in the USA 20 years ago when, between 1945 and 1947, the US authorities secretly injected 18 terminally ill people with doses of plutonium equivalent to levels that would normally be received by plutonium workers in 100–800 years. Three of the human guinea pigs are still alive.

**Nuclear arms**

As a safeguard against possible terrorist attempts to seize nuclear fuel in Britain, a Bill presented to Parliament

last week extends the authorisation whereby security forces guarding UK Atomic Energy Authority establishments carry firearms to cover other nuclear installations housing "accessible" nuclear materials and UKAEA police accompanying fissionable material in transit. MPs unhappy about the Bill have already promised action at its second reading.

**EEC fish limits**

In a move anticipating an extension of international fishing limits during next month's Law of the Sea conference in New York the European Commission has called for the setting up of a 200 mile community limit around EEC states. Under the proposals, presented in Brussels last week, each nation will retain exclusive rights over a 12 mile strip within the wider community zone surrounding its own territory. A scientific and technical committee would advise fisheries officials of the Nine on necessary conservation measures before catch quotas and share-out proportions are drawn up for Community waters.

THE Delaney Clause of the Food Additives Amendment forbids the use of food additives that are carcinogenic, or animal feed additives that are carcinogenic and leave residues in the meat. The bureaucratic axe is being sharpened for bacon. On January 19 this year the FDA banned Red No. 2 (Amaranth), and on January 7 announced a forthcoming ban on diethylstilbestrol (DES) in beef production at an estimated cost of \$503 million annually to consumers. Representative James Delaney, evidently not satisfied with the effectiveness of his clause, introduced special and apparently superfluous legislation (HR 9837) for the latter purpose. Not to be outdone, the National Cancer Institute (NCI) recently warned pregnant women against eating beef liver.

Herbst and co-workers reported in 1975 on "benign alterations of the genital tract", especially abnormal vaginal mucosa, in a series of 110 females who had been exposed *in utero* when their mothers received DES prescribed during pregnancy. No cases of cancer were observed, although vaginal adenosis, which is suspected by some authors of being a "precancerous lesion", occurred in 35% of cases. The absence of cancer fits Herbst's earlier observation that the risk of cancer may be considerably less than 4 cases for 1,000 exposures. However, the dosage of DES received by the pregnant women is of extraordinary interest; it was

increased stepwise from the sixth to the 35th week for a total of 12.3 grams and a daily average of 60 mg per patient.

In other investigations, the "DES" content of liver from implanted cattle

**Delaney's year****THOMAS H. JUKES**

was found to be 0.12 parts per 10<sup>9</sup>, so that 12.3 grams would be present in 100,000 tons of contaminated liver. The total amount of beef liver produced in the USA is about 140,000 tons per year. More than a century of beef production would have been needed to supply DES in beef liver to the women in the study, none of whom produced offspring who deve-

loped cancer. This assumes that the "residues" are actually DES, which is now known not to be the case. No wonder Mr Delaney is impatient for his ban; he may be worried that common sense will take over.

In a speech in the Senate, calling for a ban on DES in beef production, Senator Edward Kennedy said the ban had been requested by Dr Frank Rauscher, Director of NCI, and that public funds of about \$700 million annually were furnished to NCI, which provides scientific guidance to him on questions of cancer. Perhaps a small allocation, say \$100, should be set aside for the purchase of a pocket-size calculator to compute the actual risk from a daily intake of one molecule of DES, which NCI scientists have testified might cause cancer. Part of the \$100 could be used for a textbook on nutrition, so that NCI could learn that beef liver is the best dietary source of folic acid, and that folic acid deficiency is common during pregnancy.

Indeed, folic acid was discovered, as a result of the anaemia in pregnant women caused by its deficiency, by Dr Lucy Wills in 1931. The deficiency is still prevalent throughout the world, as noted by the World Food Congress in Rome, 1973. A continuation of the dietary lack of folic acid in pregnancy will be aided by NCI's recommendation against consuming beef liver. The protective effect against cancer of this recommendation seems dubious.

## Receptor maps for viruses

from Arie J. Zuckerman

VIRUSES are not motile and they rely on such processes as diffusion and transport within body fluids to bring them into contact with susceptible cells. The critical step in successful viral infection is the susceptibility of cells, and the means by which viruses are incorporated into host cells has been the subject of much research. The susceptibility of cells is usually determined by early steps in virus-cell interactions which include the attachment and penetration of the virions and the release of the viral nucleic acid in the cells. With some animal viruses such as the influenza viruses and some of the picornaviruses such as Cocksackie virus and poliovirus, attachment is associated with the presence of specific receptors for viral adsorption on the cell surface, but whether receptors are required for all viruses is not known. The presence or absence of receptors on the cell surface depends on several factors which include the particular type of tissue or organ, stage of maturity, changes in the physiological environment such as culture *in vitro*, and genetic factors involving cellular rather than immunological mechanisms.

On the other hand, there are also viruses, including arboviruses, poxviruses and herpes viruses, which will grow in a variety of cell types, and therefore there appears to be little specificity about the adsorption process of such viruses. In these instances a mechanism such as phagocytosis or viropexis may be important in the incorporation of virus into susceptible cells. Another mode of viral entry entails fusion of the viral envelope with the plasma cell membrane. Fusion takes place by a process of alignment of the two membrane structures, followed by the formation of a channel between virus and the cytoplasm through which the nucleocapsid passes into the cell. A more recently described mode of entry of virus into the cell is by a process of membrane fission rather than by viropexis.

Lonberg-Holm and his colleagues point out on page 679 of this issue of

*Nature* that the specific receptors for several nonenveloped viruses are present on cells in limited number and therefore these can be saturated with excess virus. They report results of experiments in which the attachment to HeLa cells of highly purified virus particles radiolabelled with carbon, sulphur and phosphorus was measured. Four receptor families were found. The first family contains receptors to human rhinovirus types 2, 1A and 1B. The second family contains receptors to human rhinovirus type 14 and Cocksackie A21 and a number of other rhinovirus serotypes. The third family contains poliovirus, and the fourth contains Cocksackie B3 and probably the other Cocksackie B serotypes as well as several serotypes of adenovirus. It is reasonable to consider that receptor specificity influences virus tropism in the tissues thereby contributing to the patterns of pathogenesis of virus infections. An example is the finding that Cocksackie A21 shares receptors with a large number of human rhinoviruses and this may be related to the ability of Cocksackie A21 to cause coryza. Another example is that both Cocksackie B viruses and adenoviruses produce persistent infections in HeLa cells cultured in the presence of human serum.

Burrows pointed out, however, (*Microbial Pathogenicity in Man and Animals*, 303-332, Cambridge University Press, 1972) that many investigators have attempted to associate characteristics of virus growth and behaviour *in vitro* with virus behaviour in the intact host. Characteristics such as tissue receptor activity, the production of or susceptibility to interferon, growth and cytopathogenicity in cultured cells and virulence for laboratory animals have all been linked to differences in virulence for the normal host. The determinants of virulence, although clearly related to those of virus growth, differ markedly between viruses and indeed between strains of the same virus. It was Chaproniere and Andrewes (*Virology*, 4, 351; 1957) who

stressed that the ability of many viruses to grow in monolayer cell cultures derived from tissues or hosts which are not susceptible to the virus, limits the usefulness of such cultures for basic studies of susceptibility as they relate to the intact host.

It is generally considered that the morphological and functional capacity of cells maintained in organ culture may offer a system for cultivating viruses which closely simulates conditions in the intact host. Examples of the specificity of the effect on the target organ and differential susceptibility of different hosts are found within each class of viruses and organ cultures have reproduced many, but not all, of the phenomena of specificity observed in the intact animal. Extension of the studies reported by Lonberg-Holm and his colleagues and the precise identification of the properties of the specific virus receptors may provide a key to the understanding of viral pathogenesis and perhaps also to the prophylaxis and even therapy of virus infections. □

### A hundred years ago

After discussing the results obtained by Stoney, Thompson, and Clerk-Maxwell, mainly derived from the properties of gases, I come to the conclusion that in the present state of our knowledge the best approximation that we can make to the size of the ultimate atoms of matter is the mean of their determinations. I adopt for simplicity  $\frac{1}{1000}$ th of an inch as the unit of length, and  $\frac{1}{1000}$ th of an inch cube, or  $\frac{1}{1000000000}$ th of a cubic inch, as the unit of volume. In the case of a true gas the number of atoms in the length of  $\frac{1}{1000}$ th of an inch at 0 °C, and a pressure of one atmosphere, would be 21,770, and hence, in  $\frac{1}{1000}$ th of an inch cube, about 10,320,000,000,000.

From *Nature*, 13 (February 24), 332; 1876.

# Charm: what else could it be?

from W. T. Toner

THE peculiar bubble chamber event cautiously put forward by the European "Gargamelle" collaboration as possible evidence for charm now has two companions (Deden *et al.*, *Phys. Lett.*, **58B**, 361; 1975; Bleitschau *et al.*, *Phys. Lett.*, **60B**, 207; 1976), and four similar events have been found in pictures from the fifteen foot diameter bubble chamber in the neutrino beam at the Fermi National Accelerator Laboratory (FNAL) near Chicago. One event could always have been a freak chance but not three, still less seven. A new physical effect has been dis-

covered.

All seven events are of the type shown in Fig. 1, where an unseen neutrino from the beam interacts with a nucleus in the chamber liquid to produce several particles one of which is, as usual, a negative mu-meson. Two of the other particles are uncommon: a positron and a neutral V particle, so called because of the pattern made by the tracks from its decay a few centimetres from the main interaction in which it was produced. The Vs are members of the group of "strange" particles. The positron signals the

weak (radioactive  $\beta^+$ ) decay of some particles whose lifetime must be extremely long on the subnuclear time-scale as otherwise the decay would be strong. But since the positron appears to come directly from the interaction point the decay must take place within a millimetre and the lifetime must therefore be significantly less than that of the Vs. No known particle has a lifetime in this range although some of the hypothetical charmed particles should have, and should frequently involve strange particles in their production and decay.

**Fig. 1** *a*, One of a stereoscopic set of photographs of an event in the Gargamelle bubble chamber at CERN. Only charged particles leave tracks. The neutrino beam enters from the bottom of the picture. *b*, Sketch of the tracks involved in the event. (Stereoscopic reconstruction eliminates the others.) The mu-meson ( $\mu^-$ ) leaves the chamber without interacting; the positron ( $e^+$ ) has a rapidly changing curvature and is associated with electron-positron pairs; the  $V^0$  itself leaves no track, what is seen are the two tracks from its decay. The other two particles emitted in the primary interaction are unimportant to the interpretation.

Fig. 2 A two-dimensional pattern in charge-strangeness space. There are three particles at the origin and one at each of the six corners.

What is charm or for that matter, strangeness? Both are properties akin to electric charge which are supposed to be possessed by elementary particles in quantities of  $0, \pm 1 \dots$  units. Everyday particles like the proton and neutron have charm and strangeness zero. Like electric charge, the total amounts of charm and strangeness must be conserved in all strong (nuclear) or electromagnetic interactions but unlike electric charge, neither need be conserved in  $\beta$ -decay or other weak processes.

Strangeness has been an accepted fact for more than 20 years. The concept was invented in 1952 by Pais (*Phys. Rev.* **86**, 663; 1952) to explain why the V-particles discovered by Rochester and Butler (*Nature*, **160**, 855; 1947) should be copiously produced and yet decay only slowly. Copious, strong, production of pairs having opposite and mutually cancelling strangeness would be allowed; but all particles die alone, and the metamorphosis from strange back into ordinary matter could take place only slowly, by weak decay.

The idea was enormously successful and is essential to the  $SU_3$  or Quark classification scheme which fits all particles known up to a year ago into triangular and hexagonal patterns such as that in Fig. 2 and which interrelates their properties in like manner. Electric charge is one axis of the pattern and strangeness the other. Charmed particle production and decay would obey similar rules and charm would add a third dimension to the patterns, as in Fig. 3. The most obvious experimental consequence would be the existence of the many new particles in the third dimension, with charm  $\pm 1, \pm 2$ , whose decays into uncharmed matter would be weak, and of a few new particles composed of pairs of oppositely charmed quarks with nett charm zero. These might or might not have long lifetimes.

In the case of charm, the theory came before the experimental evidence. It was invented by Bjorken and Glashow in the spirit of exploring the consequences of adding a new dimension to the patterns (*Phys. Lett.*, **11**, 255; 1964). Charm remained a theoretical toy which predicted too many new effects until the Gargamelle collaboration found another new class of neutrino interactions in which the neutrino did not turn into a charged mu meson as usual, but retained its identity (Hasert *et al.*, *Phys. Lett.*, **46B**, 138; 1973). It was difficult to reconcile this observation with the known absence of equivalent processes among strange particles without invoking charm and the elegantly constructed cancellation mechanism of Glashow, Iliopoulos and Maiani (*Phys. Rev.* **D2**, 1285; 1970) which linked charm with strangeness. A consequence was that this link should show up by the frequent appearance of strange particles in charm non-conserving weak decays and in the weak production of single charmed particles by neutrinos.

In the summer of 1974, charm was an exciting theoretical conjecture. Enthusiasts, such as Iliopoulos, were willing to wager a case of wine on its imminent discovery (*Proc. XVII Int. Conf. on High Energy Physics*, (edit. by Smith, J. R.) III-100 SRC, 1974), though others remained sceptical. A few months later the  $\psi$  (or J) particles were discovered and found to have many of the properties forecast for the charm = 0 or "hidden charm" members of the family. Although alternative explanations for the  $\psi$ s were and are still tenable it seemed to most that definite proof of the existence of charm was very near. That seems even more surely the case now, but the last stages of the search have proved difficult.

The only direct evidence other than the  $\psi$ s has come from experiments with neutrinos, which interact so rarely that their mean free path is hundreds of Earth diameters. Any apparatus designed to observe large numbers of interactions is necessarily massive, and is clumsy in even the most skilled hands. A group using a detector weighing several hundred tons composed of iron slabs interleaved with scintillation counters and spark chambers reported two "di-muon" events at the 1974 conference (see C. Rubbia, *loc. cit.* IV-119) and were later able to show with many more events that weak decays were taking place among the products of neutrino interactions at a rate which could not be explained by any known particle (Benvenuti *et al.*, *Phys. Rev. Lett.* **35**, 1199; 1975). But although many events had been seen and the effect was by then undisputed,

Fig. 3 A three-dimensional pattern in charge-strangeness-charm space. There are four particles in the centre, at the origin, and one at each of the twelve corners.

charm was a very plausible rather than a necessary interpretation.

The new bubble chamber events clearly establish the expected link with strangeness and set loose bounds on the lifetime of the new particles but even their graphic detail is insufficient to determine the precise nature of the interaction because in each event there are two neutrinos whose energies are unknown: the one which initiated the event and a second one emitted in an unknown direction from the  $\beta$ -decay. Without mass values and decay schemes one cannot begin to construct the pattern to see if it fits with charm, let alone make the sophisticated tests needed to prove that it solves the theorists' problems.

The next step is to find cases where the decay does not involve a second neutrino in order to establish the masses of the supposed charmed particles. Events of this type will be harder to identify because they will also lack the positron which singles out the weak decay. One such event with other strikingly characteristic features of charm has been reported (Cazzoli *et al.*, *Phys. Rev. Lett.* **34**, 1125; 1975) but subsequent experiments with greater sensitivity have failed to reveal others of the same kind. It may be necessary to collect many events with less obvious distinguishing features and search in the mass distributions of different combinations of supposed decay products for narrow peaks, which would be alternative evidence for the existence of particles with unusually long lifetimes. This is a sure and well-timed method of finding new subnuclear states although it takes time and patience. Meanwhile, the commonest answer to the question what else it could be is: something else very like charm.  $\square$

## Bacterial cytochromes *c* structure

from D. R. Thatcher

COMPARISONS of protein structure at the three-dimensional level are able to distinguish similarities, and therefore probable evolutionary connections, which would not be convincing at the amino acid sequence level. The best example of the application of this approach is the discovery of the characteristic super-secondary structure of enzymes which bind dinucleotides. Now that the X-ray crystal structure of four different types of cytochromes *c* is known, a detailed three-dimensional comparison has been made (Dickerson, Timovich and Almasy, *J. molec. Biol.*, **100**, 473; 1976), and the evolutionary implications discussed.

Eukaryotic cytochromes *c* form a clearly homologous group of proteins, both at the three-dimensional level (horse, bonito and tuna crystal structures are available and show an almost identical folding pattern) and at the amino acid sequence level (sequences from over 70 different eukaryotes have similar lengths and have a minimum of 25% of their sequence identical). By contrast bacterial cytochromes *c* show a formidable variation in chemical structure and physical properties; a reflection of the extreme antiquity and diverse modes of energy metabolism in this group of organisms. Dickerson *et al.* have compared the already published three-dimensional structures of tuna cytochrome *c* and *Rhodospirillum rubrum* cytochrome *c*<sub>2</sub> (a purple non-sulphur bacterium) with the new structures of cytochrome *c*<sub>550</sub> from *Paracoccus denitrificans* and *Pseudomonas aeruginosa* cytochrome *c*<sub>551</sub>.

All four cytochromes differ significantly in the length of their polypeptide chains (cytochrome *c*=103 residues; *c*<sub>2</sub>=112 residues; *c*<sub>550</sub>=134 residues and *c*<sub>551</sub>=82 residues).

Although the variation in amino acid sequence between these cytochromes is large (in the case of *c*<sub>551</sub> primary structural similarity can barely be discerned), the overall folding pattern around the haem prosthetic group is recognisable in all four cytochromes. The bacterial cytochromes mainly differ from the tuna cytochrome *c* by additional residues in the external loops around positions 53 and 75 (cytochrome *c* numbering) whilst *c*<sub>550</sub> also has an insertion in a loop in the 20's region and also possesses a 15-residue tail. The small size of *c*<sub>551</sub> is due to a massive deletion (39–58 in tuna cytochrome *c* numbering) of a loop at the bottom of the molecule. The folding of

the rest of the molecule is however conserved and *c*<sub>551</sub> is clearly related to the other cytochromes.

Dickerson *et al.* go on to propose that this same deletion probably occurs in cytochrome *f* (involved in algal photosynthesis), *c*<sub>555</sub> (a photosynthetic cytochrome of the green sulphur and purple sulphur bacteria), *c*<sub>553</sub> (from the sulphate respirer *Desulphovibrio*) and the *c*<sub>s</sub> of *Pseudomonas mendocina*. This assumption makes the sequence alignment of all these cytochromes with eukaryotic cytochrome *c* much more credible and suggests the existence of a large evolutionarily homologous group of cytochromes whose members all possess a similar polypeptide folding pattern (the cytochrome fold). It is tempting to assume that the different electron transport pathways in which these diverse cytochromes operate also have an evolutionary connection and Dickerson *et al.* explore the way in which their data can be interpreted in terms of the development of bacterial energy metabolism.

Dickerson *et al.* have drawn attention to the remarkable sequence work of Ambler and colleagues (Ambler *Handbook of Biophysics and Molecular Biology*, 1976; Ambler, Meyer and Kamen, *Proc. natn. Acad. Sci. U.S.A.*, in the press) on other cytochromes *c*<sub>2</sub> in the purple-non sulphur bacteria. Some of these *c*<sub>2</sub>'s align almost exactly with eukaryotic cytochrome *c* (*Rhodococcus vannelli*, for example) whilst other *c*<sub>2</sub>'s have, like *Paracoccus* *c*<sub>550</sub>, additional residues around residues 20, 50 and 70 (such as *Rhodospseudomonas capsulata*). In fact this range of structural variation within *c*<sub>2</sub> has now been extended by the finding of Ambler and Meyer (personal communication) that the *c*<sub>2</sub> of *Rhodospirillum tenue* has the massive deletion characteristic of *c*<sub>551</sub>. We are then left with the intriguing observation that the range of structural variation within cytochromes *c*<sub>2</sub> of the purple non-sulphur bacteria is as great as in all other cytochromes possessing the cytochrome fold.

Dickerson *et al.* consider that the main evolutionary implication of this homology is that bacterial and eukaryotic respiration arose from the dual function cyclic photophosphorylation and respiratory electron transport chain of purple non-sulphur bacteria by loss of the photosynthetic capability.

This interpretation confirms previous schemata for prokaryote evolution (such as Hall, *J. theor. Biol.*, **30**, 429–454, 1971 and in the *Evolution of Bioenergetic Processes*, edit. by Broda, E., 1975) but the evidence really hinges on the question of whether the different cytochromes *c* are evolutionarily representative of the whole electron transport pathways of which they are

members or whether this phylogeny has been muddled by genetic transfer. Physiological studies within the purple non-sulphur bacteria, which have representatives of each major type of cytochrome should resolve this question to some extent. Nevertheless, the purple non-sulphur bacteria could be the key to our understanding the molecular evolution of cytochrome *c*.

## Palaeomagnetic diversity

from Peter J. Smith

PALAEOMAGNETIC studies were begun early this century in an attempt to determine the characteristics of the Earth's magnetic field before the few hundred years of direct observation. By the 1960s, however, they had come to be associated more particularly with the growing evidence in favour of continental drift and seafloor spreading. With the now-widespread acceptance of the principal tenets of the new global tectonics, there has been a tendency for palaeomagnetism to revert more frequently to its original aims, although it is still used widely to elucidate possible continental and/or polar movements (especially those preceding the onset of Wegenerian drift) and has, in addition, become a useful tool for solving particular geological problems (for example, in stratigraphy).

This modern diversity of roles is well illustrated by the many reports that have appeared in the past few months alone. Roy *et al.* (*Geophys. Res. Lett.*, **2**, 537; 1975), for example, have carried out a straight palaeomagnetic directional study of the world's oldest red beds—argillites, 2.3 billion yr old, found in the Huron Supergroup of Ontario. Perhaps 'straight' is hardly the right word in this context, for it is seldom easy to obtain a reliable direction from rocks of such an age. In this case, however, a combination of thermal, chemical and alternating field cleaning appears to give a reliable ancient pole at 67°N, 158°E from a magnetisation acquired at, or within a few tens of millions of years of, the formation of the beds. The new pole is ~100 Myr older than the oldest previous Laurentian poles; and its significance is that in the context of previous poles it provides evidence that the apparent polar wandering path relative to Laurentia from 2.3 to 1.9 billion yr ago was mainly latitudinal and from north to south.

Paradoxically, not only can it be

difficult to obtain a good direction from very old sediments because of their age, it can be equally difficult to obtain a good direction from very young sediments because of their extreme youth. The problem is that the most recent sediments are still unconsolidated and thus subject to erosion, slumping and many other processes likely to distort whatever magnetisation they may already have acquired. Moreover, the 175 1-m cores taken from the top of the sediment in Lake Geneva by Creer *et al.* (*Earth planet. Sci. Lett.*, **28**, 127; 1975) were also disturbed during handling and kept in storage for more than a year before any palaeomagnetic measurements were made on them. It is thus all the more surprising that no less than 39 of these cores gave "satisfactory and interpretable" declination-depth curves. Comparison of these results with the historic-archaeomagnetic declination curve has enabled Creer and his colleagues to estimate the sedimentation rate and its variation in Lake Geneva over the past 400 yr.

By contrast, Thompson's (*Geophys. J.*, **43**, 847; 1975) measurements of magnetic declination in lake sediments have been concerned with a much longer time scale. Cores from Lake

Windermere, Blelham Tarn and Ennerdale Lake in NW England and from Lough Neagh in Northern Ireland show that an oscillation in declination (about true north) with a period of about 2,700 yr has been occurring for at least the past 10,000 yr. Such oscillations are probably due to a combination of dipole wobble, drifting non-dipole sources and stationary intensity-varying non-dipole centres—which presumably explains why declination-time curves from Britain, Switzerland, the Aegean Sea and the Black Sea are difficult to correlate. However, as long as the core magnetisation is stable and at least one horizon is dated absolutely or cross-correlated, recent NW European sediments may be dated against the British declination mastercurve.

Thompson's sediments were all normally magnetised, of course; it is necessary to go back a few more thousand years to the most recent (short) reversal. Not that the reversal pattern is yet perfectly clear, even for the past few million years. For example, the Olduvai normal event within the Matuyama reversed epoch was originally dated at  $\sim 1.9$  Myr and the subsequently discovered Gilsa event in the same epoch was dated at about 1.6 Myr. In short, there appeared to be two separate events—a view sup-

ported by an early report suggesting that the Gilsa type section in Iceland included two normal flows possibly separated by a reversed one.

Unfortunately, it has since become clear that the original Olduvai date may not be accurate; indeed, the wide limits now placed on it are such as to throw doubt on the whole existence of two separate events. This doubt has now been reinforced by Watkins *et al.* (*Earth planet. Sci. Lett.*, **27**, 436; 1975) who have re-examined the Gilsa section and find that although there are two normal flows there is no reversed flow between them. Thus only one normal event is definitely represented (at  $1.58 \pm 0.08$  Myr); and the question of whether the Gilsa and Olduvai events are identical or distinct remains open.

Returning now to the almost single (normal) polarity of the Brunhes epoch, Watkins and Richardson (*Geophys. J.*, **43**, 501; 1975) have been looking again at the contrast in palaeomagnetic data between the northern and southern hemispheres. Second-order differences between hemispheres were first discovered by Wilson (*Geophys. J.*, **19**, 417; 1970 and **22**, 491; 1971) who concluded that during the Upper Cainozoic the axial dipole was displaced along the rotational axis

ONE cannot help admiring the way certain species of plant and animal have exploited to their own advantage situations created by man. Even the most ugly and destructive activities have provided opportunities for those species with a sufficiently wide range of tolerance or the capacity to evolve such a tolerance. As a result urban environments have become populated by species such as the starling whose cliff and tree nesting and roosting habits, coupled with the capacity to feed in short turf, have provided it with a competitive opportunity. Among plants, the rose bay willow herb (*Chamaenerion angustifolium*) is a particularly successful invader of demolition sites, arriving as wind borne seeds and propagating vegetatively once established by means of stolons which give rise to erect stems. It is intolerant of shade and its natural habitat is open scree slopes. This is one of the many weed species which has survived in open localities since the close of the last glaciation and has spread extensively as man has provided it with new opportunities.

The mining of heavy metals and the tipping of spoil has created habitats which are toxic and inhospitable to most plant species, but some appear capable of evolving tolerance to such conditions and expand their populations as a result. For example, the bladder

campion (*Silene vulgaris*), another periglacial species turned weed, has developed races tolerant of high zinc concentrations and able to invade mine spoil (Gries, *Flora, Jena*, **156**, 271; 1966). A similar process has been observed operating in a number of species, particularly grasses, in the British Isles (Bradshaw *et al.* in *Ecology and the Industrial Society*, edit. by Goodman, G. T., Edwards, R. W., and Lambert, J. M., 327, Blackwell, Oxford; 1965).

Orchids are not normally regarded as a group of plants exhibiting heavy

## Orchids adapting

from Peter D. Moore

metal tolerance, but some recent observations by Richards and Swan (*Watsonia*, **11**, 1; 1976) in Northumberland in the north of England have altered this. They have found the narrow-lipped helleborine (*Epipactis leptochila*) growing on eleven sites, 180 miles north of the nearest previously recorded station. All the sites consisted of bare, open river gravels and most of them contained very high levels of zinc (up to 2,300 p.p.m. air-dry soil), and had a neutral pH.

The characteristic habitat of *Epi-*

*pactis leptochila* is beneath beech canopies on chalk and limestone in southern Britain. The plants in Northumberland could be derived from some previously undiscovered, relict population, or they could have invaded directly from the south of England. Richards and Swan consider it possible that the species has been in the area for 80 yr or more, having re-examined older, less critical identifications, but the origin of the species in the area remains uncertain. What is of greater importance and interest is the development of tolerance to zinc and its resultant success in polluted gravels where mining activities have occurred. At such sites the general vegetation is sparse due to toxicity, hence there is little competition from other herbaceous species, which is one character these northern sites have in common with the southern habitat of *Epipactis leptochila*.

As Bradshaw *et al.* have shown, not all plant species possess the ability to adapt to soils polluted with toxic metals, but evidently *Epipactis leptochila* does, and the Northumberland populations must have been subjected to considerable selective pressure for zinc tolerance. Like the starling and the rose bay willow herb, this is a species with latent talents that is now proving its worth by exploiting habitats made derelict and inhospitable by man. □

to the north by  $285 \pm 74$  km. Later, however, Watkins (*Geophys. J.*, **28**, 193; 1972) pointed out that, although the northern hemisphere palaeomagnetic results for the Brunhes alone are consistent with a dipole offset to the north by 300–400 km, the southern hemisphere data require no such offset. He therefore suggested that the simplest model consistent with data from both hemispheres would have a main centred dipole with a weaker axial dipole some distance to the north.

In a more thorough analysis, Watkins and Richardson now show that the Brunhes palaeomagnetic data are best satisfied by a major dipole offset to the north together with two minor axial dipoles offset arbitrarily to the core-mantle interface (one in each hemisphere). These minor dipoles have moments of 1–4% of that of the main dipole, the one in the southern hemisphere having the same polarity as the main dipole and the one in the northern hemisphere opposing the main dipole. This is apparently the simplest model consistent with all current Brunhes palaeomagnetic results although more complex models could be devised (and may be necessary later to explain better data).

Finally, Bhattacharyya and Leu (*J. Geophys. Res.*, **80**, 4461; 1975) have used the magnetism of rocks indirectly to investigate a much more local effect. From an analysis of magnetic anomalies over Yellowstone National Park, they show that the Curie point isotherm below this geothermal area is particularly shallow. This is only to be expected and in any case has been proved before using other methods. The point of this confirmation, however, is its suggestion that aeromagnetic data may prove useful in regional reconnaissance for potential geothermal energy resources □

## Tail-wagging antibodies?

from C. C. F. Blake

Now that X-ray studies have established a broad understanding of the antigen binding function of immunoglobulins, attention is being turned to the Fc region and how its complement fixation and B-cell activation functions are influenced by binding of antigen.

The first successful structural study of a whole myeloma protein, the IgG1 Dob, by both low resolution X-ray analysis and electron microscopy (Sarma *et al.*, *J. biol. Chem.*, **246**, 3753; 1971; Lebow and Davies, *J. ultrastr. Res.*, **40**, 349; 1972) revealed that the molecule was T-shaped, but little else. Recently Huber and his

colleagues (Colman *et al.*, *J. molec. Biol.*, **100**, 257; 1976) reported a second low resolution study, of the IgG1 Kol, which has produced much more information. There are two reasons for this. first, high-resolution structural information on the Fab region is now available and second, the Kol protein does not have the deletion in the Fab-Fc hinge region that the Dob protein has. Since the resolution of Huber's map is only 5 Å, only the quaternary structure of the molecule—the arrangement of the various domains—can be analysed in any detail. Changes at this level of structure, however, could be highly significant, and some very intriguing results have been obtained, even though, or rather because, there is no electron density for the Fc region of the molecule.

One of the characteristics of X-ray analysis of crystal structures is that it is only possible to see side-chains or parts of molecules that are positionally stable in the crystal. Thus the lack of electron density in that part of the crystal that should contain the Fc of Kol, must indicate that the whole region can, and does, take up at least two orientations relative to the well-defined Fab regions. Huber has interpreted this as indicating the presence of a hinge in the molecule at the point at which the electron density fades out—immediately C-terminal of the inter-heavy chain disulphide bridges. If this is so the hinge is different from the classical one proposed to account for the Y→T transformation which must be N-terminal of these bridges. It should be noted that the angle between the two Fab arms is  $125^\circ$  in Kol, in contrast to the  $180^\circ$  found in Dob.

Yet a third hinge region may be present in the molecule, coincident with the switch regions between the V and C domains of the Fab arms. Interpretation of the Fab region of the Kol protein in terms of the known structures of the human  $V_k$  dimer fragment Rei, and the mouse McPC 603 Fab fragment, has shown that the V and C domains are not in the same relative orientation as that found in the Fab fragments so far analysed. The difference can be judged by the angle of intersection of the pseudodyads that relate the light and heavy chains in the two domains, which changes from  $120^\circ$  in the Fab fragments to  $170^\circ$  in the Kol protein. Colman *et al.* refer to this change as “bending the elbow” of the Fab arms—in the Kol protein therefore the arms are almost straight.

Huber and his colleagues speculate that these two new hinge regions may permit antibodies to act as allosteric proteins, in which the allosteric effect is transmitted through the polypeptide chain from one domain to another.

They suggest the possibility that hapten binding is accompanied by a “bending of the elbow” and that the elbow movement is sensed by the hinge causing a change in the Fc region that by implication influences complement fixation. Although there is little other evidence that complement fixation is accompanied by conformational changes, the present hypothesis is certainly plausible in view of the extraordinary domain structure of the immunoglobulins, and we now await the results of hapten binding to the Kol protein with considerable interest. □

## Tunguska revisited

from David W Hughes

At about 7.17 a.m. local time on June 30, 1908 in the basin of the River Podkamennaya Tunguska, Central Siberia (latitude  $60^\circ 55'N$ , longitude  $101^\circ 57'E$ ) a gigantic explosion occurred. The ancient trees of the mighty Yenissi taiga were torn up by their roots and in places piled up in thick layers by the explosion wave, their trunks pointing radially away from the centre of the explosion. The devastation extended over an area of radius 30–40 km, the centre of the area having been ravaged by fire, searing being traceable for 18 km. A farmer 60 km away told how his shirt was almost burnt off his back, the explosion throwing him off the steps of his house and several feet across the ground. Eye witnesses up to 500 km away saw, in a cloudless sky, the flight and explosion of a blindingly bright, pale blue bolide, “which made even the light of the Sun appear dark”. This left in its wake a thick dust trail. The explosion took the form of a vertical column of fire and threw incandescent matter up to a height of 20 km. The sound of the explosion, like gun fire, reverberated thousands of kilometres away, seismographs registered an earthquake; the explosion air wave, recorded on microbarographs in many meteorological stations, went twice round the world. Magnetic disturbances similar to those subsequently recorded after atmospheric nuclear explosions were recorded at the Irkutsk Observatory.

After the explosion the nights were exceptionally bright over Western Asia and Europe, the enhanced night brightness slowly diminishing and disappearing after two months. In mid-July, two weeks after the explosion, the coefficient of transparency of the atmosphere was found to be noticeably depressed over California. This, it was suggested, was due to the loss of vast amounts of material from the incident body as it

travelled through the atmosphere. Observations indicated this loss to be several million tons, a hundred times more than the normal annual influx of meteoric matter.

Fortunately the fall region was very sparsely populated, the only inhabitants being scattered bands of nomadic Evenki reindeer herders. Due to the untimely occurrence of political upheavals in Russia the first cursory inspection of the impact site did not take place for 19 years when eventually Leonid A. Kulik headed an expedition organised by the Academy of Sciences of the USSR.

Many expeditions have since visited the area and many papers have been written discussing the phenomenon and putting forward ideas as to its cause. One of the latest papers appeared in a recent issue of *Physics of the Earth and Planetary Interiors* (11, 61; 1975). In it Ari Ben-Menahem of the Adolpho Bloch Geophysical Observatory, Rehovot, Israel re-analyses the old seismograms of the Tunguska event and deduces the parameters of the original explosion by comparing the old data with contemporary records of the seismic and acoustic effects of the air explosion that took place at Lop-Nor, Sinkiang on October 14, 1907 and the series of air explosions from nuclear tests at the USSR test site at Novaya Zemlya (74°N, 150°E).

The Tunguska sound waves were of acoustic modes  $S_0$  and  $S_1$  and travelled at group velocities between 280 and 310 m s<sup>-1</sup>. The seismic event was excited by the air explosion at the source, energy being radiated outward from the epicentre by a series of wave motions. The Rayleigh mode, a rolling motion of the Earth's surface, moved at about 2.7 to 3.5 km s<sup>-1</sup>. SH body waves, where the displacements are horizontal and perpendicular to the direction of propagation were recorded only at Irkutsk and the time of their arrival, coupled with arrival times of other waves at other observatories gives, according to Ben-Menahem, the explosion time to be 00 h 14 m 28 s UT. This time differs by about 30 s from previous estimates. The time delay between the arrival of the SH wave and the Rayleigh wave indicates that the main explosion occurred at a height of 8.5 km above the ground. The direction and extent of fallen trees around the epicentre suggest that this phenomenon was caused by the superposition of two waves—a spherical shock wave (due to the explosion, equivalent to a vertical point impulse of  $7 \times 10^{18}$  dyne s) and a conical ballistic wave (due to the moving incident object, equivalent to a horizontal point impulse of  $1.4 \times 10^{18}$  dyne s). The extent of the damage and the magnitude of the acoustic and seismic waves

indicate that the explosion had an energy of  $(5 \pm 1) \times 10^{23}$  ergs, equivalent to  $12.5 \pm 2.5$  megatons of TNT.

Ben-Menahem does not leap into the controversy as to the actual form of the incident object simply referring to it as a "UFO". Jackson and Ryan (*Nature*, 245, 88; 1973) thought it might have been a black hole with the mass of a large asteroid ( $10^{20}$ – $10^{22}$  g) and a negligible geometrical radius. This would have shot straight through the Earth but unfortunately for the theory (although fortunately for us) the exit point, latitude, 40–50°N longitude 30–40°W, in the mid-Atlantic was not marked by an equally severe shock and blast wave. Hunt, Palmer and Penny (*Phil. Trans. R. Soc. Lond.*, A252, 275; 1960) consider the possibility of an extraterrestrial almost-critical mass of fissionable material becoming tamped on entering the atmosphere. It is difficult, however, to conceive how a sufficient amount of, say, deuterium and tritium can be compressed and heated to several million degrees centigrade and maintained in that state sufficiently long for the self heating to carry the reaction to the explosive stage merely by entry into the Earth's atmosphere. Cowan, Athuri and Libby (*Nature*, 206, 861; 1965) suggest that an incident anti-matter body annihilated itself in the atmosphere, but no large anti-matter bodies have, as yet, been observed and it is hard to understand how it penetrated to such a depth in the atmosphere and why the explosion maximised at the end of the trajectory and not midway along it.

The most likely theory, that a small comet struck the Earth, was put forward by Whipple (*Q. Jl R. Meteorol Soc.*, 56, 287; 1930) and Astapovich (*Astr. J.*, 10, 465; 1933). The trajectory of the bolide indicated that the comet was travelling in the opposite direction to the Earth and that the head-on collision was at a velocity of 60 km s<sup>-1</sup>. The cometary nucleus, which, according to Whipple, is a large dirty snowball—a loose collection of dust and rock interspersed with water, methane and ammonia ices—exploded above the Earth's surface. If most of the energy came from the dissipation of kinetic energy and only a negligible portion from the chemically explosive reactions between the air and the radicals in the nucleus then the mass of the incident comet can be calculated to be approximately  $3 \times 10^{10}$  g. The fact that this comet nucleus has a diameter of about 40 m, more than an order of magnitude below the diameters estimated for visual comets, explains why it wasn't seen as it approached on its collision course to the Earth.

Further evidence favouring this hypo-

thesis is that the night sky luminescence after the fall was only observed over Siberia, Russia and Western Europe. Calculations of the comet orbit indicate that the dust and gas tail, which is directed away from the Sun, extended in a north-westerly direction from the point of impact. The dissipation of this tail in the atmosphere increased the night sky brightness by about 50–100 times. The discovery of many small (5–450  $\mu$ m diameter) magnetite and silicate globules in soil samples taken from the Tunguska site also supports the comet hypothesis. These were formed when molten 'rain drops' of dust solidified as they slowly drifted to Earth after the explosion of the retarded nucleus. Flux estimates indicate that a cometary nucleus of this size will hit the Earth about every 2,000 yr, the rarity of the event giving ample justification for visiting Tunguska yet again.

## Far-infrared balloon astronomy

from a Correspondent

THE far-infrared region of the electromagnetic spectrum—wavelengths between 20  $\mu$ m and 1 mm—is probably the last regime to be explored by the astronomer. The reason for this apparent lack of resolve is not that the wavelength range is uninteresting—far from it when we realise that the majority of the many clouds of dust scattered throughout our Galaxy radiate most of their energy at precisely these wavelengths. The problems are technological; in the far-infrared, the Earth's atmosphere is virtually opaque to external radiation because of severe attenuation by water vapour molecules. There are very poor transmission windows at wavelengths of 350  $\mu$ m, 450  $\mu$ m, and around 800  $\mu$ m, but these are accessible only from very high, dry sites such as Mauna Kea at 14,000 feet in Hawaii. Even then, transmission figures better than 30% are very rare. The obvious answer is to observe from above the absorbing layers in the atmosphere, and with dramatic improvements in balloon astronomy, many exciting discoveries are being made.

The University College London (UCL) group, led by R. E. Jennings, has pioneered balloon far-infrared astronomy and its latest flights have produced a catalogue of far-infrared sources in the Galactic plane. The 40-cm telescope, operating at an altitude of about 100,000 feet is directed to raster scan selected regions of the Milky Way, most of these having

been chosen because they are known from radio observations to contain complex H II regions.

These ionised gas domains surrounding a recently formed, high luminosity star are most intriguing astronomical objects. The unravelling of the detailed mechanisms of these star formation centres occupies a considerable fraction of astronomical effort and the problems are many and complex. The cores of these regions are thick with dust, often rendering optical identification of the ionising star or protostar extremely difficult, if not impossible. Near-infrared observations however do often reveal stars and protostars surrounded by very hot dust shells whose signals can be the free-free radio continuum emission of the H II region. These regions are also rich sites of molecular clouds, and emission maps of many and various molecules have been obtained at wavelengths of a few millimetres or centimetres for the most intense sources. To attempt to piece together the energetics of the emission nebulae, one must determine the total luminosities of the gas, dust and molecules and so derive the luminosity of the exciting star or stars, which must be the powerhouse of the whole region.

The key to understanding these regions is the presence of dust. The dust grains may be associated with the Stromgren sphere of the H II region and in this case are being heated by the direct flux of stellar ultraviolet radiation or by Lyman  $\alpha$  radiation of the hydrogen gas surrounding the star. Alternatively, the grains could be associated with the dense molecular clouds found in and around H II regions, the grain heating being caused by stellar or protostellar objects within these molecular clouds. In the former case, the dust emission, peaking at say 100  $\mu\text{m}$ , should be centred on the position of free-free continuum emission, whereas in the latter, the far-infrared emission should follow the contours of the molecular emission.

Using the UCL balloon system, operating in the wavelength range 40  $\mu\text{m}$  to 350  $\mu\text{m}$ , Furniss *et al.* (*Astrophys J.*, **202**, 400; 1975) have produced the most detailed far-infrared map of the complex region W3 currently available. Their map reveals that the far-infrared emission seems to follow the radio emission in general, although there does appear to be a long spur projecting westwards from the main source. The authors claim that recent radio free-free emission has also been reported to possess this spur feature and so the tie-in with the radio emission rather than the molecular cloud emission would seem to be more favoured for this source at least.

This, however, is only one source and there are many others; the Great

Nebula region of M42 in Orion, for instance, one of the most exciting and complex regions in the sky, shows many differences to W3. It is also found that as one observes at longer wavelengths ( $\sim 1\text{ mm}$ ) one is looking at the cooler dust and this component does appear to follow the molecular cloud emission rather than the H II continuum free-free emission. Once again the complexities of the regions are daunting and challenging. Theoretically one is not at all sure what size are the dust grains in the regions, or of what material; silicates or graphites are the usual choice. Laboratory spectral analysis of selected grain compositions is urgently required by the grain theoretician. Observationally one requires better high resolution, far-infrared and molecular maps and a near-infrared search for the dust-enshrouded protostars in the H II regions before the vastly complex physics and mechanics of these birthplaces of stars can be understood fully. In the far-infrared, one looks to the future for balloon and aircraft-based spectrometers and interferometers. The larger diameter balloon-based telescopes and the first non-military, infrared satellite, scheduled for launch in 1981, will open up a new era of observing in this wavelength range.  $\square$

## System for steroids

from Robert Shields

An understanding of the way in which steroid hormones regulate gene expression has been frustrated continuously by the lack of suitable model systems in which hormone action can be studied *in vitro*. Ideally what is required are hormonally responsive cell lines where mutant cells can be isolated and the mechanism of hormone action can then be dissected in the way that proved so successful in prokaryotes. Several steroid responsive cell lines are now available, including some potentially useful mutants (Sibley and Tomkins, *Cell* **2**, 213; 1974) but they all have a number of drawbacks. Now it looks as if the endocrinologists' prayer is about to be answered, for not only is an almost ideal system available, but combining as it does both endocrinology and tumour virology it should hit the double grant jackpot.

Recently it has been shown that physiological concentrations of glucocorticoids can stimulate the production of mouse mammary tumour virus (MMTV) in a number of cell lines established from mouse mammary adenocarcinomas (Parks *et al.*, *Science*, **184**, 158; 1974). This increase in virus production results from increases in virus specific RNA transcribed from the DNA provirus integrated in the host cell genome (Ringold *et al.*,

*Virology*, **65**, 135; 1975; Parks *et al.*, *J. biol. Chem.*, **250**, 3330; 1975). Induction of this viral RNA is mediated through the classical steroid-receptor mechanism since binding of various glucocorticoids to the receptor and transfer of the receptor-bound steroid to the cell nucleus are correlated with the increase in virus production (Young *et al.*, *J. biol. Chem.*, **250**, 3337; 1975; Ringold *et al.*, *Cell*, **6**, 299; 1975). Whether the increases in virus specific RNA produced by glucocorticoids involves a decrease in RNA degradation or an increase in transcription (which seems more likely) is not yet known. This is a vital point since transcriptional compared with post-transcriptional control has been a contentious point in steroid action for some time (see News and Views, *Nature*, **258**, 477; 1975). In any event the action of the steroid appears to be direct since inhibitors of protein and DNA synthesis do not block increases in viral RNA, no general increase in RNA synthesis is seen, and the concentration of the virus specific RNA doubles within 30 min of steroid addition. This effect of glucocorticoids is not confined to B-type RNA tumour viruses (such as MMTV). Glucocorticoids also increase C-type RNA virus produced in cells treated with halogenated pyrimidines (Paran *et al.*, *Proc. natn. Acad. Sci. U.S.A.* **70**, 2391; 1973) and enhance the production of polyoma (DNA) virus from productively infected mouse embryo cells (Morhenn *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **70**, 1088; 1973).

What is particularly interesting about these systems is that steroids appear to be unable to initiate the transcription of virus sequences, and merely enhance the production of viral RNAs that are produced constitutively. Hence synthesis of C-type virus in KA31 non-producer cells is not induced by glucocorticoids but if virus is first induced with IUdr, virus production is increased many-fold by the hormone. Nor is constitutive production of viral RNA sufficient for a hormone effect since in murine epithelial cell lines constitutively transcribing both B-type and C-type virus sequences only the B-type transcripts are increased (Parks *loc cit*). Thus it may generally prove to be that steroids are only gene amplifiers and not true inducers.

Glucocorticoid control over virus production is a particularly good model system because viral RNA can be quantitated and tumour virologists have all the tools necessary to characterise mutant cells defective in various stages of viral production. In the not too distant future it may prove possible to remove the DNA provirus from the cell, together with its steroid responsive control elements.  $\square$

## X-ray studies of linear polyiodide chains in $\alpha$ -cyclodextrin channels and a model for the starch-iodine complex

M. Noltemeyer & W. Saenger

Max-Planck-Institut für experimentelle Medizin, Abteilung Chemie, D-3400 Göttingen, Hermann-Rein-Strasse 3, West Germany

*The crystal structures of complexes of  $\alpha$ -cyclodextrin (cyclohexaamylose) with  $\text{Li}^+$ - and  $\text{Cd}^{2+}$ -polyiodide have been analysed by single crystal X-ray methods. The molecules are arranged head to head and linked by hydrogen bonds yielding endless stacks with channel cavities of about 5 Å diameter in which the iodine chains are located. In the  $\text{Li}^+$  complex, the polyiodide chain is slightly zigzagged.*

LINEAR polyiodine and polyiodide chains included in organic matrices are interesting for their unusual physical properties. The best known examples in analytical chemistry are the "blue starch-iodine" reaction, and in optics the polarisation filters based on complexes between polyiodide and organic polymers<sup>1</sup>. The nature of the blue or black colour of these compounds has been studied spectrophotometrically<sup>2</sup> and explained by the electron gas theory<sup>3</sup>. The one-dimensional metallic properties, such as anisotropic conductivity and weak paramagnetism<sup>4</sup>, of polyiodide and polyiodine<sup>5</sup> chains have been pointed out. As no detailed picture of an isolated linear polyiodide chain<sup>6</sup> had been developed, it seemed necessary to study the  $\alpha$ -cyclodextrin-polyiodine complex which preliminary studies have indicated contain well defined polyiodide chains<sup>3,7</sup>. (Reddy *et al.*<sup>8</sup> found linear chains of polymerised  $(\text{I}_3^-)_n$  units in the  $\text{HI}_3$  benzamide complex. These chains, however, occur in pairs which are stabilised by proton bridges.)

$\alpha$ -Cyclodextrin (cyclohexaamylose,  $\alpha$ -CD) is obtained through degradation of starch by *Bacillus macerans* amylase. It consists of six  $\alpha$  (1 $\rightarrow$ 4) linked glucoses (Fig. 1) and forms a truncated cone with height 8 Å, diameter 14 Å and an annular aperture of 5 Å. Owing to this aperture  $\alpha$ -CD can form inclusion complexes with small molecules<sup>3,7</sup> and these complexes crystallise in cage or channel structures, depending on whether the  $\alpha$ -CD molecules are arranged crosswise or stacked on top of each other like coins in a roll<sup>9</sup>. The channel type structures bear some relationship to the helical starch molecules for the  $\alpha$ -CD molecules form a hollow cylinder, with a geometry similar to that deduced for starch<sup>9</sup>.

When  $\alpha$ -CD is crystallised from aqueous solution in the presence of iodine, cage type crystal structures with isolated iodine molecules are formed<sup>10</sup>. When metal iodides are added to the solution, channel type structures with polyiodide chains develop, exhibiting either triclinic, tetragonal or hexagonal space group symmetries, depending specifically on the added cation (W. S., U. Bergmann, M. N. and P. C. Manor, unpublished). This article describes the crystal structures of the

complex  $(\alpha\text{-CD})_2 \cdot \text{LiI}_3 \cdot \text{I}_2 \cdot 8\text{H}_2\text{O}$  (triclinic) and  $(\alpha\text{-CD})_2 \cdot \text{Cd}_{1/2} \cdot \text{I}_2 \cdot 26\text{H}_2\text{O}$  (tetragonal).

### Polyiodide chain in $(\alpha\text{-CD})_2 \cdot \text{LiI}_3 \cdot \text{I}_2 \cdot 8\text{H}_2\text{O}$

Table 1 shows data for the triclinic, pseudohexagonal crystals of  $(\alpha\text{-CD})_2 \cdot \text{LiI}_3 \cdot \text{I}_2 \cdot 8\text{H}_2\text{O}$ . The heavy atom structure has been solved using tangent formula refinement of the rough model obtained from a Patterson distribution while the  $\alpha$ -CD atoms, the water molecules and the cation had to be located from difference Fourier syntheses. The structure was refined by full matrix least squares cycles to a discrepancy index  $R = 8.8\%$ .

The crystal structure of the complex is determined by hexagonally packed  $\alpha$ -CD stacks parallel to the crystallographic  $c$  axis with unit cell repeat distance 15.88 Å (Fig. 2a). In these stacks, the  $\alpha$ -CD molecules are tilted by about 7° against the

stack axis, thereby prohibiting a truly hexagonal space group. The  $\alpha$ -CD molecules are arranged head to head to form dimers which include five iodine atoms (Fig. 3) and are linked along the stacks through intermolecular O(2)  $\cdots$  O(3) and O(6)  $\cdots$  O(6) hydrogen bonds and through bonds to the eight water molecules located in the 'empty' space between the stacks. Further, the Li $^+$  cations are coordinated to O(2) and O(3) hydroxyl groups of  $\alpha$ -CD molecules joined in dimers and to one water molecule, the ligands forming a distorted tetragonal pyramid; the shortest Li $^+$   $\cdots$  I distance, 5.05 Å exceeds ion-ion contact of 2.88 Å.

The individual  $\alpha$ -CD molecules display almost hexagonal symmetry. The glucoses are in the C1 chair conformation with all C(6)–O(6) bonds in the preferred *gauche*, *gauche* position<sup>11</sup>, that is they are pointing away from the  $\alpha$ -CD molecular centre (Fig. 3). The wide sides of the  $\alpha$ -CD cones are lined by the O(2) and O(3) hydroxyl groups which form a ring of intramolecular hydrogen bonds between adjacent glucoses with O  $\cdots$  O distances in the range 2.78–3.03 Å.

The arrangement of the iodine atoms in the polyiodide chain follows the inclination of the  $\alpha$ -CD molecules towards the stack axis (Fig. 3). In an  $\alpha$ -CD dimer, the positions of four iodine atoms lying in the narrow  $\alpha$ -CD cavities are fully occupied but the iodine atom near the wide O(2), O(3) rim of the  $\alpha$ -CD torus is twofold disordered at 70%: 30% occupancies. Since the two disordered iodine sites are only 1.7 Å away from each other they cannot be occupied simultaneously and at all events clearly belong to one of the neighbouring I $_2$  units; therefore, alternating I $_2$  and I $_3^-$  units can be distinguished.

As often observed, the I $_3^-$  units are not strictly linear<sup>12</sup> but bent to about 170° and the two I–I distances are not equal to each other. In the I $_2$  units, the standard I–I distance of 2.67 Å is lengthened to 2.81 and 2.87 Å and the van der Waals' separation between iodine atoms of 4.3 Å is shortened to at least 4.03 Å (Fig. 3).

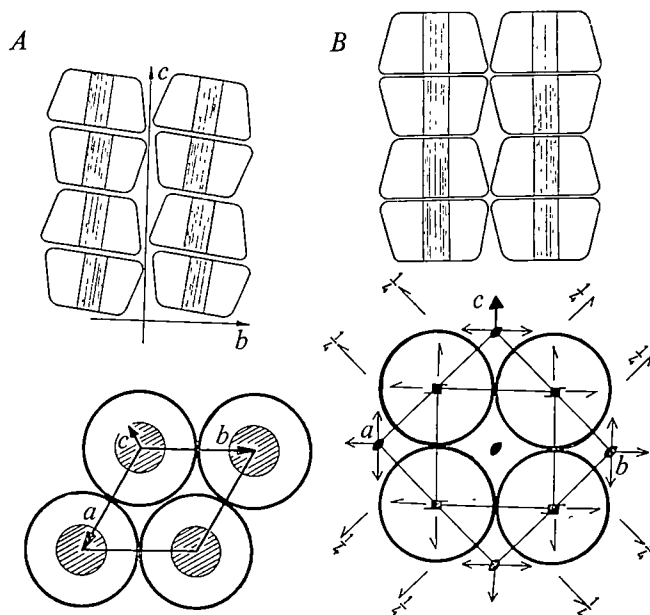

### Polyiodide chain in ( $\alpha$ -CD) $_2$ ·Cd $_{1/2}$ ·I $_2$ ·26H $_2$ O

The ( $\alpha$ -CD) $_2$ ·Cd $_{1/2}$ ·I $_2$ ·26H $_2$ O complex crystallises in the high symmetry space group P4 $_2$ 2 $_1$ 2. The heavy atoms were located by direct methods but the  $\alpha$ -CD molecule could only be found by trial and error. The cation and water molecules were located from difference Fourier syntheses and the atomic parameters were refined to  $R$  = 12.0%. Two half, independent  $\alpha$ -CD molecules constitute the asymmetric unit and are related to the other two halves by the diad component in the 4 $_2$  operation (Figs 2b and 4). Thus the  $\alpha$ -CD molecular axes coincide with the 4 $_2$  axis, the two  $\alpha$ -CD molecules again being arranged as dimers in a head to head fashion, but the intermolecular O(2)  $\cdots$  O(3) and O(6)  $\cdots$  O(6) hydrogen bonding pattern is not the same because the  $\alpha$ -CD molecules are rotated differently against each other (Figs 3 and 4). The dimers form stacks which are only loosely packed owing to the

requirements of the tetragonal lattice (Fig. 2b) and the open space between the stacks is filled by 26 water molecules per  $\alpha$ -CD dimer, some of them being statistically disordered. The Cd $^{2+}$  cation itself is twofold disordered, with both sites located on the twofold axes. They are coordinated octahedrally only by water molecules and > 9.97 Å from the polyiodide chain. The conformation of the  $\alpha$ -CD molecules themselves is similar, as discussed above.

Four of the five iodine atoms in the dimer are located on the 4 $_2$  axis and therefore they must be colinear. Similarly as in the ( $\alpha$ -CD) $_2$ ·LiI $_3$ ·8H $_2$ O complex, the iodine atom near the wide O(2), O(3) rim of the  $\alpha$ -CD torus is twofold disordered in equal amounts, which leads again to angles near 170° in the polyiodide chain. The two sites are too close together (1.24 Å) to allow simultaneous occupation (Fig. 4). In contrast to the separation into I $_3^-$  and I $_2$  units in the Li $^+$ -complex, however, the distribution of the iodine atoms follows a pattern, (I $_2$   $\cdots$  I $^-$   $\cdots$  I $_2$ ) $_n$ , usually considered as I $_5^-$ , with the iodide ion I $^-$  being disordered. The distances between the central iodine ion and the next iodine molecules, 3.17 and 3.14 Å, are comparable with previously observed I $_5^-$  structures<sup>13</sup>. The separation of 3.32 Å between the I $_5^-$  units is considerably shorter than the expected van der Waals' distance of 4.3 Å. These

Fig. 2 The packing scheme of  $\alpha$ -CD stacks in (A) the triclinic ( $\alpha$ -CD) $_2$ ·LiI $_3$ ·8H $_2$ O complex, (B) the tetragonal ( $\alpha$ -CD) $_2$ ·Cd $_{1/2}$ ·I $_2$ ·26H $_2$ O complex. The unit cell constants (a) and (b) are determined by the dimensions of the closely packed  $\alpha$ -CD molecules (see also Table 1).

Fig. 3 The structure of the  $(\alpha\text{-CD})_2 \cdot \text{LiI}_3 \cdot 8\text{H}_2\text{O}$  complex, projected on the  $a,c$  plane, water molecules and  $\text{Li}^+$  ion not drawn. o, C; O, O; fully and statistically occupied iodine sites are indicated by filled and hatched ellipses representing the anisotropic thermal vibration of these atoms. Distances between iodine atoms are given in Å units. The crystallographic asymmetric unit is marked by dashed lines.

results indicate that in this polyiodide chain extensive delocalisation of electrons occurs.

### Conductivity measurements

Several complexes of polyiodide with organic molecules have been investigated by X-ray crystallography<sup>13-15</sup>. In these structures the polyiodide chains consist of clearly distinguishable  $\text{I}_2$  and  $\text{I}_6^-$  units in a zigzag arrangement. Linear, isolated polyiodide chains<sup>6</sup> have been observed in detail only in the two crystal structures described above and in the trimesic acid

polyiodide<sup>15</sup> complex. Although in the two  $\alpha\text{-CD}$  complexes the iodine and  $\alpha\text{-CD}$  atoms were located and refined on the basis of three-dimensional X-ray data, the structure of the polyiodide chain in the trimesic acid complex was derived from one dimensional diffuse layer lines.

In the trimesic acid polyiodide complex, the periodicity along the polyiodide chain is also about 15.5 Å, five iodine atoms are arranged as centrosymmetric ( $\text{I}_2 \cdots \text{I}^- \cdots \text{I}_2$ ) units with I-I distances of 3.26 Å, 2.74 Å and 3.50 Å<sup>15</sup>, in close agreement with the distances observed for the tetragonal complex described above: 3.14 (3.17), 2.96 (2.97) and 3.32 Å. In the latter the tendency to achieve equidistant spacings is more obvious, and extensive delocalisation of electrons should be expected.

For that reason, preliminary conductivity measurements were carried out in the direction of the polyiodide chain of the  $(\alpha\text{-CD})_2 \cdot \text{Cd}_{1/2} \cdot \text{I}_2 \cdot 2\text{I}_2 \cdot 26\text{H}_2\text{O}$  complex. The conductivity was about  $10^{-6} \Omega^{-1} \text{cm}^{-1}$ , in agreement with results obtained previously with the same complex (M. M. Labes, personal

Fig. 4 The structure of the  $(\alpha\text{-CD})_2 \cdot \text{Cd}_{1/2} \cdot \text{I}_2 \cdot 2\text{I}_2 \cdot 26\text{H}_2\text{O}$  complex. For further details, see legend to Fig. 3.

communication), and suggests that the polyiodide chain has the properties of a semiconductor. In summary, in strictly linear polyiodide chains  $I_6^-$  units with a fine structure  $(I_2 \cdots I \cdots I_2)^-$  seem to be preferred but in nonlinear, slightly zigzagged polyiodide chains  $I_2$  and  $I_3^-$  units can be distinguished. In complexes between polyiodide and polymer organic molecules such as starch or the polarisation filter polymers there are no crystallographic restrictions and it is to be assumed that slightly zigzagged chains will occur. It is an outstanding feature of the  $\alpha$ -CD-polyiodine complex that the cations are located outside the  $\alpha$ -CD channels at distances well beyond the expected  $Li^+ \cdots I^-$  or  $Cd^{2+} \cdots I^-$  ion pair interaction, yielding a negatively charged polyiodide embedded in the insulating organic material  $\alpha$ -CD. In other structures, the tendency to form ion pairs with polyiodide is obvious<sup>6,14</sup>.

## Intermolecular forces

Charge transfer interactions between iodine atoms and the ether-like O(4) linkages of  $\alpha$ -CD molecules have been reported to stabilise the  $\alpha$ -CD (or starch)-polyiodide complexes<sup>18</sup>. Our own and earlier<sup>10</sup> X-ray crystal studies show that the main interactions between iodine atoms and  $\alpha$ -CD molecules are van der Waals' contacts with the C(3)-H and C(5)-H methin hydrogen atoms: viewed from the iodine atom positions, the O(4) atoms are buried behind these hydrogen atoms and at least 0.68 Å further away than the  $I \cdots O$  van der Waals'

contact of 3.55 Å. Therefore, distances in the range between covalent and van der Waals' which are demanded for charge transfer type interactions<sup>17</sup> are not possible. As for the  $\alpha$ -CD-polyiodide complexes, it is unlikely that the starch-polyiodide complexes are stabilised by  $I \cdots O$  charge transfer interactions.

We thank the Deutsche Forschungsgemeinschaft for a grant and for computing facilities. We thank Professor F. Cramer for encouragement and support. Computations were carried out at the Gesellschaft für wissenschaftliche Datenverarbeitung, Göttingen.

# The role of long range forces in ordered arrays of tobacco mosaic virus

V. Adrian Parsegian & Stephen L. Brenner

Physical Sciences Laboratory, Division of Computer Research and Technology, National Institutes of Health, Bethesda, Maryland 20014

*We examine the role of electrostatic repulsion and van der Waals' attraction in determining interviral spacings in 'equilibrium' gels of tobacco mosaic virus. The observed spacings are inconsistent with a force-balance model. Experimental probes of the role of forces are suggested.*

EVER since Bernal and Fankuchen's description, in 1941, of the parallel packing of tobacco mosaic virus (TMV) particles in the ordered phase of a two-phase system<sup>1</sup>, the TMV system has been considered an ideal example of spontaneous self-organisation. Since some biological structures, such as muscle sarcomere<sup>2,3</sup>, visual cornea<sup>4-8</sup>, and the gel of sickle cell haemoglobin (ref. 9 and A. P. Minton, personal communication), appear to be ordered arrays of long proteins or protein aggregates, one is tempted to make analogies between those structures and the array of the rod-like TMV particles. Possibly the observed spacings in TMV gels result from balancing the electrodynamic van der Waals' attraction, and electrostatic repulsion<sup>10-12</sup>. Primarily because of limitations in previous physical theory, this assumption has never been adequately examined. Here we have used new methods of computation to explore the role of long range forces in the TMV system.

There has been a fairly clear but arbitrary dichotomy in theoretical analyses. First, it has been shown that without any attractive force between rod-like particles, steric interference between asymmetric bodies is sufficient to cause a separation of the rod population into an ordered phase of parallel rods in

equilibrium with another phase of randomly oriented rods in suspension<sup>13,14</sup>. Second, work on long-range interactions has shown that energies of attraction can be comparable to the energy of Brownian (random) motion when bodies are close compared with their size<sup>15</sup>. Such interactions might therefore have a significant role in overcoming Brownian motion to align like particles.

The relative importance of these factors in the formation of the observed ordered arrays has remained an open question. The truncated virial expansion technique<sup>13,14</sup> used to describe the consequences of steric repulsion is not very accurate at the high particle concentrations at which observations were made. Such a treatment predicts transition densities, but cannot provide unambiguous values for the rod-rod spacing. The alternative lattice models are also not designed to predict observed spacings (ref. 16, and A. P. Minton, personal communication). Although experimental examination of uncharged polypeptides in organic solvents<sup>17</sup> shows that ordering of very long rods arises primarily from steric repulsion, none of the available hard rod models is able to account for the observed transition densities in TMV suspensions<sup>18</sup>.

In the following, we compare observed interviral separations with those predicted by force-balance. We use the theory of balancing forces to derive a constraint between separations and the salt concentrations in the medium, and we use recently published absorption spectra to make a numerical calculation of the van der Waals' attraction between proteins in salt water.

Two conclusions are immediately apparent: first, the magnitudes of the observed spacings are always much greater than

those expected from the positions of the energy minima. Second, the observed change in separation on varying the salt concentration in the medium cannot be fitted by shifts in the positions of equilibrium. (This is true even if one chooses unphysical coefficients for the competing forces.)

We suggest experiments for more critical examination of the role of forces, including repetition of the early spacing measurements<sup>1</sup> in more stringently defined conditions of pH and salt concentration in the medium.

### Force-balance constraint between spacing and salt concentration

The leading term in the electrostatic repulsive force per unit length between parallel rods is<sup>19</sup>

$$f^{es} = \frac{2v^2e^2}{\epsilon a} \left(\frac{2}{\pi}\right)^{1/2} \frac{\exp[-\kappa(R-2a)]}{\kappa R} \quad (1)$$

Equation (1) is valid when the rod length is much greater than the separation of the rods.  $R$  is the interaxial distance,  $a$  the rod radius,  $v$  the net number of unit ionic charges per unit length of the rod, assumed to be smeared uniformly on the outermost surfaces. The Debye constant  $\kappa$  is

$$\kappa^2 = \frac{8\pi ne^2}{\epsilon kT}, \quad n = \frac{1}{2} \sum_{\{n_i^0\}} n_i^0 z_i^2 \quad (2)$$

with  $(-e)$  the electronic charge,  $\epsilon$  the dielectric constant of the medium, which is assumed uniform,  $k$  the Boltzmann constant,  $T$  the absolute temperature, and the  $n_i^0$  are the concentrations of ions of valence  $z_i$  in the bathing medium far from the rods. Equation (1) assumes that the radius  $a$  is greater than the Debye length  $\kappa^{-1}$ , and that the electrostatic energy of a counterion near the rod is smaller than the thermal energy  $kT$ . Expressions more general than equation (1) have been derived and may be applied if needed<sup>10,19</sup>.

The electrodynamic attractive force per unit length between the same two rods has the approximate form<sup>10,20</sup>

$$f^{ed} = -\frac{2\pi A_H}{3R^2} S \quad (3)$$

where  $S$  is the double sum

$$S = \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \frac{[(2m+2n+1)!!]^2 (2m+2n-1)}{m!n!(m-1)!(n-1)!} \left(\frac{a}{2R}\right)^{2m+2n} \quad (4)$$

(The double factorial is the product  $q!! = q(q-2)(q-4) \dots (1 \text{ or } 2)$ .) Equation (3) neglects the retardation damping of van der Waals' forces. It also assumes that the dependence of the force on distance is obtained by pairwise summation of inverse sixth power interactions between incremental parts of the rods,

and that the rods are of uniform composition (although the formula may be very simply generalised to describe rods composed of concentric cylindrical layers, as might be appropriate for TMV particles). The magnitude of the coefficient  $A_H$  can be obtained from electromagnetic spectra of protein and water and will be computed below. 'Many-body' effects which might give a different form to  $f^{ed}$  will be negligible because of ionic screening of the low-frequency charge fluctuation forces most likely to demonstrate these effects. Again, more general formulae exist<sup>20</sup> and may be used if necessary.

If the interaxial spacings  $R$  observed by X-ray diffraction are the result solely of balancing electrostatic repulsion  $f^{es}$  and electrodynamic attraction  $f^{ed}$ , then these forces must sum to zero at the observed spacings  $R$ . Setting  $f^{es} = -f^{ed}$  and sequestering coefficients, we have

$$F(R, \kappa) = \frac{S/R^2}{\exp[-\kappa(R-2a)]/\sqrt{(\kappa R)}} \quad (5)$$

$$= \frac{v^2e^2}{A_H} \left(\frac{2}{\pi}\right)^{1/2} \frac{3}{\pi \epsilon a}$$

That is,  $F(R, \kappa)$  is a constant for all predicted pairs of values of  $R$  and  $\kappa$ . The equation

$$F(R, \kappa) = \text{constant} = C$$

provides a constraint between spacing and salt concentration depending on the value of the constant  $C$  where

$$C = \left(\frac{v^2}{A_H}\right) \left(\frac{2}{\pi}\right)^{1/2} \left(\frac{3e^2}{\pi \epsilon a}\right) \quad (6)$$

### Computation

We can compare the behaviour predicted in equation (5) with the available data on the TMV 'equilibrium gels'. Bernal and Fankuchen<sup>1</sup> provide a table of interaxis spacings as functions of salt concentrations; their results are presented in columns 1 and 2 of Table 1. The Debye constant corresponding to the various salt concentrations is given in column 3. The function  $F(R, \kappa)$  defined in equation (5) is then tabulated in the fourth column. According to the arguments given in the last section,  $F(R, \kappa)$  should be a constant if the spacing  $R$  corresponds to an energy minimum. This is not the case.

The criterion  $F(R, \kappa) = C$  is a very sensitive test of the force-balance picture. This can be seen in Fig. 1, where the values of  $R$  and  $\kappa$  satisfying  $F(R, \kappa) = C$  are plotted for  $C = 0.01, 0.1, 5, 50$ , and  $100 \text{ \AA}^{-2}$ ; the experimental points are included as well. Note that there are very few experimental points, and that a relatively small error in spacing suggests a large variation in  $C$ . In fact, any value of  $C$  between 5 and 100 seems to be a reasonable choice based on available data. Unreported experimental error might be one cause of the irregular behaviour of the points plotted on Fig. 1.

The points at 186 and 182  $\text{\AA}$  correspond to surface-surface distances that are much too small for the present theory to be quantitative. We have chosen a rod radius of 90  $\text{\AA}$  for the calculations. The TMV particle is a composite structure built of subunits some 25  $\text{\AA}$  apart at the viral surface<sup>21</sup>. These subunits protrude from the viral rod, and units from adjacent parallel rods can dovetail by 30  $\text{\AA}$  (the closest axis-axis distance is 150  $\text{\AA}$  for dry preparations, while accurate X-ray studies<sup>21</sup> on the wet particle suggest a particle diameter of 180  $\text{\AA}$ ). The minimum interaxial distance of 173  $\text{\AA}$  observed by Bernal and Fankuchen is probably accurate, but arises from a 7  $\text{\AA}$  dovetailing of the viral subunits. Given the graininess of the viral

Table 1

$\bar{R}^*$ ( $\text{\AA}$ )	Normality* equivalents ( $l^{-1}$ )	$\kappa$ ( $\text{\AA}^{-1}$ )	$F(R, \kappa)^\dagger$ ( $\text{\AA}^{-2}$ )

\* Experimental values for interaxis spacing  $R$  and normality from Table III of ref. 1, salt =  $(\text{NH}_4)_2\text{SO}_4$ .

† See equation (5)

Fig. 1 The position of force-balance as a function of salt concentration in the bathing medium is plotted here for five values of the constant  $F(R, \kappa) = C$ . a,  $0.01 \text{ Å}^{-2}$ ; b,  $0.1$ ; c,  $5$ ; d,  $50$ ; e,  $100$ , ●, experiment. The experimental points of Bernal and Fankuchen<sup>4</sup> are included for illustrative purposes only, and not as evidence for the propriety of the force-balance picture. The curve for  $C = 0.01 \text{ Å}^{-2}$  ends abruptly at  $R = 198 \text{ Å}$  because no energy minima are found at smaller separations (attraction is always greater than repulsion).

surface it is inappropriate to use equation (5), which assumes a smooth cylindrical surface, for separations  $< 200 \text{ Å}$ .

The theory above assumes that the viral rods will interact in pairs, which is in accord with Coulombic repulsions in salt solutions where the density of the mobile ions exceed the volume density of charges fixed to large particles, that is, where the Debye length of the medium is less than distances between the large bodies. (In fact the salt concentrations used experimentally are probably too high for equation (1) to be used with confidence for the repulsion of two viral particles.) The assumption of pairwise rod-rod attraction conforms well with the criterion that the polarisability of the whole gel is linear in rod density<sup>22</sup>.

### Attractive forces and energy minima

Is there any *a priori* estimate of the constant  $C$  using equation (5)? For computation of the repulsive force, we know that there are probably between one and two ionic charges per protein subunit (D. L. D. Caspar, personal communication). We have estimated a Hamaker coefficient in the context of the Lifshitz formalism<sup>23-27</sup> using spectroscopic data for water at frequencies at up to  $25 \text{ eV}$  (refs 28-29), and for bovine serum albumin in the frequency range  $2-82 \text{ eV}$  (ref. 30). These data were fitted to the form of damped linear oscillators by the method of Knott and Shrager<sup>31,32</sup>.  $A_H$  was then computed by numerical integration, using the theory of Dzyaloshinskii *et al.*<sup>23-27</sup>. We neglected retardation damping of the van der Waals' force and assumed complete screening<sup>33-36</sup> of the low frequency fluctuations by salt.  $A_H$  was found to be between  $5 \times 10^{-14} \text{ erg}$  and  $9 \times 10^{-14} \text{ erg}$  depending on the accuracy of the optical data.

For a rod with 2,130 subunits per  $3,000 \text{ Å}$  length and a  $90 \text{ Å}$  radius<sup>21</sup>, the constant  $C$  from equation (7) will be roughly between  $0.01$  and  $0.1 \text{ Å}^{-2}$ . This range of values is lower than all values in Table 1 whatever the spacing and salt concentration. That is, inter-rod distances are always greater than those expected from force-balance. Note that  $C$  is independent of the length. This is helpful since viral length can be indeterminate because of end-to-end aggregation of viral particles<sup>37</sup>. Since our theory does not apply to the experimental conditions of Bernal and Fankuchen, one cannot draw any firm conclusions. The erratic estimates of the 'constant'  $C$  in Table 1 fall, however, well outside the reasonably expected range.

It further seems that well depths (the interaction energy at the equilibrium separation) are not large, but only  $\lesssim kT$  (ref. 10).

This may be compared to the guess of  $50 kT$  proposed in early work on force balance in muscle<sup>11</sup>. Inclusion of retardation screening of van der Waals' attraction would only weaken the depth of the expected energy minimum.

### Discussion

We expect that attractive forces will not strongly influence the arrangement of rod-like proteins at interaxial spacings  $> 200 \text{ Å}$ . They may be important in circumstances of high concentrations of weakly charged particles. It is now possible to delineate those circumstances more precisely, and to develop a better intuition about the organisation of proteins in experimental systems less accessible but more functional than TMV suspensions.

The most critical examination so far on long range forces in TMV gels is the 1953 study of Gerald Oster<sup>37,38</sup>. Working in a regime of low virus concentrations (2.5% by weight), and very low salt concentrations ( $\sim 5 \text{ mM}$ ), he observed that the addition of electrolyte destroys the gel even while screening repulsive forces. He concluded that repulsion is the dominant factor in ordering; that to within experimental accuracy the Onsager model gave accurate estimates of viral concentrations in both phases, and that attractive forces need not be considered until fairly high viral concentrations, where, in addition, there was almost no electric charge on the particles. In this regime a third, precipitated, iridescent phase has also been observed in TMV, the existence of which is sensitive to electrolyte in the medium<sup>38</sup>.

Our theory supports Oster's view and predicts negligible attraction between cylindrical particles in dilute solution. Since the interesting cases for the packing of linear proteins in other systems occur at higher volume fractions and higher salt concentrations than in Oster's work, it would be worthwhile to extend his observations to this regime to check our theoretical argument.

On this basis, it is possible to describe the experimental situations which would be most amenable to direct analysis. Specifically, one should work with low salt concentrations (probably  $< 0.5 \text{ M}$ ), low net charge densities on the rods (near the isoelectric point,  $\text{pH } 3.3$  (ref. 1, noting that there is zero net charge at  $\text{pH } 4.5$  when salt is absent from the bathing medium (D. L. D. Caspar, personal communication)) at interviral distances larger than the distance between viral subunits ( $21 \text{ Å}$ , ref. 21), and using solutions of monovalent salts rather than divalent or mixed valence salts. In these conditions, one may measure mean interaxial distances  $R$  for rods in the ordered (gel) phase of a two-phase system. These should be measured as a function of salt concentration (or Debye constant  $\kappa$ ) at all  $\text{pH}$  where a two-phase system exists.

The determination of phase diagrams for TMV in water at various  $\text{pH}$  and salt concentrations can facilitate theoretical study. The concentrations of protein in regions of two phases (ordered and disordered) need to be mapped as a function of  $\text{pH}$ , salt concentration and temperature.

The concentration of weakly charged viral particles in the dilute disordered phase can indicate the depth of any significant interparticle energy. The repulsion-only theory suggests that there will be of the order of one particle per  $\pi l^2 d/4$  volume where  $d$  and  $l$  are the effective particle diameter and length. Note that the diameter  $d$  is here an effective diameter, because of electrostatic repulsion, and  $l$  may be an effective length due to end-to-end aggregation<sup>37,39</sup>. They will be greater than the physical dimensions of the virus and be sensitive to salt concentration. If there is a strong binding (a negative energy  $-W$ ) between each particle with its neighbours in the ordered phase, the concentration in the dilute phase will go down as  $\exp(-W/kT)$  and  $W$  will be sensitive to salt concentration. Since this argument is only approximate, the existence of  $W$  will not be demonstrated unless the dilute concentration is qualitatively less than predicted for  $W = 0$ .

On the theoretical side, it would be useful to know the properties of a system of rods having a sloping repulsive potential and

a weak attractive force. This might best be done as a perturbation of the pure hard-rod solution of Onsager since this model seems to include the dominant features of rod ordering<sup>18</sup>. Brenner *et al.*<sup>40,41</sup> have made initial attempts at including a shallow square well potential. Quantitative estimates of rod spacing await a more refined statistical-mechanical theory.

A better explanation of ordering in TMV arrays is needed before reliable conclusions can be drawn on the questionable role of balancing forces among muscle proteins<sup>2,3,10-12,42-44</sup> or among proteins from other cells. We do not believe that long range protein attraction is a strong determinant of order in either viral or cellular protein arrays.

# Reiteration frequency of the gene for tissue-specific histone H5 in the chicken genome

A. C. Scott & J. R. E. Wells

Department of Biochemistry, University of Adelaide, Adelaide, South Australia 5001

*Chicken erythroid cells contain a tissue specific histone known as H5 in addition to the five major histone species found in other organisms. The mRNA coding for this histone has been isolated by indirect immunoprecipitation from immature, non-dividing reticulocytes in which this is the only histone synthesised. The mRNA has been modified by the enzymatic addition of a 3' polyadenylic acid tract, and transcribed into complementary DNA (cDNA) using the RNA-dependent DNA-polymerase from avian myeloblastosis virus. Studies on the hybridisation of this cDNA indicate that the gene coding for the H5 histone is reiterated 10 times in the chicken genome.*

ANALYSIS of the eukaryotic genome is difficult because of the complexity of the DNA and the presence of sequences which are repeated many times<sup>1,2</sup>. Nevertheless the kinetics of reassociation of pure mRNA, or its complementary DNA (cDNA) back to the total DNA of the genome, can be used to calculate the reiteration frequency of specific gene sequences. Such hybridisations have shown that many mRNAs, including those for globin<sup>3,4</sup>, silk fibroin<sup>5</sup>, and ovalbumin<sup>6</sup>, are transcribed from unique sequences in the DNA. It has been demonstrated that most of the mRNA in a variety of cells is transcribed from this 'unique' fraction of the DNA<sup>7-9</sup>. Two exceptions to this are the genes for feather keratins<sup>10</sup>, and histones<sup>11,12</sup> which are both found in the 'moderately repetitive' DNA. The histone genes in sea urchin embryos are present as tandemly repeated blocks

reiterated some 400-1,000 times (species variation) in the genome<sup>11,13</sup>. Cross hybridisation experiments indicate that the histone genes are also reiterated in the *Drosophila*<sup>14</sup> and *Xenopus*<sup>15</sup> genomes. Recent results show, however, that these genes are only reiterated some 10-20-fold in the genome of man<sup>15</sup> and mouse (quoted in ref. 15).

Histone gene reiteration frequencies have all been calculated from experiments in which highly labelled mRNA coding for all five histones was used as a probe. The nucleated red blood cells of birds, amphibians, and fish contain a sixth tissue-specific histone species known as H5 (ref. 16; the nomenclature is taken from reference 17). It has been suggested that this histone is involved in the final termination of transcription in these cells<sup>18</sup>. H5 is the only histone produced by the immature non-dividing reticulocyte<sup>19</sup> and its synthesis is therefore independent of DNA synthesis, unlike that of the other histones<sup>20,21</sup>. The mRNAs coding for these other histones are detectable only during S-phase and are rapidly turned over on cessation of DNA synthesis<sup>22,24</sup>. H5 mRNA on the other hand must be quite stable in the absence of DNA synthesis and thus subject to quite different controls. Whatever the biological significance of this, from a practical viewpoint it enables us to isolate the mRNA for a single histone species<sup>25</sup>. We report here the isolation of this mRNA, its transcription to produce cDNA, and the use of this cDNA to estimate the reiteration frequency of the gene coding for this highly unusual histone in the chicken genome.

## Isolation of H5 mRNA

Although H5 is the only histone produced by the avian reticulocyte<sup>19</sup>, the main protein product of this cell

**Fig. 1** *a*, Profile at 260 nm of sucrose gradient containing RNA from H5-synthesising polysomes. Chicken polysomes were prepared as described<sup>25</sup> and diluted to 25  $A_{260}$  units  $\text{ml}^{-1}$  in 25 mM Tris (pH 7.6), 25 mM NaCl, 5 mM  $\text{MgCl}_2$ , 1  $\mu\text{g ml}^{-1}$  Trichodermin (Leo Pharmaceutical Products), 0.1  $\text{mg ml}^{-1}$  heparin. An aliquot (40  $\mu\text{g ml}^{-1}$ ) of rabbit anti-H5 (purified as described<sup>25</sup>) was added and the mixture incubated at 0 °C for 1 h. The antibody-polysome complexes were then precipitated by the addition of purified goat anti-rabbit immunoglobulin (1 mg per 30  $\mu\text{g}$  anti-H5). After 2 h at 0 °C (ref. 27) the precipitate was washed<sup>28</sup> to remove non specifically bound polysomes, and the RNA from the remaining polysomes was extracted with phenol<sup>29</sup>. This RNA was disaggregated in formamide, diluted, and centrifuged through a 10–40% (w/v) sucrose-sodium dodecyl sulphate (SDS) gradient<sup>25</sup> in a Beckman SW41 centrifuge rotor at 40,000 r.p.m. for 16 h. The fraction indicated by the bar was pooled and further purified as below. *b*, Profile at 260 nm of sucrose gradient containing purified H5 mRNA. The RNA described above was purified by 2 cycles of oligo(dT)-cellulose chromatography<sup>30</sup>, and the unbound RNA was then treated with formamide, diluted and centrifuged as above.

is globin<sup>25</sup>. Furthermore, since the expected size of the H5 mRNA is very close to that of globin mRNA<sup>25</sup>, it is impossible to use techniques based solely on the size of the mRNA to purify it. This has prompted the adoption of immunological methods to separate H5-producing polysomes. Indirect immunoprecipitation<sup>26</sup> is used to maximise the yield of H5 mRNA while minimising contamination with other mRNAs, especially globin mRNA. RNA was extracted from the polysomes<sup>29</sup>, and the 8–12S RNA separated on sucrose gradients (Fig. 1*a*). Polyadenylic acid-containing RNA was removed by two passages through oligo(dT)-cellulose and the unbound H5 mRNA repurified by further sucrose gradient fractionation. The 10S RNA thus produced (Fig 1*b*) did not act as a template for AMV RNA-dependent DNA-polymerase in conditions in which chicken globin mRNA was transcribed to 70% efficiency. This property, together with the lack of binding to oligo(dT)-cellulose, suggests that H5 mRNA is similar to other histone mRNAs in not having a 3' polyadenylic

acid tract<sup>31,32</sup>. The H5 mRNA can be efficiently translated in the wheat embryo cell-free translation system to produce a single major product which coelectrophoreses with a  $^{14}\text{C}$ -labelled H5 standard, on two different polyacrylamide gel systems (Fig. 2). The 10S mRNA thus contains very little translatable globin mRNA and the only mRNA detectable is that coding for H5. This does not exclude the possibility that 10S-sized non-mRNA contaminants are present in the RNA however.

### Production and characterisation of H5 cDNA

In reactions which involve reassociation of trace amounts of a specific probe to a vast excess of total genomic DNA<sup>36</sup> it is essential that the probe is labelled to a high specific activity. This condition is fulfilled by the cDNAs produced from purified mRNA by AMV RNA-dependent DNA-polymerase, since highly labelled deoxynucleotide triphosphates are used as substrates<sup>37</sup>. A further advantage is that such cDNA probes do not suffer from the instability problems associated with RNA probes<sup>38</sup>. H5 mRNA was not, however, copied by the enzyme due to the absence of a 3' polyadenylic acid tract. This tract hybridises to short pieces of oligo(dT) which then act as a primer for the enzyme<sup>39</sup>. A short stretch of adenylic acid residues was therefore added to the 3' end of the mRNA, by an ATP-polynucleotidyltransferase prepared from maize<sup>40</sup>. The modified mRNA was then transcribed into cDNA and

**Fig. 2** Analysis on polyacrylamide gels of the translation products of H5 mRNA *in vitro*. H5 mRNA (0.5  $\mu\text{g}$ ) was translated in the wheat embryo cell-free system of Shih and Kaesberg<sup>33</sup> modified as described<sup>25</sup>. The labelled cell-free products were electrophoresed on *a* the SDS-urea gels of Swank and Munkres<sup>34</sup> and *b* the low pH urea gels of Panyun and Chalkley<sup>36</sup> as modified<sup>19</sup>. The gels were then sliced and radioactivity measured as described<sup>25</sup>.  $\blacktriangle$ — $\blacktriangle$   $^3\text{H}$ -labelled product of translation *in vitro*;  $\cdots$   $^{14}\text{C}$ -labelled H5 standard. Electrophoresis is from left to right in both cases. The  $^{14}\text{C}$  counts accounted for 10% spillover into the  $^3\text{H}$  channel and this was subtracted. The position of a  $^{14}\text{C}$  globin standard is indicated.

**Fig. 3** Estimation of the size of the cDNA produced from polyadenylated H5 mRNA. H5 mRNA (1  $\mu$ g) was incubated at 30 °C for 3 h in a 30- $\mu$ l incubation mix containing 70 mM Tris-acetate (pH 8.6), 10 mM dithiothreitol, 1 mM ATP, 1 mM  $MnCl_2$  and 50  $\mu$ g  $ml^{-1}$  of ATP-poly nucleotidyl transferase. The modified RNA was then ethanol precipitated and cDNA was synthesised from it, in the same tube, as described<sup>10</sup>. A portion of the purified cDNA was then electrophoresed on 4% polyacrylamide gels containing formamide<sup>47</sup>. 4S, 5S, 18S and 28S RNA were included as internal markers. Following electrophoresis the gels were scanned at 280 nm and then sliced and the pattern of radioactivity determined<sup>48</sup>.

formamide gel analysis of the product indicated an average length of 450 nucleotides (Fig. 3).

Although little other mRNA translational activity was detectable in the H5 mRNA preparation (Fig. 2), 10S-sized ribosomal RNA (rRNA) breakdown products have been described<sup>38</sup>. It is theoretically possible that the cDNA was preferentially copied from such contaminating RNA and it was therefore essential to prove that the cDNA made was complementary to H5 mRNA, and not to such contaminants. Since the two likely contaminating RNA species in the H5 mRNA preparation were rRNA and globin mRNA, this was readily tested by hybridising the cDNA to purified globin mRNA, 18S rRNA and 28S rRNA. The hybridisations were carried out in RNA excess and taken to a  $R_0t$  of 1 to ensure completion of the reaction. Hybrids were then assayed with S1 nuclease, a single-strand specific nuclease isolated from *Aspergillus*<sup>41</sup>. The data from such experiments allowed a direct estimate of the percentage of sequences in the cDNA preparation which were complementary to these different RNAs and are given in Table 1. The results show that H5 cDNA is contaminated only to about 3% with sequences complementary to rRNA (largely to 18S RNA) and a similar amount complementary to globin mRNA. If the globin mRNA used in these hybridisations had not, however, been purified by oligo(dT)-cellulose chromatography, then 85% of the H5 cDNA was protected from S1 degradation by the formation of hybrids (Table 1). This is merely indicative of the fact that chicken globin mRNA

**Table 1** Extent of cross hybridisation of H5 cDNA

RNA added	$R_0t$ (mol s $l^{-1}$ )	Hybridisation (%)
18S rRNA	$6.8 \times 10^{-1}$	2.2
28S rRNA	$7.2 \times 10^{-1}$	1.0
'Crude' globin mRNA	$5.0 \times 10^{-1}$	85.4
'Purified' globin mRNA	$5.5 \times 10^{-1}$	3.0
H5 mRNA	$3.0 \times 10^{-1}$	89.0

H5 cDNA 2000 c.p.m. was hybridised to several electrophoretically pure RNA samples to the indicated  $R_0t$  values. The percentage of cDNA hybridised was then calculated by S1 nuclease assays. The percentage has been corrected by subtraction of the background due to S1-insensitive counts (about 4%). The 'crude' and 'purified' chicken globin mRNA refer to the same sample before and after purification by oligo(dT)-cellulose chromatography (see text).

preparations which have not been purified by oligo(dT)-cellulose chromatography<sup>42</sup>, contain a small amount of H5 mRNA. Because these hybridisations are done in a vast excess of RNA (compared with cDNA), sufficient of this contaminating H5 mRNA hybridises to protect 85% of the H5 cDNA from degradation by S1.

The kinetics and extent of the back-hybridisation of the H5 cDNA to excess, unlabelled H5 mRNA, can also provide some information about the fidelity of the copying of mRNA into cDNA. The kinetics of this hybridisation reaction are dependent on the sequence complexity of the mRNA and this can be estimated by comparison with a kinetic standard<sup>10</sup>. The standard used was the hybridisation of rabbit globin mRNA to its cDNA, and as determined by resistance of the hybrids to S1 nuclease, these hybridise in a sharp transition with a mid-point ( $R_0t_{1/2}$ ) of

**Fig. 4** Hybridisation of H5 mRNA and rabbit globin mRNA to their respective cDNAs. The reaction mixtures (50  $\mu$ l) contained 2,000 c.p.m. of H5 cDNA or 5,000 c.p.m. of globin cDNA, and varying amounts of mRNA. Hybridisation and S1 assays were as described<sup>10</sup>. ■—■, H5 mRNA-cDNA; ▲—▲, globin mRNA-cDNA.

$5 \times 10^{-4}$  (Fig. 4). This corresponds to a complexity of about 1,300 nucleotides for  $\alpha$  plus  $\beta$  globin mRNA, since it is known that cDNA probes to these two mRNAs do not cross hybridise to any appreciable extent<sup>13</sup>. In contrast, H5 mRNA hybridises to its cDNA with a similar sharp

Fig. 5 Reassociation of H5 cDNA with excess chicken reticulocyte nuclear DNA. Three separate hybridisations were carried out in high salt buffer and the percent hybridisation assayed with nuclease S1 as described<sup>10</sup>. The three samples were: ●—●, H-chicken DNA-DNA; □—□, H5 cDNA-DNA; ■—■, chicken globin cDNA-DNA.

transition but with a  $R_{0.1/2}$  of about  $2.8 \times 10^{-4}$  (Fig. 4). This corresponds to a complexity of some 730 nucleotides which is the approximate size of the H5 mRNA (Fig. 1b). This indicates that H5 is coded by a single species of mRNA. The low  $R_{0.1/2}$  value and the sharpness of the transition also indicate that the H5 mRNA is not contaminated to any significant extent with other mRNAs.

### H5 gene reiteration frequency

The reiteration frequency of the H5 gene can be estimated by annealing the cDNA from H5 mRNA with a vast excess of total chicken DNA<sup>16</sup>. To determine the  $C_{0.1/2}$  for unique sequences, chicken globin cDNA was reannealed to chromosomal DNA and a mid-point ( $C_{0.1/2}$ ) of  $1.2 \times 10^2$  was obtained (Fig. 5). This is very similar to the  $C_{0.1/2}$  for the reassociation of total chicken DNA unique sequences (Fig. 5 and ref. 6), and is indicative of the fact that there are only 1 or 2 copies of the globin genes in the chicken genome. The hybridisation of H5 cDNA to chromosomal RNA, on the other hand, has a  $C_{0.1/2}$  of  $1.2 \times 10^2$  which means that the rate of the reaction is an order of magnitude faster than the unique rate. Since the globin and H5 cDNAs are of similar size and their G+C content is probably very similar (on the basis of the amino acid

analysis of the proteins), then this difference in rate must reflect a reiteration of the H5 gene in the chicken genome. The extent of reiteration is directly proportional to the  $C_{0.1/2}$  value compared with the kinetic standard<sup>16</sup>, and so the H5 gene is reiterated about 10 times. Furthermore, as the hybridisation goes to over 70% completion, the minor contaminating species in the H5 cDNA are not responsible for the reaction.

We have therefore demonstrated that the gene coding for H5 histone is reiterated in the chicken genome as are histone genes in all other organisms examined. The extent of reiteration is similar to that found in man<sup>15</sup> and mouse<sup>15</sup> but far less than is found in sea urchins<sup>11</sup>. The reason for the clustering of histone genes in sea urchins<sup>11,12,44</sup> is unknown but may be involved in the coordinate control of histone synthesis or in the linkage of histone mRNA synthesis to DNA synthesis<sup>23,45,46</sup>. Since H5 is subject to neither of these controls, and indeed is made only in red blood cells, the presence or absence of clustering of H5 genes with other histone genes may shed some light on this phenomenon. We are currently investigating the organisation of H5 histone genes in relation to other histone genes in the chicken genome.

We thank Dr J. W. Beard for the gift of purified AMV polymerase and Mr R. Crawford for supplying the globin cDNA.

# Organisation of the genes coding for 5S RNA in the Chinese hamster

Peter J. Stambrook

Case Western Reserve University, Department of Biology, Cleveland, Ohio 44106

*Hybridisation of iodinated mouse 5S RNA with Chinese hamster DNA fractionated on a CsCl gradient, identifies two separate DNA components that hybridise with the labelled probe. One component is slightly, and one considerably heavier than the main band DNA. This suggests that the gene coding for 5S RNA in the Chinese hamster may constitute two distinct populations differing in G+C content of their adjacent spacer regions.*

THE organisation of the genes coding for ribosomal 5S RNA in eukaryotes has been best studied in the frog *Xenopus*<sup>1,2</sup>. In this system the 5S genes occur as clusters of tandem repeats of alternating transcribed and non-transcribed nucleotide sequences which have been localised at the ends of most of the chromosomes by *in situ* hybridisation<sup>3</sup>. Analysis of the primary sequence of 5S ribosomal RNA (rRNA) has revealed two populations differing slightly in nucleotide sequence. One population is found predominantly in oocytes, the other in somatic cells<sup>4,5</sup>. In contrast to *Xenopus*, information regarding the organisation of the 5S genes in mammals is sparse. The organisation of these genes in the Chinese hamster was studied by examining their buoyant density characteristics in isopycnic CsCl gradients and here I report the results.

DNA from Chinese hamster V79 tissue culture cells was centrifuged to equilibrium in neutral CsCl. The gradients were fractionated and the DNA in each fraction was denatured and trapped on nitrocellulose filters as described previously<sup>6</sup>. To localise the 5S genes within the gradients, the DNA in each fraction was hybridised with <sup>125</sup>I-labelled 5S RNA obtained from a mouse liver ribosomal pellet. The mouse 5S RNA was prepared by gel filtration on a 90-cm Sephadex G-100 column and on acrylamide gel electrophoresis ran as a sharp band, well separated from a tRNA marker. Iodination was by the procedure described by Prenskey *et al.*<sup>7</sup>, yielding an RNA with specific activity of  $\sim 5 \times 10^6$ – $10^7$  c.p.m.  $\mu\text{g}^{-1}$ .

## Hybridisation with mouse 5S RNA

Mouse 5S RNA was selected as a probe for detecting the Chinese hamster 5S genes, so as to reduce the amount of hybridisation by RNAs contaminating the 5S RNA preparation. The nucleotide sequence of Chinese hamster 5S RNA (ref. 8) is virtually identical to that of other mammals examined<sup>9–12</sup> so mouse 5S RNA should hybridise faithfully to the Chinese hamster DNA, whereas contaminating RNA degradation products which are copurified with the 5S RNA, should cross hybridise poorly, if at all.

When the fractionated Chinese hamster DNA was hybridised with the mouse <sup>125</sup>I-5S RNA preparation, hybridisation occurred as a single broad peak with a shoulder on the heavy side of the DNA (Fig. 1a). The position of the radioactivity is reminiscent of the position at which the Chinese hamster ribosomal genes band in neutral CsCl<sup>6</sup>, suggesting that in addition to hybridisation of 5S RNA sequences, hybridisation of rRNA degradation

products which had been copurified with the 5S RNA, and which should also effectively cross hybridise with Chinese hamster DNA was also being detected.

To test the extent to which labelled ribosomal degradation products were contributing to the hybridisation shown in Fig. 1a, the DNA from fractions of a parallel gradient, which had been prepared at the same time, was hybridised with the same number of input counts of labelled mouse 5S RNA, but this time in the presence of an excess amount of unlabelled Chinese hamster rRNA (25  $\mu\text{g ml}^{-1}$ ). The results (Fig. 1b) show that about half of the hybridised radioactivity was taken out

**Fig 1** Hybridisation of iodinated mouse 5S RNA to Chinese hamster DNA. Chinese hamster DNA (50  $\mu\text{g}$ ) with a molecular weight of about  $10^7$  was fractionated in each of three identical CsCl gradients. The DNA of each fraction was denatured, trapped on nitrocellulose filters and hybridised with <sup>125</sup>I-mouse 5S RNA in the presence of the appropriate competing RNA. *a*, Chinese hamster DNA (50  $\mu\text{g}$ ) hybridised with a <sup>125</sup>I-mouse 5S RNA preparation ( $3 \times 10^6$  c.p.m. per 3 ml). *b*, Chinese hamster DNA (50  $\mu\text{g}$ ) hybridised with <sup>125</sup>I-mouse 5S RNA ( $3 \times 10^6$  c.p.m. per 3 ml) plus unlabelled Chinese hamster rRNA (25  $\mu\text{g ml}^{-1}$ ). *c*, Chinese hamster DNA (50  $\mu\text{g}$ ) hybridised with <sup>125</sup>I-mouse 5S RNA ( $3 \times 10^6$  c.p.m. per 3 ml) in the presence of unlabelled Chinese hamster rRNA (25  $\mu\text{g ml}^{-1}$ ) plus unlabelled *X. laevis* oocyte 5S RNA (20  $\mu\text{g ml}^{-1}$ ). —,  $A_{260}$ ; ●, radioactivity.

by competition, and that the radioactivity remaining resided in two discrete peaks, one considerably denser than the bulk of the DNA and the other only slightly heavier than the main band. To explore the possibility that these two peaks are due to hybridisation by sequences contained in 5S RNA, an additional competition hybridisation experiment was performed. The DNA in fractions from a third gradient, prepared at the same time as the previous two, was hybridised with the mouse <sup>125</sup>I-labelled 5S RNA preparation in the presence of unlabelled Chinese hamster rRNA (25  $\mu\text{g ml}^{-1}$ ) plus excess unlabelled 5S RNA (20  $\mu\text{g ml}^{-1}$ ) prepared from *Xenopus laevis* oocytes (a gift from Dr Ronald Brown). A 5S RNA competitor from such a distant evolutionary source was selected to reduce as much as possible the inclusion of RNAs that might contaminate the 5S RNA preparation and cross hybridise with the Chinese hamster DNA. If one of the radioactive peaks in Fig. 1b

represents hybridisation by a contaminating RNA in the mouse liver 5S RNA preparation, one would expect that in the presence of unlabelled rRNA and *Xenopus* oocyte 5S RNA one peak would disappear and the other, due to the contaminant, would remain intact. When the hybridisation reaction was performed in the presence of the two competing RNA populations, both peaks of radioactivity were virtually eliminated (Fig. 1b).

It is important to exclude any artefacts such as physical trapping of 5S DNA in the main band as the source of the hybridising material in the larger peak. To this end a series of four experiments, described in Fig. 2, was performed. Two 25-ml CsCl gradients each containing 1 mg of Chinese hamster DNA sheared to a molecular weight of about  $5 \times 10^6$  daltons were fractionated, and the heavy regions of the gradients containing the smaller peak of hybridisation were retained. The heavy region of one gradient was mixed with 100  $\mu$ g *Escherichia coli* DNA and that of the second gradient was mixed with 100  $\mu$ g Chinese hamster DNA. The DNA mixtures were banded in neutral CsCl, the gradients fractionated, and the DNA in each fraction hybridised with  $^{125}$ I-labelled mouse 5S RNA in the presence of a rRNA competitor. *E. coli* DNA has a 50% G+C content and as predicted bands at a density of 1.710 g cm $^{-3}$  (Fig. 2a). The peak of 5S RNA hybridisation occurs at a density of 1.718 with no significant hybridisation associated with the bulk of the *E. coli* DNA, indicating that physical trapping of 5S DNA sequences in the gradient has not occurred.

Fig. 2 Hybridisation to Chinese hamster ribosomal and 5S genes in a neutral CsCl gradient. A CsCl gradient containing 100  $\mu$ g Chinese hamster DNA was fractionated and DNA from each fraction was denatured and adsorbed on to nitrocellulose filters. The filters were cut in half and one set of filter halves was hybridised with  $^{125}$ I-mouse 5S RNA in the presence of unlabelled Chinese hamster rRNA (25  $\mu$ g ml $^{-1}$ ). The second set of filter halves was hybridised with  $^3$ H-ribosomal cRNA from *X. laevis* (provided by Dr Donald D. Brown). The *Xenopus* ribosomal cRNA hybridises specifically with sequences complementary to 18S and 28S RNA within the Chinese hamster genome<sup>6</sup>. The results described in Fig. 3 show that the ribosomal genes band directly between the two peaks of radioactivity generated by hybridisation of the mouse  $^{125}$ I-5S RNA preparation, thus excluding hybridisation by rRNA sequences as a source for either of the peaks. These results are also consistent with the observation that Chinese hamster rDNA has a buoyant density of 1.708 as determined by analytical ultracentrifugation of a partially purified rDNA preparation (unpublished data).

When *E. coli* DNA alone was banded in CsCl and hybridised with  $^{125}$ I-labelled 5S RNA, no radioactivity was retained on the filters (Fig. 2b), eliminating the exchange of radioactive iodine from the RNA probe to the DNA on the filters as the

source of the larger peak of radioactivity. When Chinese hamster DNA, containing the additional heavy DNA from the larger gradient, was banded in CsCl and hybridised, the bulk DNA banded as expected at a density of 1.700 (Fig. 2c). Hybridisation results in two peaks of radioactivity at 1.718 and 1.702, with the heavier peak substantially enriched. The important observation is that both radioactive peaks band faithfully at their predicted densities. In a situation where the region of a gradient containing the heavy peak has been removed and the DNA is rebanded in CsCl, only one peak of radioactivity at a density of 1.702 is revealed on subsequent fractionation and hybridisation (Fig. 2d). The combined results of these experiments confirm that the two peaks of radioactivity obtained on hybridisation with  $^{125}$ I-labelled 5S RNA reflect true populations of DNA that band faithfully at densities of 1.718 and 1.702 respectively.

The possibility remains that one of the two radioactive peaks is due to residual hybridisation of labelled rRNA degradation products and that the added *Xenopus* 5S RNA in Fig. 1c contains sufficient rRNA sequences to complete the competition. This interpretation was eliminated by an experiment in which the DNA from fractions of a gradient was trapped on nitrocellulose filters and the filters cut in half. One set of filter halves was hybridised with mouse  $^{125}$ I-labelled 5S RNA in the presence of excess unlabelled rRNA and the other set of filter halves was hybridised with a ribosomal  $^3$ H complementary RNA (cRNA) synthesised from purified *Xenopus* rDNA (provided by Dr Donald D. Brown). The *Xenopus* ribosomal cRNA hybridises specifically with sequences complementary to 18S and 28S RNA within the Chinese hamster genome<sup>6</sup>. The results described in Fig. 3 show that the ribosomal genes band directly between the two peaks of radioactivity generated by hybridisation of the mouse  $^{125}$ I-5S RNA preparation, thus excluding hybridisation by rRNA sequences as a source for either of the peaks. These results are also consistent with the observation that Chinese hamster rDNA has a buoyant density of 1.708 as determined by analytical ultracentrifugation of a partially purified rDNA preparation (unpublished data).

## Organisation of 5S RNA genes

The data obtained from these experiments allow three interpretations. The first is that a mouse liver polysomal pellet and *Xenopus laevis* oocytes contain an RNA in common that is neither 5S RNA, rRNA nor tRNA, and which hybridises effectively with Chinese hamster DNA. Although unlikely, this possibility has not, as yet, been completely excluded.

A second interpretation would argue that 5S genes occur as a series of clusters within blocks of high G+C non-5S DNA. The rationale is that two peaks of hybridisation can be generated by random breakage of DNA which would result in pure 5S DNA molecules from the internal region of the cluster and a small fraction of 5S DNA molecules containing varying amounts of the external high G+C non-5S DNA. Such a distribution seems unlikely for at least two reasons. First, one would predict that as the DNA is sheared to a smaller size the amount of radioactivity contributed by the smaller peak should decrease, yet the ratio of small peak to large peak remains relatively constant for DNAs between  $5 \times 10^6$  and  $2 \times 10^7$  daltons. When the DNA is further sheared to between  $5 \times 10^5$  and  $7 \times 10^5$  daltons, hybridisation occurs as a single broad band with a peak of radioactivity at about 1.715 g cm $^{-3}$  (unpublished). These data, however, cannot distinguish between a single component comprising a broad band with a peak at 1.715 g cm $^{-3}$  and two components of different buoyant density that cannot be resolved. Second, since the fragments containing the external regions should be heterogeneous with respect to their content of high G+C DNA, one would expect such fragments to band as a broad smear in the heavy part of the gradient. In fact, however, the smaller peak of radioactivity bands sharply,

Fig. 3 Rebanding of the DNA hybridising with  $^{125}\text{I}$ -5S RNA. *a*, Chinese hamster DNA banding at  $1.718\text{ g cm}^{-3}$  from a 25-ml  $\text{CsCl}$  gradient containing 1 mg DNA (sheared to  $5 \times 10^6$  daltons) was added to 100  $\mu\text{g}$  *E. coli* DNA (about  $10^7$  daltons). This DNA mixture was recentrifuged in neutral  $\text{CsCl}$ , the gradient was fractionated, and the DNA was hybridised with mouse  $^{125}\text{I}$ -5S RNA in the presence of rRNA competitor. *b*, *E. coli* DNA was banded in neutral  $\text{CsCl}$ , the gradient was fractionated, and the DNA in each fraction was hybridised with mouse  $^{125}\text{I}$ -5S RNA in the presence of a rRNA competitor. *c*, Chinese hamster DNA banding at  $1.718\text{ g cm}^{-3}$  from a 25-ml  $\text{CsCl}$  gradient containing 1 mg DNA ( $5 \times 10^6$  daltons) was added to 100  $\mu\text{g}$  Chinese hamster DNA ( $5 \times 10^6$ ) and recentrifuged in  $\text{CsCl}$ . The gradient was fractionated, the DNA hybridised with mouse  $^{125}\text{I}$ -5S RNA in the presence of a rRNA competitor. *d*, 100  $\mu\text{g}$  Chinese hamster DNA was centrifuged in neutral  $\text{CsCl}$  and the region banding at  $1.718\text{ g cm}^{-3}$  was removed. The remaining DNA was recentrifuged in  $\text{CsCl}$ , the gradient was fractionated and the DNA in each fraction hybridised with mouse  $^{125}\text{I}$ -5S RNA in the presence of a rRNA competitor. All gradients were centrifuged at the same time in a Beckman 50 Ti rotor. The filters containing the denatured DNA from all four gradients were incubated together in a reaction mixture containing 50% formamide,  $4 \times \text{SSC}$ , Chinese hamster rRNA ( $25\text{ }\mu\text{g ml}^{-1}$ ) and mouse  $^{125}\text{I}$ -5S RNA ( $1.2 \times 10^6\text{ c.p.m. per } 12\text{ ml}$ ) at  $37^\circ\text{C}$  for 30 h. The density profile of each gradient was determined from the refractive index of a 4- $\mu\text{l}$  aliquot from every fifth fraction. —  $A_{260}$ ; ---, radioactivity; O—O, density.

multiple populations of 5S genes since such heterogeneity has already been demonstrated in *X. laevis*<sup>4,5</sup>, and since in human cells, 5S genes may be scattered in a large number of chromosomes<sup>13</sup>. In HeLa cells, molecular hybridisation studies with fractionated chromosomes have suggested that the 5S genes numbering about 2,000 per haploid genome<sup>14</sup> are contained on chromosomes of all size classes with some enrichment in the largest size group<sup>13</sup>. *In situ* hybridisation with chromosomes of human diploid cells has suggested that a cluster of 5S genes is located on chromosome 1, although scattered grains were also observable over many of the other chromosomes<sup>15,16</sup>. In *X. laevis*, two gene populations were detected by differences in the primary sequence of the 5S RNAs themselves<sup>4,5</sup> rather than by differences in their spacer DNAs. Genes coding for 5S RNA have been isolated from both *X. laevis* (1) and *X. mulleri* (2) and in both cases, the spacer regions constitute most of the 5S DNA. Since the transcribed regions of *X. laevis* and *X. mulleri* 5S DNA comprise only 6 and 14% respectively of the 5S DNA<sup>2</sup>, the behaviour of this DNA in isopycnic gradients depends more on the base composition of the spacer than the transcribed region. If the same relationship between spacer and transcribed DNA exists in the 5S DNA of mammals, subpopulations of this gene differing primarily in the base composition of the spacer should be detectable in isopycnic gradients and should yield similar results to those presented in these experiments.

I thank Delores Sommerville, Bessie Smith and Estrella Feliciano for technical assistance, and Drs Ronald Brown, Douglas Caston and Igor Dawid for helpful discussions. This work was supported in part by the Carnegie Institution of Washington and the US Institutes of Health.

indicating a relatively homogeneous population of molecules.

A third interpretation of the results is that the Chinese hamster genome contains two populations of genes that code for 5S RNA but which differ in the G+C content of their adjacent spacer regions. Such differences in base composition of the spacer would confer different buoyant densities on the two gene populations in  $\text{CsCl}$  and would result in the two peaks of radioactivity generated by hybridisation. Since the G+C content of mammalian 5S RNA is 60% (refs 9–12), the corresponding DNA should have a buoyant density of  $1.720\text{ g cm}^{-3}$ . The lighter population bands at  $1.702\text{ g cm}^{-3}$  and should therefore have an A+T-rich spacer. The smaller and heavier population bands at  $1.718\text{ g cm}^{-3}$  and would therefore be predicted to contain a spacer with a base composition much like that of the transcribed region. Unequivocal identification of both peaks of radioactivity as 5S genes will require the demonstration that the RNAs hybridising in each peak are 5S RNA, and experiments to that end are currently in progress.

It is not unreasonable to expect mammalian cells to contain

# letters to nature

## Origin of the black hole in Cyg X-1

THE evidence that Cygnus X-1 is a black hole of mass  $\gtrsim 9M_{\odot}$  (ref. 1) is not conclusive, but is sufficient to warrant some consideration of the implications of such an object for the late stages of stellar evolution. We argue here that such a black hole must form directly by implosion of a star of mass  $\gtrsim 30M_{\odot}$  rather than by accretion on to a neutron star. The Galaxy may contain  $\sim 10^7$  such massive black holes.

Supernova models based on either the degenerate cores of intermediate mass stars ( $4-8M_{\odot}$ , see ref. 2) or the iron cores of more massive stars<sup>3</sup>, suggest a collapsing core of initial mass  $\sim 1.4M_{\odot}$  and hence a final gravitational mass of  $\sim 1.2M_{\odot}$ . In the more massive stars the collapse of some material of lower atomic weight than iron might increase the final mass somewhat (W. D. Arnett, private communication). The estimated masses for the X-ray sources Her X-1 ( $\sim 1.3M_{\odot}$ , A. B. Middleton and C. D. Nelson, unpublished), Cen X-3 ( $0.6-1.1M_{\odot}$ , ref. 1), and Vela X-1 ( $1.6-2.1M_{\odot}$ , refs 4, 5), which are almost certainly neutron stars because of their X-ray pulsations, accord well with these estimates and with recent calculations of the maximum mass of neutron stars  $M_{\text{lim}} \sim 1.5M_{\odot}$  (ref. 6) to  $2.4M_{\odot}$  (ref. 7). For sources without periodic X-ray variations, the mass estimates are less certain; however, with the exception of Cyg X-1, the estimated masses cluster  $\sim 1-2M_{\odot}$  (see Table 1). In summary, all known binary X-ray sources other than Cyg X-1 have masses consistent with those expected for neutron stars somewhat below  $M_{\text{lim}}$  or black holes that are only slightly above  $M_{\text{lim}}$ .

One might envisage two alternative origins for a hole  $\gtrsim 9M_{\odot}$  in Cyg X-1: either it was formed at essentially its present mass by the implosion of a massive star, or it began as a neutron star that grew to its present mass through accretion, during which growth it collapsed into a black hole when it passed  $M_{\text{lim}}$ . We first discuss the second possibility.

The time scale for growth by accretion is restricted by the Eddington limit. For

$$L_X \leq L_{\text{Edd}} = 4\pi c G m_{\text{H}} M / \sigma_T,$$

where  $\sigma_T$  is the Thomson cross section, we have

$$\tau_{\text{grow}} \equiv M/\dot{M} \geq \frac{c\sigma_T}{4\pi G m_{\text{H}}} f = 1.1 \times 10^8 f_* \text{ yr} \quad (1)$$

Here  $f \equiv L/\dot{M}c^2$  and  $f_* \equiv f/0.25$ . Since many X-ray sources seem to radiate at nearly the Eddington limit, it is reasonable to assume that  $\tau_{\text{grow}}$  will be near the lower limit given by equation (1). For black holes, we take  $f_* = 1$  because expected efficiencies are  $f = 0.42$  and  $0.06$  for maximally rotating and

non-rotating holes, respectively<sup>10</sup>. Therefore  $\tau_{\text{BH}} \gtrsim 1.1 \times 10^8 \text{ yr}$ . Since the companion of Cyg X-1 (HDE 226868) has a main sequence lifetime  $\lesssim 5 \times 10^8 \text{ yr}$  for its inferred mass  $\gtrsim 25M_{\odot}$  (ref. 1), Cyg X-1 cannot have grown from  $M_{\text{lim}} \sim 2M_{\odot}$  to  $\gtrsim 9M_{\odot}$  unless  $f_* \lesssim 0.05$ . There is no basis for assuming such a low efficiency, and we conclude that the black hole in Cyg X-1 formed, as such, at nearly its present mass.

Our conclusion, that the black hole of  $\sim 10M_{\odot}$  in Cyg X-1 was formed directly in a stellar implosion, is somewhat surprising because recent work on stellar evolution has indicated that even very massive stars may form only neutron stars of  $M \sim 1.2M_{\odot}$ . Studies by Arnett<sup>3</sup> suggest that massive stars end their lives with the collapse of an iron core of  $M \sim 1.4M_{\odot}$ , regardless of the total mass of the star. Most of these stars must explode leaving only a neutron star remnant, according to arguments involving the abundances of carbon and oxygen in the Universe.

Stars with  $M \gtrsim 10M_{\odot}$  contain layers of carbon and oxygen which can potentially be ejected. By contrast, stellar evolution implies that intermediate and low mass stars can eject no carbon and oxygen; they either trap these elements in white dwarf remnants or convert them to iron peak elements in the process of core collapse and/or explosion. To provide enough carbon and oxygen to the interstellar gas, most stars with  $M \gtrsim 10M_{\odot}$  must eject their CO layers rather than suffer a total collapse. Since the iron cores are nearly identical and their evolution and dynamics seem to be little affected by the total stellar mass, a tempting generalisation is to assume that all massive stars explode with the formation of a neutron star from the iron core.

The creation of a black hole in Cyg X-1 with an initial mass  $\gtrsim 9M_{\odot}$  indicates that this generalisation is not correct. In spite of the homogeneity of Arnett's pre-collapse configurations, the direct formation of a black hole of  $\sim 10M_{\odot}$  implies that an unknown factor, presumably associated with the increasing mass of the post-helium burning core, becomes important for sufficiently large stellar masses. This factor evidently alters either the pre-collapse configuration or the dynamics of the explosion.

A mass of  $10M_{\odot}$  for the black hole is consistent with this picture. One expects the hydrogen envelope to have been transferred from the star which made the black hole to HDE226868 in the course of evolution, so that the object which finally collapsed was a bare core. A core of  $\sim 10M_{\odot}$  would correspond to an initial main sequence mass of  $\sim 30M_{\odot}$  (ref. 3) for the star which formed the black hole. The assumption that HDE226868 now has  $M = 30M_{\odot}$  implies that it originally had a mass of  $\sim 10M_{\odot}$ .

According to Ostriker *et al.*<sup>11</sup>, the local density of stars  $\gtrsim 30M_{\odot}$  is  $\sim 2 \text{ kpc}^{-2}$ . If all such stars make black holes directly and one in ten occurs in a close binary, the density of such systems is consistent with the distance  $\sim 2 \text{ kpc}$  to Cyg X-1 (ref. 12). Many systems would spend their entire main sequence lives obscured within the dense clouds that gave them birth. Over its lifetime, the Galaxy would have produced  $\sim 10^7$  massive black holes.

## Production of heavy elements in nature

We shall describe here a possible mechanism for the production of heavy elements (with  $A > 60$ ): these elements, we suggest, may be formed in the matter ejected from the envelope of a neutron star during the starquake process.

The  $r$ -process (rapid neutron capture) is known to be capable of forming heavy elements, and is believed to take place during a supernova outburst<sup>1</sup>. Calculations<sup>2,3</sup> of a supernova outburst show, however, that the neutron fluxes might be too low to explain the synthesis of heavy elements. Because of this, neutron stars are, in our opinion, among the most promising sites for the nucleosynthesis of heavy elements.

The mechanism of heavy element formation by the fission of the even heavier elements which can exist in neutron-rich nuclear fluid, was proposed by Goepfert-Mayer and Teller<sup>4</sup> in 1947. The discovery of pulsars and their interpretation as neutron stars has provided the ideal initial conditions for the Mayer-Teller model<sup>5,6</sup>. The existence of heavy neutron-rich nuclei was discussed by Zel'dovich<sup>7</sup> and by Brueckner<sup>8</sup>, who considered neutron droplets in conditions of high pressure. Afterwards the chemical composition of neutron-star envelopes at densities  $\rho = 10^{10}$ - $10^{12}$  g cm<sup>-3</sup> was considered<sup>6,9,10</sup>. In such conditions they are made of nuclei with  $A \sim 200$ -500 and free neutrons.

We consider the case where instabilities cause the ejection of matter from the neutron star surface. It will be shown that the evolution of ejected matter ends with the formation of heavy (even superheavy) elements<sup>11</sup>. By contrast with ref. 4, matter composed of neutron-rich nuclei rather than of neutrons only will be considered. The heavy nuclei obtained in this way will be ejected from the magnetosphere of a neutron star, and may enrich interstellar space<sup>12</sup>.

Initially we have nuclei with  $(Z, A)$ , as shown in Fig. 1, point  $a$ . The chemical potential of electrons decreases as the matter expands,

$$\mu_e \sim mc^2 \left( \frac{\rho}{\mu_o \times 10^6} \right)^{1/3}$$

where  $\mu_o$  is the molecular weight of electrons, and is given by

$$\mu_o = \frac{\sum n_i A_i}{\sum n_i Z_i}$$

The  $(Z, A)$  nuclei decay by  $\beta$  emission and the new nuclei  $(Z+1, A)$  will capture free neutrons. We assume that on the boundary of stability, the relation  $Z/A = 1/4$  holds.

Capture of four neutrons

$$\beta \text{ decay } a(Z, A) \rightarrow b(Z+1, A+4)$$

$$(t_{sf} \approx 0.01 \text{ s})$$

$$B_n = 0$$

Fig. 1 Stability of superheavy nuclei. A nucleus at point  $a$  moves by  $\beta$  decay, and capture of neutrons (see inset) to point  $d$ , where it undergoes fission.

For the original nuclei at  $\rho = 10^{10}$  g cm<sup>-3</sup> we have  $Z = 161$ ,  $A = 644$  according to ref. 6. So, the  $\beta$  decay of the  $(Z, A)$  nuclei will be followed by four neutron captures by nuclei  $(Z+1, A)$ —point  $b$  of Fig. 1. The following conditions on the characteristic times will be satisfied:  $t_h \leq t_\beta$ ,  $t_\beta > t_n$ , where  $t_h$ ,  $t_\beta$ , and  $t_n$  are the time scales of hydrodynamic expansion,  $\beta$  decay and  $(n, \gamma)$  reactions, respectively. These time scales are defined by:  $t_h = 446a/\sqrt{\rho}$  in seconds, where  $a$  is an arbitrary scaling parameter,

$$t_n = \frac{m_H}{\alpha \rho \langle \sigma v \rangle}$$

where  $m_H = 1.67 \times 10^{-24}$  g,  $\alpha$  is the partial weight of neutrons in the matter,

$$t_\beta = \frac{6\Delta}{10^{-4} W_o^6}$$

where  $\Delta$  is the density of nuclear states (in all cases we assume  $\Delta = 15$ ) and  $W_o$  is the nuclear mass difference. We use here the notation introduced in ref. 1. For matter in these conditions, the neutron capture cross section  $\sigma \sim 10^{-25}$  cm<sup>2</sup>, mean velocity of neutrons  $v \sim 10^8$  cm s<sup>-1</sup>, so

$$t_n = \frac{10^{-7}}{\alpha \rho}$$

The calculated  $t_\beta$  values are given in Table 1. The characteristic time  $t_\beta$  does not depend on density, and  $t_n$  is inversely proportional to density. Nuclei moving along their 'evolutionary'

path increase their atomic number  $Z$  and approach the region of spontaneous-fission instability. The spontaneous-fission half lives ( $t_{sf}$ ) were calculated using the formula<sup>13</sup>

$$t_{sf} = 10^{-21} \times 10^{7.85 E_b(s)}$$

where

$$E_b = 19.0 - 0.36Z^2/A + \varepsilon \text{ (MeV)}$$

is the fission barrier,  $\varepsilon = 0.7$  for odd-odd nuclei,  $\varepsilon = 0.4$  for odd- $A$  nuclei, and  $\varepsilon = 0$  for even-even nuclei. Calculated half lives are given in Table 2. When nuclei reach the fission region (point  $d$  on Fig. 1) multiple fission might occur (triple or even more). Fission fragments will capture neutrons and some  $r$ -process-like recycling will take place.

Calculations on this model lead to the following picture. Within 0.4 s after the ejection of matter (at  $t_0$ ) from the star, more than half the original nuclei with  $Z = 161$ ,  $A = 644$  move on their evolutionary tracks up to the point with  $Z = 184$ ,  $A = 736$ , where spontaneous fission occurs. Half a second after the initial ejection, almost all the nuclei have done this. The density of matter at  $t = t_0 + 0.4$  s and  $t = t_0 + 0.5$  s is  $5 \times 10^6$  and  $3 \times 10^6$  g cm<sup>-3</sup>, respectively, and the characteristic times  $t_n$  are  $2 \times 10^{-14}$  and  $3 \times 10^{-14}$  s, respectively, so that  $t_n < t_\beta$ .

Both the fission fragments and the products of  $\beta$  decay can be in excited states. A probable means of de-excitation of these nuclei may be the evaporation of some neutrons, leading to the formation of neutron-deficient nuclei. The probability for such process is low but the abundance of neutron-deficient nuclei amounts to  $10^{-4}$ – $10^{-5}$  of that of heavy nuclei<sup>14</sup>.

The described picture is in a good agreement with an estimate of the number of neutron stars in the Galaxy. To obtain the observed density of heavy elements, we need  $10^9$  neutron stars assuming that 10% of their envelopes form heavy elements and are ejected from the stars. In this way the neutron star may enrich with heavy elements the surfaces of stars in its neighbourhood. This mechanism may explain the presence of promethium on the surface of some stars. The longest lived isotope of promethium is <sup>145</sup>Pm with  $t_{1/2} = 17.7$  yr. Lines of Pm have been found<sup>15,16</sup> in the spectra of some Ap stars, but confirmation is needed. Another prediction of this model is the correlation between the  $\gamma$ -ray (of energy 2 keV–10 MeV) and heavy elements outburst.

We thank G. N. Flerov, B. Kuchowicz and Ya. B. Zeldovich for their help and encouragement.

## Lunar effect in the quiet-time $D_{st}$ index

POLARISATION electric fields produced in the dynamo region should, theoretically, have a considerable effect on the distribution and energy of magnetospheric particles, but none has been found previously<sup>1–3</sup>. Here we show that the  $D_{st}$  index calculated by Sugiura and Poros<sup>4</sup> shows a semidiurnal variation, which we attribute to the effect of tides (caused by the Moon) in the dynamo region, thus verifying the theory.

The data used are the hourly values of the  $D_{st}$  index on five international quiet days in each month for 14 years (1959–72), the total number of data points being 21,000 ( $25 \times 5 \times 12 \times 14$ ). These values are obtained for each hour of universal time (UT), and are dependent on the month of the year and also on the lunar phase. We have checked carefully that the data were collected uniformly over the lunar phases.

We have found a semiannual variation in the  $D_{st}$  index which will be discussed elsewhere. Our discussion is here limited to the relation of the  $D_{st}$  index to UT and to the lunar phase, so that we have used the data averaged over the whole month and whole year.

Figure 1 shows the distribution of  $D_{st}$  values with respect to UT and lunar phase. It is found that the  $D_{st}$  values show a systematic change with lunar phase, such that the positive and negative values appear alternately. To see more, the  $D_{st}$  values are rearranged in 'geomagnetic lunar time', that is, in hours measured from the lower transit of the Moon across the meridian containing the north magnetic pole. This is shown in Fig. 2, where the abscissa shows the lunar time relating to the geomagnetic axis: at 0 h the geomag-

Fig. 1 Distribution of the  $D_{st}$  index with respect to the lunar phase and UT (in units of nT).

Although the  $D_{\text{st}}$  index derived from geomagnetic variations on the ground may include various effects, the main contribution seems to come from the ring current. We

## Evolution of periodicities exhibited by fluctuations in the intensity of chorus

Here, the power spectral analysis method<sup>4,5</sup> is used to investigate, quantitatively, the evolution of the periodicities exhibited by the intensity fluctuations of a 60-min recording of chorus. The recording was made at St John's Stadan Station, Newfoundland, Canada ( $L=3.5$ ) on March 7, 1970, at 0850 UT. The recording was started close to the peak of an intense chorus event which lasted for more than 2 h. The short (2–3 s) period fluctuations were found to be attributable to the 2-hop travel time of Whistler mode echoes of the chorus emissions, whereas long (8–16 s) periods were attributed to amplitude modulation by geomagnetic micropulsations.

Next, the chorus was filtered in the narrow frequency band (2–3 kHz), and the filtered output integrated using a time constant of 0.25 s. The integrated waveform was smoothed by means of a d.c. bandpass filter which attenuated statistical fluctuations with periods  $< 1$  s, and removed any ultra-flow frequency trends with periods  $> 100$  s, which are inimical to power spectral analysis, in the integrated waveform. The smoothed waveform was sampled at a rate of  $4 \text{ s}^{-1}$  and digitised to obtain a time series showing the temporal fluctuations in intensity of the chorus.

Figure 3 is a contour map showing, effectively, the evolution of the twelve power spectra computed. The contours were obtained by the following procedure: First the normalised values of the spectral points, especially those defining peaks, in each of the sequential power spectra were denormalised by simply multiplying them by the variance (mean square value) of the corresponding time series used to compute the spectrum. The resultant values were renormalised with respect to the largest value (corresponding to the power in the most dominant period in the entire 60-min recording of chorus) in the set of twelve power spectra, and the values scaled to lie between 0 and

Fig. 1 Dynamic (frequency-time) spectra of samples of earlier and later parts of chorus.

10. These scaled values were plotted for each power spectrum as shown by the dots and crosses in Fig 3, and contours drawn by eye. Significant power peaks or ridges are identified on the contour plot as being high, H, significant valleys are identified as being low, L

It is clear that there is a transition from more complex power spectra for earlier parts of the chorus to less complex ones for later parts. The transition time is  $\sim 25$  min. In the more complex spectra, large spectral peaks defining both short (2–3 s) and comparatively long (8–16 s) periods are present whereas in the less complex spectra, the short period peaks are absent or have small amplitude suggesting that long periods tend to dominate the later parts of chorus.

From a study of chorus recordings from South Uist, Outer Hebrides, Scotland (S.K.A., unpublished), it was

found that short period ( $< 4$  s) fluctuations in the intensity of chorus could be attributed to the 2-hop travel time of whistler-mode echoes of individual (or groups of) chorus emissions whereas comparatively long period ( $> 4$  s) fluctuations are attributable to modulation by geomagnetic micropulsations of the same period. The dominant short period of 3 s observed here is equal to the typical 2-hop travel time of a 2-kHz (the mid-frequency of the chorus examined here) whistler mode echo propagating along the  $L=3.5$  field line, within the plasmopause. The presence of short period fluctuations in intensity of the earlier parts of the chorus suggests that at the peak of the entire chorus event, the emissions have large energy and are able to echo (in the whistler mode) back and forth between conjugate hemispheres perhaps several times before dying off. It also suggests that at the peak of the chorus event some of the

Fig. 2 *a-c*, sequential power spectra of chorus time series

Fig. 3 Contours showing evolution of power spectra.

emissions were being generated inside the plasmopause.

Towards the end of the chorus event, the emissions will have little energy to echo, and so fluctuations in intensity of the chorus will be largely due to amplitude modulation by micropulsations (if present) of the magnetic field line along which the emissions (whistler mode waves) propagate. This kind of modulation, according to Coriniti and Kennel<sup>6</sup> is exponential even for small amplitude whistler mode waves. The dominant long period fluctuation for later parts of the chorus is  $\sim 16$  s; this is in fair agreement with the values of 14 s and 18 s for the eigenperiods of oscillation of the  $L=3.5$  field lines, computed by Orr and Matthew<sup>7</sup>, assuming toroidal and poloidal oscillations respectively, for an electron density of  $15 \text{ cm}^{-3}$ . The low value used for the electron density is typical for a region outside the plasmopause. Thus, it would appear that near the end of the chorus event, the emissions were mostly being generated outside the plasmopause. The presence of short (2–3 s) and comparatively long (8–16 s) periods in power spectra for earlier parts of the chorus time series also supports generation of the emissions in a region close to the plasmopause.

In this case it is possible for the emissions to have been generated or alternatively travelled, some inside, and some outside, the plasmopause.

The evolution of the power spectra of the chorus time-series is, indeed, suggestive of changes in the energy of the plasma medium, available for conversion into chorus emissions. According to the Kennel–Petschek theory<sup>8</sup>, the energy of electrons resonant with whistler mode waves is dependent on the magnetic energy per particle,  $E_e (= B^2/2\mu_0 N)$ . Since the value of the magnetic field  $B$  is dependent on the  $L$  value of the field line, and the value of the electron density  $N$  at the point in the magnetosphere where gyroresonance between the waves and the electrons is taking place depends mainly on whether the point is inside or outside the plasmopause, the evolution observed here may possibly be related to the movement of the position of the plasmopause on a time scale of  $< 1$  h.

The period of micropulsations of any particular geomagnetic field line depends on the plasma density and thus would be affected by changes of the plasmopause position. Thus, one would expect a similar evolution of the power

spectra of geomagnetic micropulsations. It is rather unfortunate that a simultaneous recording of geomagnetic micropulsations was not made at the time of the chorus event to enable a computation of the power spectra of the micropulsation time series to be made and thus to find out whether periods, and an evolution similar to those of the chorus time series would be exhibited. Nevertheless, a similar evolution of power spectra of the time series of micropulsations has been recorded elsewhere (S.K.A., unpublished).

I thank Dr M. J. Rycroft for supervising the work and Dr C. D. Reeve for recording the chorus signal.

## Large scale Palaeozoic shear zone in Australia and present extension to the Antarctic Ridge

THE Lower Proterozoic craton of central Australia is bounded to the south and south-east by shallow geosynclinal sediments of late Proterozoic to early Palaeozoic age. During the Palaeozoic these rocks were deformed into a series of upright folds, the trend of which follows the edge of the craton except in the area north and east of Adelaide where it swings to north-north-west-south-south-east, normal to the edge of the craton (Fig. 1). An analysis of this major structure gives an indication of a component of plate movement during the Palaeozoic.

The sigmoidal curve in the trend of the Palaeozoic folds has the form of a ductile shear zone analogous to the small scale, ductile shear structures described from deformed igneous rocks<sup>1</sup>. This is confirmed by the parallelism of isogons drawn for the regional change in axial plane and cleavage orientation (Fig. 2). It suggests that a regional pattern of folds on north-east-south-west axial planes was modified by a sinistral shear couple parallel to the trend of the isogons (Fig. 2).

The simple shear mechanism is also confirmed by the variations in the intensities of deformation. Finite deformation increases as the fold axial planes change in orientation from north-east-south-west to north-north-west-south-south-east. Where the rocks have a north-east-south-west trend, the folding of the cover sequence is largely controlled by the position of structures in the underlying basement which tightened during Palaeozoic deformation. Thus, in the area west of Broken Hill, in the north-eastern sector of South Australia, anticlines in the cover sequence lie over much tighter earlier, antiforms in the basement gneisses. The intensity of deformation in the cover sequence varies locally; conglomerate pebbles at the base of the Upper Proterozoic sequence show the most intense deformation in synclinal keels, where the sediments are pinched into the basement gneisses. In the anticlinal areas, the pebbles show no apparent change of shape, and the sediments may show no cleavage. East of Adelaide, where the folds have a north-north-west-south-south-east trend, folding is more regular and better developed, conglomerate pebbles show

more intense deformation throughout the fold structures, and most of the rocks have a well developed cleavage. Deformation is heterogeneous, presumably as a result of the simple shear acting on an originally heterogeneous deformation pattern.

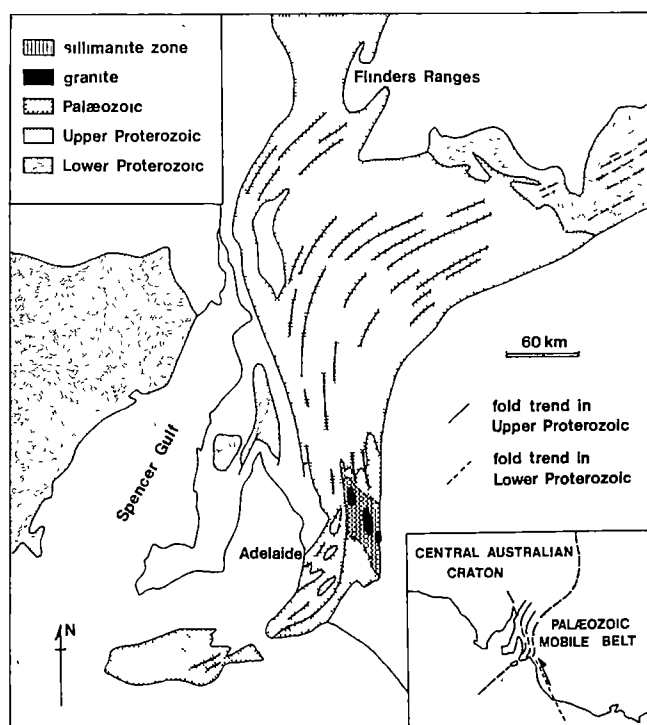

The intensity of deformation attributable to the simple shear component can be estimated from the change in orientation of the fold axial planes or cleavage, relative to the shear direction<sup>1</sup>. Thus, the shear strain can be computed throughout the zone, with a maximum shear strain,  $\gamma$ , of 1.7 (a strain ratio of 4.5:1) some 30 km north-east of Adelaide (Fig. 2).

The zone of most intense shear strain coincides with a zone of sillimanite-grade metamorphism and migmatization (Fig. 1). The high heat flow required to give this local increase in metamorphic grade may result partly from intense shear strain; or alternatively, the position of the shear zone may have been controlled by the increase in ductility over a region of high heat flow. Evidence for that hypothesis has been given by Fleming and Offler<sup>2</sup>; they showed that the high grade metamorphism began before the development of the first cleavage, and continued through two later phases of localised deformation of crenulation cleavage.

The ductile shear zone is 150 km wide, and shows left-lateral displacement of the order of 150 km (Fig. 1). In terms of plate tectonics, the zone cuts across the edge of the Australian craton and must be intracontinental; the eastern part of the Australian plate must have moved northwards some 150 km relative to the western part. Seismic evidence indicates that there may be a gradual change in crustal structure under the northern extension of this shear zone<sup>3</sup>, and studies of electrical conductivity have detected an anomaly under the Flinders Ranges in the northern part of the zone. This may reflect a change in rock fabric at depth<sup>4</sup>.

The ductile deformation along the shear must have ceased during the Palaeozoic; it was presumably most active during the mid-Palaeozoic at the time of high grade

Fig. 1 Geological map of part of South Australia showing the sigmoidal trend of the fold axial planes and the area of high grade metamorphism.

metamorphism and granite production. Large faults, however with a similar north-west-south-east trend to the shear, postdate the deposition of Permian sediments.

From examinations deep crustal seismic profiles, Burwash *et al.*<sup>5</sup> suggested that major faults and shear zones in the Churchill Province of Canada extend down to the mantle, and Beach<sup>6</sup> claimed that the major shear in the Laxford region of north-western Scotland almost certainly penetrated to the mantle. According to Beach<sup>6</sup>, shear zones in north-western Scotland extend for a distance of the order of 10 times the amount of displacement. By analogy, the South Australian shear zone, with a displacement of 150 km can be expected to extend for some 1,500 km. Shear zones of such size most certainly affect the base of the lithosphere, and the change in rock fabric in the upper mantle<sup>4</sup> beneath the Flinders Ranges presumably represents such deformed asthenosphere.

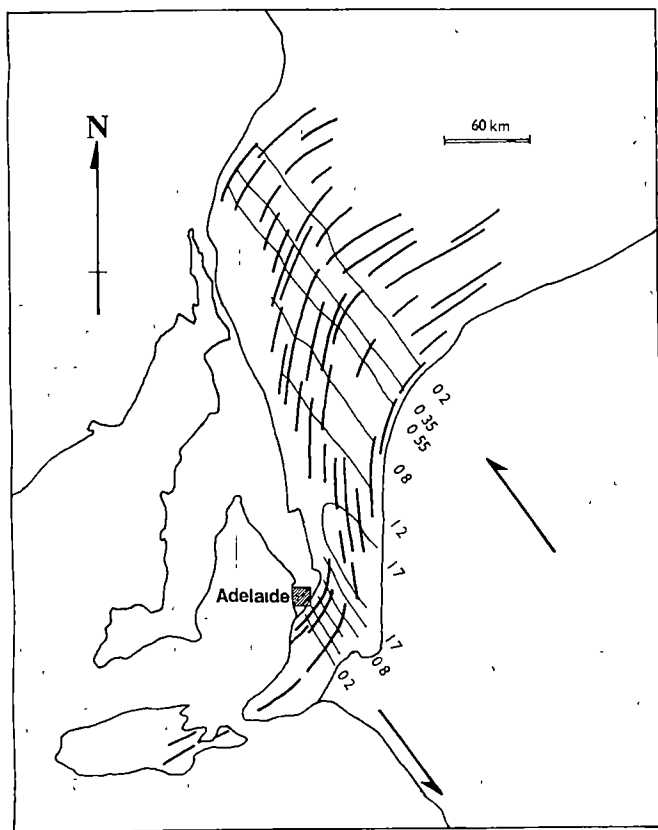

Fig. 2 Isogons drawn for the regional change in the orientation of fold axial planes. Estimated shear strains are shown.

Watterson<sup>7</sup> has pointed out that the development of fabric and grain size reduction within shear zones produces a localised strain-softening effect so that major shear zones may thus be active persistently throughout geological time. Doyle *et al.*<sup>8</sup> have shown that the Adelaide region of South Australia is a zone of recent seismic activity. Cleary and Simpson<sup>9</sup> have extended this zone of seismicity to a seismic zone and a major transform fault on the Antarctic Ridge. They consider that the whole zone from South Australia to the Antarctic Ridge represents a zone of left-lateral differential shear movement formed by differences in spreading rates between different parts of the Australian plate. This is in accord with the suggestion of Wilson<sup>10</sup> that transform faults on mid-oceanic ridges originate on lines of weakness within continents. Thus, the transform fault on the Antarctic Ridge was formed where the vertical zone of sheared lithosphere and asthenosphere was crossed

by a spreading ridge along which there was a gradient in the spreading rate.

## Magnetic inclination of basaltic lavas from the Mid-Atlantic Ridge near 37°N

DURING the course of the French-American Mid-Oceanic Undersea Study (FAMOUS), many samples of basaltic pillow lava were collected from the axial region of the Mid-Atlantic Ridge near 37°N. The vertical axes and the tops of nine of these samples have been determined fairly accurately, allowing calculations of magnetic inclination at the time of the cooling of the lavas to be made with reasonable confidence.

According to modern conceptions of seafloor creation, basalts from the axial regions of the mid-ocean ridges should be young, and therefore magnetised in approximately the same direction as the present geomagnetic field. But the few magnetic measurements that have been made on basalts collected irrefutably on the crustal block responsible for the existence of the axial magnetic anomaly have yielded conflicting results<sup>1-3</sup>. Normal polarity has been found in samples from the Reykjanès Ridge<sup>1</sup> and from the Mid-Atlantic Ridge near 45°N (refs 2-4), but mixed or reversed polarities were found in two of six basalt cores drilled within the Rift Valley at the same latitude<sup>5</sup>. The mean magnetic inclination at a site cannot be reliably calculated if the number of satisfactorily reoriented samples is too small or if the direction of magnetisation is erratic within a single pillow or between samples. Although these conditions seem to have been met for samples dredged from 45°N (ref. 4), the mean magnetic inclination is 20° lower than expected.

Three of the samples discussed here (CH 31-DR 1-111; CH 31-DR 2-122; CH 31-DR 4-200) represent material dredged during the RV Jean Charcot CH 31 cruise of 1972 (refs 6 and 7). The remaining six samples (ARP 73-10-02; ARP 74-10-15; ARP 74-11-17; ARP 74-13-24; ARP 74-14-31; and ARP 74-17-40) were collected by a telemanipulated arm operated from the bathyscaphe Archimède during the FAMOUS diving programmes of 1973 and 1974 (refs 8 and 9). The locations of the sampling sites are shown in Fig. 1. Six samples were collected in the axial part of the Rift Valley, the remaining three come from the region of the intersection of the Rift Valley and Transform Fault 'A' near 36°57'N. The age of the samples can be inferred from a variety of methods.

The oxygen isotope ratio for a rock from dredge haul CH 31-DR 1 indicates that the material is very fresh, having suffered no noticeable seawater contamination (G. Pineau, M. Javoy and J. Bottinga, personal communication). Samples from dredge CH 31-DR 2, dated on a relative scale by measurements of the thickness of the palagonite-manganese coating<sup>10</sup> are dated at less than 170,000 yr BP. No age determination is available yet for samples from dredge CH 31-DR 4.

The youngest rock of the set of Archimède samples in the inner floor of the Rift Valley is probably ARP 74-10-15,

\* Location refers to numbered sites in Fig. 1. Sample number is eventually followed by core number (in brackets); U, upper specimen; L, lower specimen; G, glass on specimen.

$\dagger J_0$ , mean intensity of magnetisation before cleaning ( $10^{-4}$  e.m.u.  $\text{cm}^{-3}$ )

$\ddagger$  MDF, median destructive field in peak oersted.

$\S I_{s0}$  and  $I_s$  are magnetic inclinations before and after cleaning, respectively.

$\P \theta$ , angular deviation between the directions of magnetisations of the two specimens from the same core.

$|| I_c$ , mean inclination of core

\*\*  $I_p$  mean inclination of pillow.  $I_s$ ,  $\theta$ ,  $I_c$  and  $I_p$  calculated after a.f. demagnetisation.

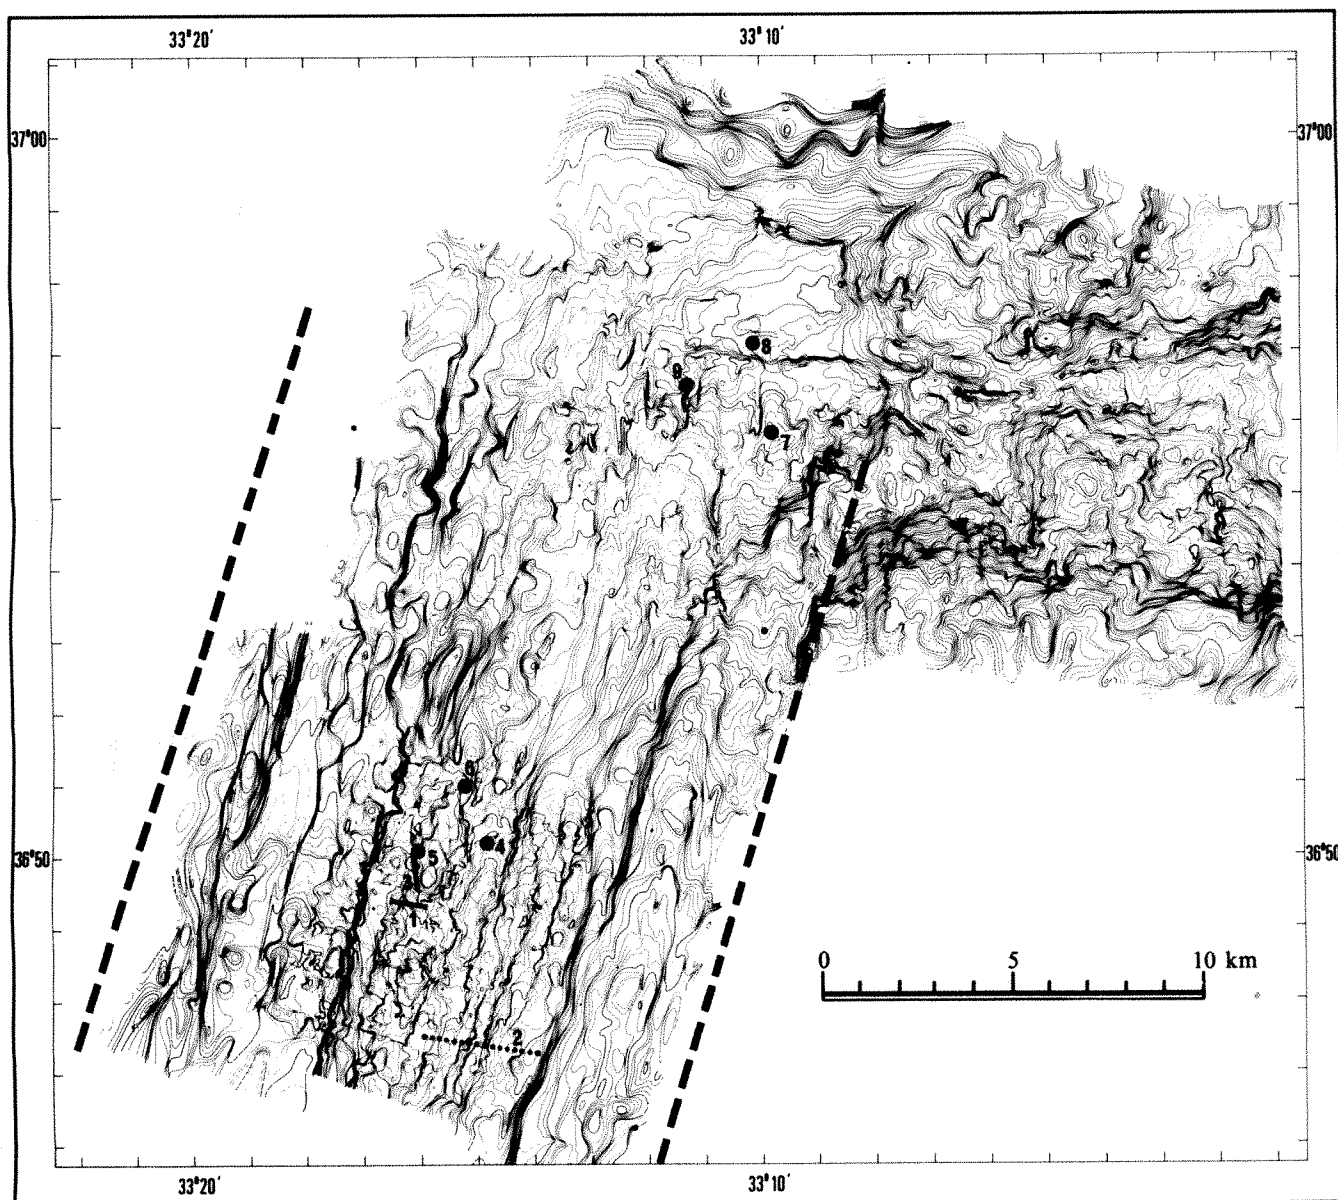

which exhibited fresh glass on the chilled margin, followed by ARP 74-11-17, which was sampled in a talus pile barren of sediment, and which showed very little preserved glass. Both are olivine basalts<sup>7,9</sup> representing the youngest eruptives in that section of the Rift Valley, probably emplaced within the past 10,000 yr (refs 10 and 11). The age of sample ARP 73-10-2 is bracketed between 30,000 and 100,000 yr on the basis of these palagonite-manganese coatings<sup>10</sup>. Fission-track dating (D. Storzer, personal communication) shows that this sample was formed less than 50,000 yr ago.

The remaining three Archimède samples (ARP 74-13-24; ARP 74-14-31; and ARP 74-17-40) come from the axial portion of Transform Fault 'A' in the region close to its intersection with the Rift Valley. Sample ARP 74-13-24 was taken 4 km east of the axis of the Rift Valley segment on a small north-south ridge which structurally is part of the Rift Valley wall. Its age should be about 270,000–300,000 yr according to spreading rates for the eastern limb of the Rift Valley, calculated from magnetic profiles<sup>8,12</sup>. Sample ARP 74-14-31, with a rosey surface showing flow direction, has a preserved glassy crust and a palagonite layer overlain by a thin manganese coating. Samples at this site, on the edge of a tension gash associated with the left lateral shear of Transform Fault 'A' (ref. 9), are the youngest specimens collected in the Transform Fault. This estimate is supported by a fission-track age (D. Storzer, personal communication) of less than 45,000 yr. Sample ARP 74-17-40, closest to the accreting plate boundary, has textural and structural features similar to those of rocks determined to be intru-

sives from field evidence. It was sampled on a tectonic scarp which exhibits a layered sequence (possibly a truncated sill) 1.5 km east of the deep axis of the Rift Valley. Its age, inferred from spreading rates, should be less than 100,000 to 113,000 yr (refs 6 and 12). Spreading rate values averaged over the Brunhes Epoch may not necessarily, however, be applicable to an area which may be tectonically and volcanically active. Fission-track ages for this general region are all less than 300,000 yr (D. Storzer, personal communication).

On the combined evidence of fission-track dating, calculated opening rates, palagonite and manganese thickness, and field observations, it seems certain that all the reoriented rocks were emplaced during the Brunhes Epoch, so that a proper scheme of reorientation should reveal that the samples are all normally magnetised. Any negative inclinations could be attributable to eruptives that cooled during the Laschamps (reverse) geomagnetic excursion, which may have occurred between 10,000 and 15,000 yr BP, or during the Blake reverse event (or excursion) with an inferred duration of about 10,000 yr and a mean age close to 110,000 yr BP (see ref. 5).

The partial reorientation of samples from the sea floor is possible first, for cores, assuming that the axis of drilling is vertical (in practice, deviation from the vertical can reach 15°; ref. 5 and, second, for magnetically viscous samples, using various magnetic tests; refs 2, 13 and 14), (these methods should obviously be applied only to rocks whose viscosity has been established; they cannot be used for the samples discussed here because their viscosity index

**Fig. 1** Bathymetry of parts of the Rift Valley and Transform Fault "A" (21) showing sampling sites (Table 1) and boundaries (heavy dashed lines) of the crust formed during the Brunhes Epoch<sup>6</sup>. The sampling sites are taken from refs 6, 8 and 9. The location of dredge 2 (dotted line) is only indicative. The numbered locations refer to the first entry in Table 1. The Rift Valley sites are all clearly within the Brunhes block and should therefore have normal polarity.

is too small<sup>15</sup>); third, for pillow-lavas exhibiting one or more volcanic features considered to be criteria of polarity<sup>1,4</sup>.

The last method is the only one which gives indications of the orientation of the pillow-lava during cooling because it is independent of possible subsequent changes of position.

De Boer *et al.*<sup>1</sup> have listed four volcanic features thought to be diagnostic of vertical and top: the flattened-oval shape of pillows; the location of necks interconnecting pillows at their bases; stemlike extensions commonly at the bases of pillows; and basal stalactites on the concave side of a crust from lava tunnels or tumuli. Of these, the last seems to be the most reliable (see, for example, ref. 16) but it can give only a polarity and cannot give the vertical because the position of the lava crust with stalactites on the tumulus or tunnel cannot be known *a priori*. In another study<sup>4</sup>, the horizontal was assumed to be parallel to the equatorial plane of the pillow but the assumed error of 20° (ref. 4) is probably too low, because the method relies strongly on questionable conceptions of how pillows form<sup>16</sup>, and assumes that the pillow cooled on a horizontal surface. A further possibility, that of using surface glass coating as

a guide to the original orientation, is not reliable because pillows often curl during their formation.

An improved criterion of orientation came from field observations made from the American submersible Alvin in the inner floor of the Rift Valley in the FAMOUS area<sup>17-19</sup>. It was noted that, on the tops of lava flows, series of ledges commonly occur along the inner walls of collapsed feeder tubes. The ledges record the various levels at which lava flowed through the tubes<sup>17</sup> much as rings in a bathtub register successive water levels<sup>18</sup>. These frozen-in lava levels were observed to be nearly horizontal *in situ*, and they provide a reliable guide to sample orientation for palaeomagnetic studies<sup>19</sup>. The nine samples for which measurements are reported here are the only ones among all the rocks sampled by the French team in the FAMOUS area showing the 'bathtub ring' criterion or a modification of the criterion. Some examples are shown in Figs 2 and 3.

In sample CH 31-DR 4-200 (Fig. 2b), a small flattish ledge occurs near the core of a pillow exhibiting a glassy margin. The upper surface of the ledge is very smooth and contrasts with the overlying, subparallel wall, which has a

rugose texture imposed by the presence of small septae and lava stalactites. The vertical is taken normal to the flattish ledge and the polarity is given by the relationship between the rugose stalactite-bearing surface and the smoother, upward-facing surface. The flattish glassy surface is tilted about  $30^\circ$  from the horizontal.

The angular discrepancy between the glassy surface and the horizontal is more extreme in the case of sample ARP 73-10-02 where the glassy surface is nearly vertical (Fig. 2c). In the interior of the pillow a series of elongate cavities with smooth flattish floors and more irregular roofs gives a good indication of the vertical at the time of cooling.

In sample ARP 74-11-17 (Fig. 2d), the glassy surface is on top and nearly horizontal. The vertical is taken to be normal to a line of small, elongate, asymmetric cavities. The true vertical could deviate slightly, because the cavities seem to be *en échelon* (Fig. 3) and the vertical axis could have been taken perpendicular to the parallel long axes of the cavities. The polarity is not, however, in doubt and is given by both the asymmetry of the cavities and by the lava stalactites on a large surface (Fig. 3).

Sample ARP 74-14-31 shows a superposition of two, approximately horizontal, ropey lava surfaces (Fig. 2a). A confirmation of the field determination is provided by an elongate cavity below the upper ropey crust and by well developed stalactites on the bottom of the sample.

Suitable samples for reorientation could not be found in the collection made from the diving saucer Cyana, because of their small size. Similarly, only the very large dredge samples could be used with any confidence.

One to three vertical cores, about 10 cm long, were drilled through each of the nine samples of reoriented pillow lava basalts. The upper and the lower parts of each core were sawn flat, giving two specimens of about 30 g. All 36 specimens were submitted to magnetic study, including alternating field treatment up to 850 oersted (Table 1). In several cases, the intensities of magnetisation and the median destructive field (MDF) were quite different from one specimen to another, even within a single core. In particular, the glassy parts of a sample are systematically much less magnetised than non-glassy parts. The very high coercivities shown by

Fig. 3 a, Close-up of cavity alignment in sample ARP 74-11-17 (Fig. 2 d); b, stalactite-bearing surface (vertical-upward into picture) at the base of ropey lava ARP 74-14-031 (shown in Fig. 2); c, close-up of horizontal cavity below upper ropey surface of sample ARP 74-14-031 (Fig. 2a).

Fig. 2 Four selected pillow lavas displaying characteristic features for reorientation (see text). Arrows, vertical-downward at the time of cooling. a, ARP 74-14-031; b, CH 31-DR-4-200; c, ARP 73-10-02C; d, ARP 74-11-17.

the glassy portions of the samples probably reflect in part the smaller grain size. As previously pointed out<sup>22</sup> the between-specimen variability indicates that large samples (or the averaging of results from several specimens from each pillow) are generally required to obtain significant data on the intensities of magnetisation of submarine extrusives.

All of the specimens have a positive magnetic inclination. The alternating field treatment induced small changes in direction, probably by the removal of weak parasitic magnetisations acquired during drilling. Because the samples are not viscous, no significance can be attached to the sign of the inclination change during cleaning. In some cases, the directions of magnetisation after cleaning remain significantly different for the upper and the lower specimen from a single core. In particular, the upper part of pillow ARP 74-13-24 is characterised by a magnetic inclination  $10\text{--}15^\circ$  higher than that of the lower part of the pillow. This may indicate variations in space of the geomagnetic field at the site of cooling, because of disturbances caused by the neighbouring lavas. The large inclination found for sample ARP 74-11-17 may be real and result from secular variation. Alternatively, it may be the result of a small error in the orientation, as discussed above.

In calculating the mean inclination of a pillow we have rejected data obtained from cores exhibiting a deviation larger than  $5^\circ$  in their directions of magnetisation (after cleaning) between the upper and the lower part of the pillow.

The overall mean magnetic inclination, calculated from the mean values for eight pillow basalts, is equal to  $56^\circ$ . It corresponds exactly with the inclination of the present geomagnetic field (International Geomagnetic Reference Field, 1965), which is the same as the inclination of an axial dipole field. At two drill sites of DSDP leg 37, west of the FAMOUS area, natural remanent inclinations were also found to be close to the dipole value for the area and to match this local anomaly sense<sup>20</sup> although anomalous shallow inclinations were found at a third site.

We thank the officers, crew and scientific parties of the Jean Charlot and the Bathyscaphe Archimède, P. Bordier for help with the magnetic measurements, D. Bideau for preparation of the samples, J. G. Moore for describing, before publication, the orientation criterion recognised during the Alvin dives, and David Needham for useful comments.

## Dune trend and the Ekman Spiral

FRICTION at the Earth's surface induces deflection of the ground wind from the geostrophic direction, the progressive change with height being known as the 'Ekman Spiral'. As the roughness of the surface increases, this deflection becomes further to the left in the Northern Hemisphere and further right in the Southern; the differences between extensive water or grass-covered areas and nearby rough surfaces, such as rooftops, are commonly  $15^\circ$  (ref. 1). The evidence presented here shows that dune fields, many of which have rougher surfaces than neighbouring areas, and within which there may be differences in roughness between dune types, show evidence of such deflections.

Deflection is most apparent in coastal dunes, probably because wind recording stations are relatively common on coasts, and because the important onshore winds encounter a marked contrast between the surface roughness of the sea and that of the dunes.

Landsberg<sup>2</sup> examined twelve parabolic dune fields on the coasts of Britain and Denmark; in eight of these the dune trends are to the left of the resultant of sand movement at the nearest wind recording station (that is, the average wind direction weighted by its ability to blow sand), and in two there is little difference. The site at Burghead in Scotland

Fig. 1 Patterns of transverse-type dunes in the fixed Qoz sand dunes of Central Sudan. Each line represents a dune crest; the winds came from a northerly direction. The wind at right angles to the longer wavelength dunes is always to the left of that normal to those with lower wavelengths

shows too marked a leftward deflection to fit with Landsberg's explanation that it is the result of the occlusion of landward winds at the recording station. The sites which show a rightward deflection do so when compared with very distant recording stations. In Gower, South Wales, Harris<sup>3</sup>, like Landsberg, invoked sheltering to explain the discrepancy between the trend of the sand moving resultant and the dunes, but here too there is a distinct leftward deflection of the dunes.

In the dune fields of the Oregon coast there is a consistent difference between the trend of the dominant winds and of the dunes: lines perpendicular to nearshore transverse dunes have an orientation from  $1.5^\circ$  to  $22^\circ$  to the left of the dominant NNW winds which are thought to form them<sup>4</sup>. One recording station, North Bend, which is some km inland from dune country, shows that the dominant wind has swung to the left (it is more westward than at the coastal stations). Cooper's<sup>5</sup> data for the California coast are sparser than those for Oregon, but again nearshore dunes set consistently to the left of the July north-westerlies which are apparently responsible for them.

In the Southern Hemisphere the trend of parabolic U-dunes on the eastern, western and southern coasts of King Island, Tasmania is almost everywhere to the right of the sand moving resultant of the onshore winds<sup>6</sup>.

Turning now to the internal evidence of the dune patterns themselves, it can be seen on both Landsberg's<sup>2</sup> and Jennings's<sup>6</sup> maps of parabolic U-dunes that the deflections consistently become more pronounced inland, presumably in response to increased surface roughness. In Oregon the direction at right angles to the mean trend of low transverse dunes is skewed well to the left of the trend of more longitudinal near-shore lee features, which presumably have lower surface roughness<sup>4</sup>. Further inland, the leftward swing becomes pronounced in the long seif-like dune ridges. Cooper related the trend of these to the yearly resultant of sand moving winds (although he did not weight these for sand movement), but the wind records at North Bend, mentioned above, support the idea that the dominant

winds veer to parallel the ridges inland. On the California coast, all the transverse ridges of Flandrian age shown on Cooper's maps<sup>5</sup> imply winds to the left of the trend of the nearshore longitudinal lee features. On the coast of Israel, transverse dunes again indicate a wind to the left of closely associated longitudinal features (a fact which Rim explained as due to an asymmetry in the sand supply)<sup>7</sup>

Desert dunes are not as likely to show such clear evidence of discordance as coastal dunes because wind recording stations are very sparse and are themselves often in terrain as rough or rougher than dune surfaces, and also wind regimes are more complex, since they include relevant winds from many more directions than the simple onshore winds responsible for most coastal dune forms. In spite of these difficulties, many inconsistencies of trend can be explained with the Ekman Spiral. It is found that, as with coastal dunes, the rougher-surfaced transverse dunes are commonly skewed more than longitudinal dunes.

Sprigg<sup>8</sup> suggested that there had been a 4°–5° southward shift in windbelts since the time of dune formation in central Australia, because the sand ridges trend to the right of the wind, but a simple application of the Ekman Spiral shows that if the wind recording stations were in smoother terrain, the dunes should indeed show this trend. The common rightward asymmetry (though not the orientation) of these ridges has been explained with the Spiral by Mabbutt and others<sup>9</sup>. Brookfield<sup>10</sup> found no simple pattern of deviations, but did note that well developed ridges in the Simpson Desert were aligned to the right of the resultant sand movement, and more recently Twidale's<sup>11</sup> maps shows that, in most cases, transverse-type dunes in the same desert would be perpendicular to winds which are to the right of those which parallel the sand ridges.

In the Northern Hemisphere, Clos Arceduc<sup>12</sup> has repeatedly used air photographs to show that long seif or 'slouk' dunes cannot be longitudinal to the winds flowing over nearby barchans. Most of his seifs are to the right of this putative wind, a fact which could be explained if the wind deviated to the left of the geostrophic direction as it passes over the rougher surface of the transverse barchans. Indeed over groups of barchans the deviation is more marked than over single ones (compare numbers 31 and 34 with 37 on Fig. 2 of ref. 12). In the Ténéré Desert, Warren<sup>13</sup> showed that the wind at right angles to transverse zibar would be 14° to the left of one parallel to closely associated seif dunes, and nearby, near the oasis of Bilma, a small dune field of seifs and barchans again indicates that the wind at right angles to the barchans would be to the left of the main trend<sup>14</sup>.

Hack's<sup>15</sup> maps of the Navajo county of the south-western USA show yet again that transverse dunes would be perpendicular to winds which are to the left of long straight seif-like dunes. Near the Salton Sea, Long and Sharp<sup>16</sup>, using wind records from an admittedly distant station, noted that barchans had moved to the left of the dominant winds, during both a 7-yr and a 15-yr period.

The evidence of desert dunes is not, however, entirely in favour of this Ekman Spiral hypothesis. In a pattern in Libya which was very similar to the one in the Ténéré discussed above, McKee and Tibbetts<sup>17</sup>, found that transverse zibar indicated a wind to the right of the one which would parallel the local seifs, and further south in southern Niger, Grove and Warren<sup>18</sup>, found megadune patterns east of Termit and south-west of Agadem in which the transverse features are again apparently aligned to a wind to the right of the one parallel to the longitudinal ones.

The morphology of Pleistocene-fixed dune sands is difficult to interpret in the absence of wind data for the period of their formation, but there is some evidence of divergences over different dune types. In Central Sudan<sup>19</sup> transverse dunes with long wavelengths (rougher surfaces) are invariably at right angles to winds which would have been to

the left of those perpendicular to juxtaposed transverse dunes of lower wavelengths (less rough) (Fig. 1). These large areas of uniform roughness may offer an opportunity to measure the value of surface roughness parameter.

## Electrical properties of magnetisable liquids

RECENTLY developed magnetisable liquids comprising colloidal suspensions of soft ferromagnetic particles have attracted considerable scientific and technological interest<sup>1–3</sup>. The ferromagnetic grains are coated with a special film which prevents them from clustering together and maintains a true colloidal dispersion<sup>4</sup>. We have investigated the sensitivity of their electrical properties to magnetic fields and found some new 'magneto-electric' effects. An interpretation of these observations is suggested.

Conductance and capacitance measurements of a commercial magnetisable liquid (Ferrofluid water base, A01, 200 gauss saturation, Ferrofluidics Corporation) were made using a Metrohm conductivity probe (type E A 608). This is of a standard type for conductivity measurements and consists of a pair of parallel electrode plates coated with porous platinum. The conductivity of the fluid between the plates  $\sigma$  is obtained from the measured conductance  $S$  through the geometrical factor  $c$ , where  $c \approx \sigma/S \text{ cm}^{-1}$ .

For the probe we used the value of  $c$  was stated by the manufacturers to be  $c = 0.83 \text{ cm}^{-1}$ . Capacitance measurements were made with the same probe. All the a.c. measurements were made on a General Radio type 1650-B bridge operated with an external signal generator.

The frequency dependence of conductivity and capacitance for the liquid is shown in Fig. 1. Note that, although the conductivity is approximately constant over the frequency range, the capacitance varies as  $f^{-2}$  over most of the range. At low frequencies the measured capacitance becomes very large ( $\approx 1 \mu\text{F}$ ).

Figure 2 represents the d.c. characteristic of the magnetisable liquid. As in the case of the a.c. measurements, the geometrical factor  $c$  may be used in order to derive the conductivity from the measurements. Below 5 V, the voltage corresponding to a steady current takes some time to reach a steady value, indicating that not only is the resistance larger than the measured a.c. values, but the capacitance is also significantly larger than those found with a.c. down to 40 Hz. The time constant of 0.5 V was  $\sim 3 \text{ min}$ .

Similar experiments were performed in the presence of magnetic fields, to determine the effect of applied homogeneous and inhomogeneous fields on the electrical properties of the liquid. A solenoid coil wound round the entire column of liquid was

Fig. 1 Measured capacitance ( $C$ ,  $\circ$ ) and electrical conductivity ( $\sigma$ ,  $\Delta$ ) as a function of frequency ( $f$ ) of the magnetisable liquid.

used as the source of a relatively homogeneous field. The relative permeability of the liquid was found to be  $\sim 1.2$  in other measurements (not reported here). It may, therefore, be assumed that the liquid and probe hardly influence the homogeneity of the applied magnetic field. For inhomogeneous fields, a small horseshoe magnet was fitted around the measurement tube, and produced a magnetic field in the liquid varying from zero to 600 gauss.

Homogeneous fields were found to have a negligible effect on the resistance of the magnetisable liquid, but large changes in the current could be effected in the low-voltage region ( $< 5$  V) by appropriately aligning the position of the horseshoe magnet. Thus, for example, at 0.5 V the current increased by  $2 \mu\text{A}$  from its value of  $40 \mu\text{A}$  in the absence of a field, representing a 5% overall change.

Fig. 2 d.c. Voltage-current characteristics of the magnetisable liquid.

It was also established that a homogeneous field produced changes in the capacitance as measured on the a.c. bridge. At 750 Hz, for example, the change in capacitance as a function of magnetic field applied perpendicularly to the conduction path is shown in Fig. 3. At 270 gauss, the increase in capacitance is  $\sim 0.3\%$ . A magneto-resistance effect is also noted but the effect is considerably weaker.

Figure 1 suggests that the unusually large measured capacitances are not bulk values for the liquid but arise from a polarised layer on the surface of the porous electrodes, (or an analogous effect in the colloid), the resistance seems to represent a bulk property. Accordingly the specific resistivity (or conductivity) of the liquid may be estimated, whereas no simple derivation of the dielectric constant can be obtained from the capacitance measurement.

If the liquid is represented in a simplified model, with the electric path between the two electrodes having a resistance  $r$  and series capacitance  $C_s$ , then the admittance across the probe is

$$Y_s = \frac{1}{r + (1/j\omega C_s)} = \frac{r - (1/j\omega C_s)}{r^2 + (1/\omega^2 C_s^2)} \quad (1)$$

The General Radio Bridge, however, measures a capacitance  $C$  as if it were in parallel with a resistance  $R$ . In such a configuration, the admittance would be

$$Y_p = \frac{1}{R} + j\omega C_p \quad (2)$$

Comparing the real and imaginary parts of equations (1) and (2),

$$\frac{1}{R} = \frac{\omega^2 C_s^2 r}{\omega^2 r^2 C_s^2 + 1} \quad (3a)$$

and

$$C_p = \frac{C_s}{1 + \omega^2 r^2 C_s^2} \quad (3b)$$

at high frequencies such that

$$\omega^2 r^2 C_s^2 \gg 1$$

$$R \approx r = \frac{1}{S} \text{ (constant)} \quad (4a)$$

and

$$C_p \approx \frac{1}{\omega^2 r^2 C_s} \quad (4b)$$

Equations (4a) and (4b) give a satisfactory description of the experimental results. Above 80 Hz, the measured conductivity  $S$  remains almost constant, while the capacitance varies as  $\omega^{-2}$  (or  $f^{-2}$ ).

Information about the characteristic dielectric properties of the liquid are not easily obtained from the capacitance measurements because of the complex dependence of the polarisable layer on the specific nature of the electrodes used, and it was found that different electrodes yield different values of capacitance. It is hoped that a better understanding of the polarisable layer or its equivalence will be gained in future investigations.

Support for the above model is provided by the voltage-current characteristic. The large time constants and correspondingly large resistances observed at low voltages indicate high values of the layer capacitance. When the voltage increases, however, there seems to be a gradual breakdown effect, and the measured d.c. resistance approaches its a.c. value of  $330 \Omega$ . Under a.c. conditions the proposed layer behaves as a coupling capacitance  $C_s$  according to equation (1), and therefore a similar

Fig. 3 Increase of capacitance ( $\Delta C$ ) as a function of applied magnetic field  $B$  for the magnetisable liquid.

bulk resistance is measured. The a.c. measurements of capacitance made use of small signals and consequently no breakdown effect was encountered.

The cross effects of magnetic fields on the voltage-current characteristics are like the capacitance attributed here to the proposed polarised layer. This is consistent with the observation that the capacitance changes more strongly with magnetic field than does the conductivity in the a.c. measurements. Moreover, at high voltages the influence of the magnetic field on the d.c. measurements drops to zero because of the presumed breakdown of the layer. It is proposed that inhomogeneous fields exert a stronger influence on the voltage-current characteristic at low voltages than do homogeneous fields because they can more easily produce irregularities in the layer which might thereby be locally 'punctured'.

Different electrodes and ferrofluids might increase the magneto-electric effect. It is believed that this phenomenon is affected by the saturation magnetisation of the liquid, as well as by the solvent and dilution of the colloid used. If the effect can be sufficiently enhanced, possible applications may be found in energy conversion and signal processing. From a theoretical viewpoint, we believe that the observed phenomena in magnetisable liquids provide a new means of probing layer effects in colloids and might help provide further insight into the electrical behaviour of colloids in general.

can be prepared<sup>2</sup>, such values are insufficient to make it of use as an electrolyte in solid state batteries at room temperature. There is, however, considerable interest in producing solid electrolytes, based on AgI combined with organic cation iodides to give high silver-ion conductivity at room temperature<sup>4-9</sup>. We report here on the conductivities of representatives of three hitherto unexamined classes of compounds, AgI-selenonium iodide, AgI-telluronium iodide and AgI-bis-sulphonium diiodide.

As a representative of the AgI-SeI system,  $(\text{CH}_3)_3\text{SeI}$ , prepared from  $(\text{CH}_3)_3\text{Se}$  and  $\text{CH}_3\text{I}$  (ref. 10) was mixed with varying amounts of AgI to produce samples containing 90, 85 and 80 mol % AgI. The powdered samples were suspended in distilled water and heated to  $90 \pm 5^\circ\text{C}$  for a total of 16 h. The solid product was filtered off and washed with ethanol and dry ether, before being pressed as a three-layer pellet, the outer layers of which were silver powder mixed with powdered electrolyte. The conductivities for each of the three samples at this stage were  $< 10^{-5} \Omega^{-1} \text{cm}^{-1}$  at  $21^\circ\text{C}$ . The pellets were then heated in nitrogen to  $140 \pm 2^\circ\text{C}$  for 9 h, after which the conductivities at  $21^\circ\text{C}$  reached the values shown in Fig. 1. For comparison, we show also results for AgI- $(\text{CH}_3)_3\text{SI}$ . The conductivity for the Se-containing electrolyte was  $4 \times 10^{-3} \Omega^{-1} \text{cm}^{-1}$  at 85 mol % AgI, compared with  $2.7 \times 10^{-2} \Omega^{-1} \text{cm}^{-1}$  for the S-containing electrolyte at the same mol %. A ten-fold deterioration in conductivity was observed over a period of a few weeks, which may have been caused by the presence of moisture<sup>11</sup>.

The loss of conductivity makes the AgI- $(\text{CH}_3)_3\text{SeI}$  system unsuitable for battery use, although other Se-containing systems may be more suitable. The first member of the AgI-TeI system that we have studied is  $\text{Ag}_{5.5}(\text{CH}_3)_3\text{TeI}_{6.5}$  which was prepared by grinding together appropriate amounts of  $(\text{CH}_3)_3\text{TeI}$ , prepared from  $(\text{CH}_3)_3\text{Te}$  and  $\text{CH}_3\text{I}$  (ref. 10), and AgI, pressing into a three-layer pellet and heating to  $140 \pm 10^\circ\text{C}$  for 7 h. The conductivity was  $< 10^{-5} \Omega^{-1} \text{cm}^{-1}$ , making it unsuitable for battery use.

The relatively poor properties of these Se- and Te-containing electrolytes, when taken in conjunction with their high toxicities and the consequent difficulties that arise in handling them indicate that such systems are unlikely to be exploited commercially for some considerable time.

We have found, however, that the performance of bis-sulphonium diiodides is altogether more encouraging. 1,3-bis(dimethylsulphonium)propane diiodide was prepared by the

Fig. 1 Conductivities of solid electrolyte systems incorporating AgI and (a)  $(\text{CH}_3)_3\text{SeI}$  ( $\square$ ); (b)  $(\text{CH}_3)_3\text{SI}$  ( $\circ$ ); (c)  $(\text{CH}_3)_3\text{S}^+(\text{CH}_2)_3\text{S}^+(\text{CH}_3)_2\text{I}^-$  ( $\Delta$ ) as a function of mol % AgI.

## Search for new silver-ion solid electrolytes for use in batteries

THE  $\alpha$ -phase of AgI, which is stable above  $146^\circ\text{C}$ , has a silver-ion conductivity of  $1 \Omega^{-1} \text{cm}^{-1}$  at  $150^\circ\text{C}$  (ref. 1), which would make it a suitable solid electrolyte for high temperature batteries. The room-temperature conductivity of the stable phase of AgI is disappointingly low ( $10^{-6} \Omega^{-1} \text{cm}^{-1}$ ) and although samples with conductivities approaching  $3 \times 10^{-4} \Omega^{-1} \text{cm}^{-1}$

method of Protiva, Jilek and Exner<sup>12</sup>, ground up with the correct amount of AgI and pressed into three-layer pellets, the outer layers comprising a mixture of silver powder and powdered electrolyte. Pellets containing 96, 95, 94, 93, 92 and 90 mol % AgI were prepared in this way, these proportions being selected because the conductivity maximum for a dication would be expected to be within this region, by analogy with the dimethonium results<sup>4</sup>. The pellets were heated in nitrogen at  $120 \pm 2^\circ \text{C}$  for 66 h, after which their conductivities at  $21^\circ \text{C}$  were measured. The values are presented in the Fig. 1. The conductivity is  $1.0 \times 10^{-2} \Omega^{-1} \text{cm}^{-1}$  for 93 mol % AgI–7 mol %  $(\text{CH}_3)_2\text{S}^+(\text{CH}_2)_3\text{S}^+(\text{CH}_3)_2 2\text{I}^-$ , which remained constant over a period of several weeks. This stability, which contrasts with the results for Se- and Te-containing electrolytes, makes this system a plausible choice for use in a solid state cell. Conductivity results for the systems  $\text{AgI}-\text{R}_2\text{S}^+(\text{CH}_2)_m\text{S}^+\text{R}_2 2\text{I}^-$  and  $\text{AgI}-(\text{CH}_2)_n\text{S}^+(\text{CH}_2)_m\text{S}^+(\text{CH}_2)_n 2\text{I}^-$ , and their use in solid-state electrochemical cells will be reported later.

We thank Mallory Batteries (UK) Ltd for support, Mr M. I. Needham for NMR spectra and Mr C. L. Groves for preparing  $\text{CH}_3\text{S}(\text{CH}_2)_3\text{SCH}_3$  from which the dication was prepared.

## Fossil hominid femora and the evolution of walking

THE evolutionary origins of human bipedalisms are still poorly understood, but recent discoveries of fossil hominid femora in Africa reveal some interesting details. Especially important are several new fossils discovered by the expedition led by R. E. F. Leakey to East Rudolf, Kenya<sup>1-9</sup>. The purpose of this paper is to find the morphological and functional affinities among higher primates of these and other fossil femora in the hope of revealing more about the nature of early hominid locomotion.

The hominid fossils analysed here include two from Swartkrans, South Africa (SK 82 and SK 97), discovered in 1949 by Broom and Robinson<sup>10</sup>, dated variably between 1.5 and 3 Myr<sup>11-15</sup>, and classified as *Paranthropus* or *Australopithecus robustus*; and three from east of Lake Rudolf discovered by R. E. F. Leakey's expedition in 1972<sup>3-9</sup> and classified as *Australopithecus* sp. indet. (KNM-ER 1503, dated between 1.8 and 2.6 Myr) and *Homo* sp. indet. (KNM-ER 1472 and 1481c, both dated between 1.6 and 3 Myr)<sup>16</sup>.

The comparative sample consists of either the left or right femur from 57 *Homo sapiens*, 42 *Pan troglodytes*, 16 *Pan paniscus*, 66 *Gorilla gorilla*, and 34 *Pongo pygmaeus*.

Ten measurements are used to represent the shape of the

proximal femur. These are the vertical head diameter, vertical neck diameter, anteroposterior neck diameter, transverse shaft diameter, anteroposterior shaft diameter, the projected distance from the centre of the head to the lateral surface of the greater trochanter measured perpendicular to the shaft axis, neck length, two measurements from the inferior border of the lesser trochanter: one to the superior surface of the neck, and one to the centre of the head, and the projection of the greater trochanter above the neck. A full description is given elsewhere<sup>17</sup>.

These data were analysed using canonical variates analysis<sup>18</sup>. The measurements are first adjusted for possible allometric effects, using average within-taxon allometry coefficients between each measurement and a standard size variable<sup>19-21</sup>. They are then converted to ratios of the size reference variable for each specimen, producing dimensionless shape variables which are relatively independent of factors of size. Canonical analysis is performed by entering each taxon as a separate group. All of the hominid fossils are entered as a single group in the original calculations.

Figure 1 displays the results by plotting the first, second and fourth canonical variates, which together account for 82.9% of the total variance (47.3%, 30.9%, and 4.7% for axes 1, 2, and 4, respectively). The third canonical variate is not plotted because it merely acts to separate *Pan* from the other hominoids. The fossil hominid femora are quite variable, which might be expected considering the changes in locomotor adaptation in human evolution and their possible time span. The three femora that have been classified<sup>3-10</sup> as *Australopithecus* (SK 82, SK 97, and KNM-ER 1503) are separated from *Homo sapiens*. The two fossils classified as *Homo* (KNM-ER 1472 and 1481c) are closer to modern *Homo sapiens*.

On the first canonical variate all of the hominids are separated from the rest of the primates. The variables with the highest correlation with this variate include the neck length and the distance that the greater trochanter projects above the neck. The neck is very long in all of the fossil femora and moderately long in modern *Homo*. The human greater trochanter is lower than in the other hominoids, but in all of the early hominids the greater trochanter barely projects at all. Presumably the differences in the projection of the greater trochanter reflect differences in the function of the gluteus medius, gluteus minimus, and piriformis muscles which attach on the greater trochanter. The two glutei muscles act primarily as abductors in bipedal

Fig. 1 Distribution of group centroids and fossils on the first, second, and fourth canonical variates which account for 82.9% of the total variance

hominids—their pull is essential to the lateral support system in the human hip<sup>22</sup>. The length of the femoral neck is another feature which is associated with the abductor mechanism of the bipedal hominid hip, since the length of the neck is related to the length of the abductor lever arm. The very long femoral neck of the early hominids may imply that they had mechanically efficient lateral support mechanisms in their hips<sup>23</sup>.

The second canonical variate maximises the separation of *Pongo* from the other hominoids, and the variables with high correlations with this axis are those which describe the unique morphology of the orangutan hip. The third variate separates the two species of *Pan* from the rest of the primates. It is on the fourth variate that the fossil hominid femora differ significantly from modern *Homo*. Traits most closely associated with this axis are the same as those associated with the first variate, except the head size is also heavily weighted. In the three hominid fossils classified as *Australopithecus* (KNM-ER 1503, SK 82, SK 97) the head diameters are uniquely small, but in the two classified as *Homo* (KNM-ER 1481c and 1472) they are more similar to extant hominids. As a consequence of this resemblance and others, the two early *Homo* femora lie nearer to the modern *Homo* group on the fourth canonical axis, with the australopithecine femora in an isolated position.

Other axes account for the small residual variances, but offer no other useful interpretation.

Figure 2 compares the relative size of each dimension in the two most complete fossil hominids (KNM-ER 1481c and SK 97) and *Homo sapiens*. The significant fact revealed by this figure is the similarity between the two hominid fossils in many traits and how different they are in the same way from *Homo sapiens*. The only conspicuous differences between the two fossils are in their relative head size and relative anterior-posterior shaft thickness. This result contrasts with the preliminary visual assessment and many univariate comparisons concerning KNM-ER 1481c.

These results can be related to what is known of australopithecine hip-joint mechanics. Although these fossil hominids were bipedal, their pelvic girdles are morphologically different from modern humans in having laterally splayed iliac blades, small acetabulae, and long femoral necks. Lovejoy *et al.*<sup>23</sup> give a biochemical explanation of these differences suggesting that the evolutionary changes between the hip of the australopithecines and *Homo sapiens* is a result of encephalisation: the increase in cranial size in human evolution meant a concomitant increase in size in the birth canal. The intermediate position of the two East Rudolf femora classified as *Homo* could be related

to the intermediate cranial capacity apparent in that population.

Although the present study deals with only one half of a joint and not with a total functional unit, the proximal femur is an integral part of hominid locomotion. Its morphology is highly correlated with that of the pelvis and other parts of the hindlimb. Unfortunately, there are no published reports of complete pelvises associated with femora in the early hominid fossil collections except for Sts 14 from Sterkfontein, South Africa, but a large part of its proximal femur is missing, including the head and most of the neck.

The findings do support the idea expressed by Leakey and others<sup>3-9</sup> that there were at least two distinctive forms of hominids with one more closely related to the later hominids than the other. The distinctively long neck of all of the early hominids indicates that the abductor lever arm was probably long which would yield a favourable bio-mechanical arrangement for the lateral support system in the hip which is necessary for human walking. The differences between the fossils classified as *Homo* and *Australopithecus* may imply that the hip joint mechanics were different. A major morphological difference is the size of the femoral head. If Lovejoy *et al.*<sup>23</sup> are correct in their assessment of early hominid hip biomechanics, the large femoral heads might be a result of a widened birth canal. Whether or not there was more than one kind of gait among the early hominids is still uncertain.

## Hypothesis for origin of planktonic patchiness

ALTHOUGH environmental heterogeneity can contribute to the observed patchiness in oceanic planktonic populations, biological interactions between phytoplankton and herbivorous copepods can lead to similar patterns. The phenomenon of spontaneous pattern generation even in a homogeneous environment through the interplay of reaction and movement is a very general property of the class of mathematical 'reaction-diffusion' equations used to model such systems, and there are several ways in which such patterns may occur. The result may be either spatiotemporal patterns<sup>1</sup> or time-independent spatial patterns. Usually one thinks of diffusion as damping inhomogeneities, and a hypothesis put forward by Steele<sup>2</sup> essentially relies on a balance reached between the dehomogenising aspects of local interaction and the homogenising influence of diffusion to produce pattern. On the other hand, it has also been suggested<sup>3-6</sup> that in some conditions diffusion can destabilise an otherwise stable interaction (in the manner originally suggested by Turing<sup>7</sup>) to produce pattern. We have explored<sup>5</sup> this further in a nonlinear analysis that describes the final stages of pattern formation, and the resultant calculations provide some insights into the spatial scale of patterns which might arise in this way.

The results that we describe depend on two hypothesised properties of the full equations: an autocatalytic effect in phytoplankton density which is attributed to a reduced efficiency of herbivory as phytoplankton density increases (a Holling<sup>8</sup> Type 2 functional response), and differential dispersal rates which favour higher herbivore motility. Both assumptions may be justified on theoretical grounds (the work of Holling for the first, and the greater mobility of herbivores by comparison with phytoplankton for the second), but the data are at present insufficient to provide the real test.

The relevant equations<sup>5</sup> thus take the form

$$\partial P/\partial t = aP + eP^2 - bPH + \nabla \cdot (\mu \nabla P)$$

$$\partial H/\partial t = cPH - dH^2 + \nabla \cdot (\nu \nabla H)$$

where  $P$  is phytoplankton density,  $H$  herbivore density,  $t$  time, and  $\mu$  and  $\nu$  are species-specific diffusion coefficients.  $a$ ,  $b$ ,  $c$ ,  $d$  and  $e$  are all assumed positive. The assumption of passive diffusion is made for simplicity only; more complicated movement patterns can also lead to diffusive instability.

Assuming homogeneity of dispersal rates and restricting attention to one space dimension, we obtain the modified equations

$$\partial P/\partial t = aP + eP^2 - bPH + \mu(\partial^2 P/\partial x^2)$$

$$\partial H/\partial t = cPH - dH^2 + \nu(\partial^2 H/\partial x^2)$$

In the linearised study of small disturbances, one exposes the system to small amplitude perturbations of the initial form

$$P = c_1 \cos qx, H = c_2 \cos qx$$

(Rather general disturbances can be Fourier synthesised from such perturbations.)

The system is seen to have a spatially uniform stable equilibrium

$$P = (ad)/(bc - ed), H = (ac)/(bc - ed)$$

provided  $bc - ed > 0$ ,  $c > e$ , and

$$R = \nu/\mu < [1/\{\sqrt{(b/d)} - \sqrt{[(b/d) - (e/c)]}\}]^2 = R_{cr}$$

We note that  $R_{cr} > 1$ .

When  $R > R_{cr}$ , the local activation effect due to the autocatalytic term interacts with the long range inhibition<sup>9</sup> to destabilise the uniform state. For  $R$  slightly greater than  $R_{cr}$ , a perturbation will serve to destabilise if its initial wavelength is approximately equal to  $1/q_{cr}$ , where

$$q_{cr} = [\sqrt{(b/d)}/\sqrt{[(b/d) - (e/c)]}] - 1$$

By a combination of successive approximations and multiple time scales, we have shown<sup>5</sup> that for  $R$  slightly greater than  $R_{cr}$ , the uniform state is replaced by a new steady state in which plant and herbivore are more concentrated in certain regions (with an overall elevation in mean herbivore density). The limit to the growth of the perturbation is a result of the distortion of the initial periodic spatial distribution due to nonlinear interactions.

When two-dimensional effects are introduced, we expect (as happens in the discrete spatial case) that perturbations of large enough amplitude will be shown to destabilise systems which are stable to small perturbations, and that generally the new steady state which arises from instability of the uniform state will either be net-like or spot-like, depending on a certain combination of parameters. This type of analysis is valid for initially homogeneous regions that are large compared with  $1/q_{cr}$ .

We emphasise that we offer here only one mechanism for generating pattern—not necessarily the principal one. In eventually distinguishing between hypotheses, however, it should be helpful to do the kind of nonlinear analysis we have carried out. To our knowledge this has not previously been done for any of the hypotheses.

## Intercalary regeneration in imaginal wing disk of *Drosophila melanogaster*

In this paper we show for the first time that the developmental capacity of imaginal disk cells from *Drosophila* can be altered by appropriate grafting operations. The appendages of amphibians and immature arthropods, and the imaginal disks of holometabolous insects, are capable of undergoing pattern regulation when parts are removed. (Pattern regulation is used here to describe the alteration of cell fates in response to an

abnormal situation in a developing system; we include under this term both regeneration and duplication.) Regulation then occurs during growth of the tissue by cell division, a process termed epimorphosis<sup>1</sup>. A characteristic feature of epimorphic regulation which has recently been recognised, is the different regulative responses shown by complementary pieces. For example when an imaginal disk of *Drosophila* is bisected and allowed to grow for some time, one of the two fragments usually regenerates the missing parts, while the other undergoes duplication of the presumptive pattern already present<sup>2</sup>. Similarly, whereas the stump of an amputated amphibian or cockroach limb can regenerate distally, the amputated distal part, if kept alive by grafting to a host animal, can also undergo pattern regulation by forming the distal pattern elements, thereby duplicating itself<sup>3-6</sup>.

It has been suggested<sup>1,2</sup> that the complementarity between regeneration and duplication can be understood if it is assumed that new positional values<sup>1</sup> can be generated during growth only in a fixed sequence, a proximal-to-distal sequence in the case of a regenerating limb<sup>7</sup>. The spatial pattern of differentiation thus could be established by a temporal sequence of events occurring autonomously in the dividing cells as the tissue grows out from the cut edge. Under certain circumstances, however, it is clear that the developmental fate of a cell is a function not only of its history but also of its position with respect to other cells. For example, during regeneration from the stump of a cockroach leg or during duplication from the distal leg fragment, the newly produced cells attain positional values only more distal than those of their progenitors. But when the distal part of a leg is grafted to a stump at a more proximal level, intercalary regeneration occurs between the graft and the stump, and the cells produced by the graft can attain more proximal positional values<sup>8</sup>. The results of other graft combinations indicate that the graft can have a similar effect on the development of the stump<sup>9</sup>. Similar results

Fig. 1 Simplified fate map of the imaginal wing disk of *Drosophila melanogaster*, showing only the markers which are genotypically recognisable in our combinations (abbreviations as in Table 1). From Bryant<sup>13</sup>. The positions of the cuts used to generate the fragments are also indicated.

Fig. 2 a, Mosaic wing spread and posterior row produced by a 02/28 combination. The arrangement of posterior row bristles of alternate genotype is similar to that found in mosaics produced *in situ*<sup>19,20</sup>. b, Mosaic notum produced by a +02/y;mwh 68 combination.

have been reported for the legs of other insects<sup>10</sup>, for regenerating amphibian limbs<sup>11</sup> and for developing chick limbs<sup>12</sup>.

When a fragment of a *Drosophila* imaginal disk is transplanted to a mature host larva, it undergoes metamorphosis with the host, and the cells of the fragment differentiate those structures which they would have formed *in situ*. This has made possible the establishment of detailed fate maps of several of the imaginal disks, and that for the wing disk is shown in Fig. 1. If, however, the fragment is cultured in an adult abdomen for several days (to allow for growth) before transfer to a host larva for metamorphosis, it can either regenerate the missing parts or duplicate the presumptive pattern already present<sup>2,14</sup>. In the case of the wing disk, it was possible to localise a point in the disk which defines the direction in which regeneration usually occurs; fragments with cut surfaces facing away from this point show regeneration, whereas those with cut surfaces facing in the direction of this point show duplication<sup>13</sup>.

In our first experiments, we studied the interaction of the presumptive notum (02 piece; Fig. 1) with the presumptive wing (28 piece). When cultured alone, the 28 piece frequently regenerates the missing notum whereas the 02 piece undergoes duplication<sup>13</sup>. Individual 02 pieces of one genotype (wild-type *Oregon-R* or *y;mwh*) were mechanically mixed with individual 28 pieces of the other genotype. Mixing was accomplished with two tungsten needles in a drop of buffered Ringer's solution, the two fragments being folded together about 20 times so that they formed a coherent mass. The combinations were transplanted to the abdomens of fertilised female adults, where they remained for 7 d. They were then dissected out of the adult hosts and re-injected into larval hosts for metamorphosis; the larger cultured combinations had to be cut into two or more fragments before they could be transplanted to larval hosts. The differentiated implants were recovered from the metamorphosed hosts and mounted between coverslips for scoring of the structures of each genotype. Control combinations were similarly produced from two 02 or two 28 pieces of different genotypes. The results show that many structures which are never produced by isolated 02 fragments<sup>13</sup> or 02 combinations (02/02, Table 1) are produced with a high frequency by cells from the 02 piece when in combination with cells from a 28 piece (02/28, Table 1). The 28 piece could simultaneously regenerate the notum, but this is not remarkable since it occurs in cultured isolated 28 pieces<sup>13</sup> or 28 combinations (28/28, Table 1). Many of the patterns produced by the 02/28 combinations were mosaic, containing cells of both genotypes (Fig. 2a) and patterns were frequently duplicated.

In this experiment all of the positional values regenerated

\*Regeneration across the anterior-posterior compartment boundary.

y; *mwh* and wild type were used in reciprocal combinations and the results combined. 02, 23, 68, Ant and Post represent the fragments illustrated in Fig. 1. Structures not found in control combinations of identical fragments but appearing in combinations of two different fragments are shown in bold. Combinations producing extensive allotypic structures following transdetermination are not included in these results.

by the 02 piece are already present in the 28 piece with which it is mixed; this suggests that the positional values of the cells derived from the 02 piece are merely being copied from adjacent cells from the 28 piece. In a second experiment, we tested for regeneration of structures which are not normally produced by either fragment, even when cultured. We mixed 02 pieces (presumptive notum) with 68 pieces (presumptive ventral wing blade, ventral hinge, and pleura). Both fragments showed duplication when cultured separately<sup>13</sup>, but in combination they showed intercalary regeneration of many of the structures not normally produced by either of them (02/68, Table 1). Again, the patterns produced were frequently mosaic and often duplicated (Fig. 2b). In six cases, cells from the 68 fragment produced parts of the notum, usually derived from the opposite end of the disk (Fig. 1).

We have also tested for intercalary regeneration in the anterior-posterior direction in the wing disk (Table 1). Fragments totally within the anterior compartment<sup>15</sup> were mixed with fragments totally within the posterior compartment (Fig. 1). Each of these fragments is taken from the edge of the disk, and is therefore expected to duplicate<sup>13</sup>; accordingly, the control combinations of anterior and posterior fragments (Ant/Ant and Post/Post, Table 1) produced only the structures expected from the fate map.

**Fig. 3** Regenerative behaviour of sectors of the wing disk. In each case, the complementary 90° and 270° sectors were cultured in adult abdomens for 7 d before transfer to host larvae for metamorphosis. R, Regeneration; D, duplication.

When mixed together, however (Ant/Post, Table 1), they showed intercalary regeneration of intermediate structures as in the 02/68 combination, but in most cases each of the fragments in the combination regenerated only those structures within its own (anterior or posterior) compartment, so that the frequency of mosaic patterns was much lower than in the previous experiments. Regeneration of specific structures in the other compartment occurred in nine cases, but this might be an underestimate of the true frequency of regeneration across the compartment border since anterior and posterior wing blade are indistinguishable in implants, and regeneration of one from the other cannot be detected. In our first and second series of experiments the wing-notum, proximal-distal and dorsal-ventral compartment boundaries were clearly transgressed, but in the case of the dorsal-ventral boundary we found some evidence for the maintenance of compartmentalisation since the genotypic boundary in mosaic patterns often coincided with the wing margin bristles or hairs, as reported previously<sup>16</sup> (Fig. 2a).

The occurrence of intercalary regeneration provides a simple explanation for the hitherto puzzling behaviour of certain wing disk fragments when cultured alone. The regulatory behaviour of segments of this disk could be accounted for, as described above<sup>13</sup>, on the basis of the direction faced by the straight cut edges. In the same culture conditions, however, each of four 90° sectors of the wing disk duplicates while the complementary 270° sectors regenerate (P.J.B., unpublished, and see Fig. 3); this cannot be accounted for in terms of the predicted regulatory behaviour of the individual cut edges of the sectors. We have also found, however, that in the first few days of culture, the two cut edges of these fragments heal together (unpublished results). If we assume that intercalary regeneration then occurs between the levels of the two fused edges, the results are easily explained. Intercalary regeneration can also account for the ability of imaginal disks to produce a normal pattern after more than half of the cells are killed by X rays (our unpublished results).

Our results also offer a way of understanding pattern reconstruction by dissociated imaginal disks. Mosaic patterns of the kind illustrated in Fig. 2a and b have been produced in many experiments where genetically marked disks are dissociated into cells and cell clumps, and reaggregated before culture and metamorphosis<sup>16-18</sup>. If mosaic patterns can develop on a large scale by intercalary regeneration between fragments from opposite ends of the disk, it seems logical to assume that the same process operating on a smaller scale could account for pattern reconstruction in dissociated and reaggregated disks. This kind of interaction

between cells obviates the need to assume that extensive cell migration<sup>17</sup> is necessary for pattern reconstruction.

We thank Becky Hsei for technical assistance. This work was supported by a grant from the National Institutes of Health.

## Are morphogenetic tissue interactions mediated by transmissible signal substances or through cell contacts?

TRANSMISSION of morphogenetic signals between embryonic cells is a special form of intercellular communication which may involve diffusible signal substances<sup>1,2</sup> or intercellular contacts<sup>3,4</sup>. We have previously presented evidence that the induction of metanephric kidney tubules is dependent on cell contacts between the interacting tissues rather than on diffusible signals<sup>5,7</sup>. Several embryonic and neoplastic tissues possess an inductive effect when tested against metanephric mesenchyme<sup>8-11</sup>. If different inductors release an extracellular, transmissible signal substance, the restriction of induction by interposed filters with varying pore sizes should be independent of the type of inductor tissue, assuming that there is no major difference in size between signal substances. If cell contacts and thus ingrowth of cytoplasmic processes into the filter are required, however, there may be differences between the transfilter inductive capacity of various inductor tissues depending on their ability to send cytoplasmic processes through the filter. That is now shown to be the case, in a comparison of the spinal cord and the mesenchyme of embryonic salivary gland as inducers of metanephric mesenchyme.

Direct combination of salivary mesenchyme with metanephric mesenchyme resulted in the formation of well shaped, coiling tubules with high mitotic activity in all 6 cases, which indicates that salivary mesenchyme like spinal cord is a potent inductor in direct combination. When a Millipore 'TA' filter (pore size 0.8  $\mu$ m, thickness 25  $\mu$ m) was interposed between the tissues only 1 of 7 explants showed any tubule response. In the other explants, the metanephric mesenchyme spread out on the filter with good viability but without tubule formation. When spinal cord was used as an inductor, transfilter tubule formation was regularly seen<sup>14</sup>.

Nuclepore filters with pore sizes between 0.2 and 0.6  $\mu$ m allowed the passage of the inductive signal from the spinal cord to the responding metanephric mesenchyme but, in

identical conditions, prevented passage of the signal from the salivary mesenchyme (Table 1). When filters with a nominal pore size of 3.0  $\mu$ m separated the salivary and kidney mesenchymes, tubules were observed in 8 of 14 explants. These filters, however, allowed the passage of whole metanephric cells through the filter and kidney tubules were often seen below the filter intermingled with salivary cells.

Light microscopy of glutaraldehyde fixed specimens with salivary mesenchyme as inductor showed the presence of cytoplasmic material throughout the 3.0- $\mu$ m pores, and variable amounts of stainable material in the 0.6- $\mu$ m pores, and this was confirmed by transmission electron microscopy. This contrasts with the abundant penetration of spinal cord material into even smaller pores<sup>6</sup>.

Scanning electron microscopy of filters where tissues were grown on one side only, demonstrated abundant cytoplasmic penetration through 3.0- $\mu$ m pores when either salivary mesenchyme or spinal cord was cultured for 48 h (Fig. 1a). Processes from the spinal cord were seen to penetrate even the smallest pores (0.1  $\mu$ m) whereas salivary mesenchyme never protruded through pores of twice that size (Table 1). Four out of seven explants with salivary mesenchyme cultured for 48 h on the lower surface of a filter with 0.6  $\mu$ m pores showed penetration of cytoplasmic processes in restricted areas. In contrast, there were abundant processes when spinal cord was cultured in identical conditions (Fig. 1b). When metanephric mesenchyme was cultured on top of various Nuclepore filters, cell processes (and whole cells) penetrated to the lower surface only through the largest pores.

Thus the two inductors, spinal cord and salivary mesenchyme, gave identical induction responses in direct combination with the responding metanephric mesenchyme, but showed marked differences in inducing capacity when separated from the responder by a filter. While spinal cord was occasionally able to pass an inductive signal through 0.1  $\mu$ m pores and did so regularly through larger channels, salivary mesenchyme required pores ten times as large to send the morphogenetic signal to the responding mesenchyme. If the message is carried by transmissible molecules, the results imply that the signal molecules are markedly different in the two inductor tissues, and that the 'salivary factor' is trapped by  $\sim$  0.6- $\mu$ m pores. Measurements of the passage of various molecules through Nuclepore filters have not lent support to such an idea, as compounds with a molecular weight as high as  $10^7$  easily pass through even the smallest pores (0.1  $\mu$ m) (ref. 6). It seems more reasonable to correlate tubule induction to the differences in the penetration of cytoplasmic material through the filters. Spinal cord is able to send thin filamentous processes through 0.1- $\mu$ m pores, whereas salivary mesenchyme requires a minimum

**Table 1** Tubule-forming response of metanephric mesenchyme and penetration of cytoplasmic processes from the inductor as a function of the type of the inductor tissue and the pore size of the interposed Nuclepore filter\*

Filter Nominal pore size ( $\mu$ m)	Inductor			
	Salivary mesenchyme Tubules	Penetration	Spinal cord Tubules†	Penetration
0.1	‡		3/30	+
0.2	0/13	—	27/31	++
0.5-0.6	0/10	±	25/25	++
3.0	8/14	+	15/15	++

\*Metanephric mesenchyme and spinal cords were dissected from 11-day mouse embryos (CBA/T6T6 $\times$ BALB/c), and salivary mesenchymes from the submandibular gland of 13-d embryos. Tubule formation was evaluated by light microscopy after 72 h of cultivation<sup>12</sup>. Nuclepore filters with a thickness of  $\sim$  15  $\mu$ m and a nominal pore size of 0.2, 0.6 or 3.0  $\mu$ m (General Electric Co., Pleasanton, California, USA) were used. According to previous measurements, the largest pores are, however, 1.5-2.0  $\mu$ m in diameter<sup>6</sup>.

†Results from ref. 6.

‡Not determined.

**Fig. 1** *a*, Scanning electron micrograph of the upper surface of a Nucleopore filter with a nominal pore size of 3.0 µm. Salivary mesenchyme cultured for 48 h on the lower surface of the filter can be seen to send cytoplasmic processes through the pores. *b*, Scanning electron micrograph of the upper surface of a 0.6-µm pore size Nucleopore filter with a piece of spinal cord cultured on the lower surface for 48 h. Numerous cytoplasmic processes can be noted on the upper surface of the filter membrane. Tissues were placed on one side of the filter only. The inductor tissues (spinal cord, salivary mesenchyme) were placed below the filter and the responding metanephric mesenchyme on top of it. After 48 h of cultivation, the explants were rinsed in PBS, fixed in 2.5% glutaraldehyde in 0.1 M cacodylate buffer at pH 7.8 for 60 min at room temperature, dehydrated in ethanol and dried by the critical point method<sup>13</sup>. Subsequently the specimens were covered with a thin layer of carbon and gold in a Balzers Micro-BA-3 evaporator and examined in a Jeol JSM-U3 scanning electron microscope (the Electron Microscope Laboratory, University of Helsinki).

pore size of 0.6 µm. Furthermore, induction of kidney tubules was never seen in transfilter situations which did not allow cytoplasmic penetration and development of contacts between inductor cells and the responding mesenchyme. The results also show that cytoplasmic penetration of filters can occur without the passage of the morphogenetic signal. The reason for this may be that contacts are either established too late, as the penetration time is a function of pore size<sup>6</sup>, or are too few. In another interactive system where the response can be quantified, the intensity of induction is a function of pore size and filter thickness<sup>15</sup>, and may correlate to the size of the contact area.

## Haploid mouse blastocysts developed from bisected zygotes

INTEREST in haploid mouse embryos as a material for studying gene action in early development and as a potential source of haploid cell lines has stimulated a number of attempts to produce this condition experimentally. We describe here a new method of producing haploid mouse embryos by bisecting fertilised eggs. Morphologically normal haploid and haplo-diploid mosaic blastocysts were formed after insertion of such fragments to empty zonae and transfer to the oviduct.

Haploid blastocysts can now be routinely obtained after parthenogenetic activation of unfertilised eggs (for review, see refs 1–3). When transferred to ectopic sites such embryos give rise in a small proportion of cases to 'growths' composed of many types of differentiated tissues, some of which may be haploid<sup>4,5</sup>. No success has yet been reported, however, in establishing haploid mammalian cell lines in culture. Haploid mouse embryos can also be obtained after microsurgical removal of one pronucleus from the fertilised egg, but for unknown reasons, very few develop into blastocysts<sup>6</sup>. Another possible method of producing haploid embryos from fertilised eggs would be to cut the pronucleate egg into halves, each containing one pronucleus. A.K.T. has recently developed such a technique (unpublished).

Pilot experiments showed, however, that early one-cell eggs subjected to harsh manipulation including microsurgery do not develop very well in culture and we decided, therefore, to test the viability of the bisected eggs in optimal conditions—that is, *in vivo*—before attempting a large scale experiment *in vitro*. As the zona pellucida is removed from the egg during the cutting procedure, the egg fragment must be inserted back into empty zonae before transfer to recipients because, up to the eight-cell stage, zona-free eggs do not survive in the oviduct<sup>7,8</sup>.

Spontaneously ovulating F<sub>1</sub>(CBA×C57BL/10) females mated with CBA-T6T6 males, and 129/J females mated with 129/J males, were killed in the early afternoon (1400–1530) on the day of the vaginal plug. The eggs were treated with hyaluronidase in phosphate-buffered saline (PBS) (200 IU ml<sup>-1</sup>) to remove cumulus cells, subjected to 0.5% Pronase to dissolve the zona pellucida<sup>9</sup>, cut into halves (A.K.T., unpublished) and cultured overnight in Whitten's medium<sup>10</sup> in liquid paraffin. Those in which both halves had divided once were transferred to PBS+0.1% bovine serum albumin and inserted microsurgically into empty zonae prepared by sucking out the contents of unfertilised eggs<sup>11,12</sup>. Blastomeres in zonae (Fig. 1a) were transferred to the oviducts of mice on day 1 of pseudopregnancy<sup>13</sup>. Three pairs of blastomeres originating from halves containing both pronuclei were also inserted into zonae and transferred to one recipient. Seventy-two hours later (day 4 of pseudopregnancy, day 5 of development of eggs) the genital tracts were flushed with PBS and the recovered embryos cultured for 3–4.5 h in medium containing Colcemid (0.2 µg ml<sup>-1</sup>) and examined in air-dried preparations<sup>14</sup>.

Table 1 summarises the results. The overall effectiveness of transplanting pairs of blastomeres into empty zonae was about 65% (range 50–100%). The recovery of transplanted eggs was, however, very low—only 16.6%. The collected embryos included six blastocysts (9%), two morulae, and three irregular embryos arrested in cleavage. These embryos together with empty zonae found in some recipients accounted for 40.3% of transplanted eggs. The majority of transplanted pairs of blastomeres most probably escaped from the zonae through the incision shortly after being transferred to the oviduct, and degenerated<sup>11</sup>.

**Fig. 1** *a*, Pair of blastomeres developed *in vitro* from a haploid egg half and transplanted into empty zona pellucida ( $\times 450$ ). *b*, 4.5-d-old gynogenetic haploid blastocyst of  $F_1(\text{CBA} \times \text{C57BL}/10)$  genotype ( $\times 600$ ). *c*, 4.5-d-old diploid blastocyst of  $F_1(\text{CBA} \times \text{C57BL}/10)$  genotype developed from an egg half which contained both pronuclei ( $\times 450$ ).

Other factors which may have been responsible for the low recovery are degeneration due to injury produced by the two successive microsurgical operations and possibly also early death of androgenetic haploids lacking an X chromosome (diploid OY embryos are believed to die during early cleavage<sup>13</sup>). The last factor could account for the loss of 25% of transplanted haploids.

In spite of the low effectiveness, these experiments show that haploid egg fragments obtained by bisecting the pronucleate egg are viable and can develop into regular blastocysts composed of both trophoblast and inner cell mass (Fig. 1*b*). The number of cells (nuclei+metaphase plates) in the six available blastocysts were as follows: 29, 32, 38, 39, 57, and 68. In three blastocysts all metaphase plates were haploid but the other three had both haploid and diploid plates ( $4 \times n + 3 \times 2n$ ;  $2 \times n + 1 \times 2n$ ;  $8 \times n + 1 \times 2n$ ) thus showing that diploidisation of some cells during cleavage which leads to  $n/2n$  mosaicism, is not peculiar to parthenogenetic haploids<sup>16,17</sup>.

In the case of  $F_1(\text{CBA} \times \text{C57BL}/10)$  eggs fertilised by CBA-T6T6 sperms it was possible to determine the gynogenetic or androgenetic origin of embryos on the basis of the presence or absence of the T6 marker chromosome. Out of five such blastocysts four definitely had no T6 chromosome and were therefore gynogenetic. In the fifth blastocyst the presence of the marker chromosome was suspected, but because the quality of the only complete metaphase plate was not very good, the ability of androgenetic halves to develop to blastocysts remains to be confirmed. The 129/J blastocyst clearly did not contain a Y chromosome (Fig. 2) but because of the lack of karyological

markers it was not possible to determine whether it carried the genome derived from the egg or from the sperm.

The only embryo recovered after transferring three pairs of blastomeres derived from egg halves containing two pronuclei, was a regular blastocyst (Fig. 1*c*) composed of 42 cells and containing in the karyotype—according to expectations—one T6 chromosome.

In view of these encouraging results attempts have been undertaken to analyse in detail development of haploid egg

**Fig. 2** Haploid metaphase plate from a blastocyst developed from a bisected 129/J egg. There is no Y chromosome in the karyotype but because of the lack of chromosome markers the origin of the blastocyst (gynogenetic or androgenetic) cannot be determined.

**Table 1** Effectiveness of transplanting pairs of blastomeres into empty zonae

Ploidy	Genotype of eggs	No. of cleaved halves used for insertion into empty zonae	No. of cleaved halves successfully inserted and transferred to recipients	No. of transfers	Stage and no. of recovered embryos (+ empty zonae)
$n$	$\text{♀ } F_1 (\text{CBA} \times \text{C57BL}/10)$ $\times$ $\text{♂ CBA-T6T6}$	93	60	11	5 Blastocysts 2 Morulae 2 Irregular embryos arrested in cleavage 13 Empty zonae

## Somatic cell genetic evidence for X-chromosome linkage of three enzymes in the mouse

THE X linkage of loci coding for glucose-6-phosphate dehydrogenase (G6PD), hypoxanthine-phosphoribosyl transferase (HPRT), and phosphoglycerate kinase (PGK) has been determined for the mouse species *Mus musculus* and *M. caroli*. Evidence was obtained from a somatic cell genetic analysis of cultured embryonic cells of an interspecific hybrid foetus. The X-chromosomal assignment of

these loci has been determined already for several other mammalian species. This evidence was obtained from genetic analyses of electrophoretic variants<sup>1</sup> and enzyme deficiencies<sup>2,3</sup>; from the expression of these genes in viable interspecific hybrids<sup>4-6</sup>; from somatic cell genetic analyses of heterozygotes<sup>7-9</sup>, and from the expression of these loci in interspecific somatic cell hybrids<sup>10</sup>.

Evidence that these loci are X-linked in the laboratory mouse, *M. musculus*, comes from the observation that both X chromosomes are active in female germ cells and that gene dosage for these loci is doubled in oocytes of normal XX females as opposed to XO females. Activity measurements of G6PD<sup>11</sup>, HPRT<sup>12</sup>, and PGK<sup>13</sup> in oocytes has shown that oocytes from XX females contain about double the activity of each of these enzymes compared with oocytes from XO females. No genetic variants for any of these enzymes have been reported in the mouse to establish independently X linkage of these loci.

We have, however, observed that *M. musculus* and *M. caroli*, a related species from Dr J. T. Marshall in Thailand, have different electrophoretic mobilities for a number of enzymes including G6PD, HPRT and PGK. Hybrids of *M. caroli* and *M. musculus* have not been reported in the wild and they cannot be mated in laboratory conditions. Both species, however, have 40 telocentric chromosomes<sup>14</sup> and a similar reproductive cycle (V.M.C., unpublished). Interspecific hybridisation between *M. caroli* and *M. musculus* was attempted using artificial insemination of *M. musculus* females with *M. caroli* sperm (unpublished results of V.M.C. and J. Karr). No hybrid offspring were born but successful implantation and development to the foetus stage (approximately 14-16 d) was observed in three cases.

A critical feature of X-gene expression is that gene dosage is doubled in females compared with males, but the levels of gene products between the sexes is equal. The basis of this compensation between the sexes is attributable to the inactivation of one of the X chromosomes in all the somatic cells of the female<sup>15,16</sup>. This inactivation occurs early in mammalian development, possibly by the blastocyst stage. Maternally and paternally derived X chromosomes are inactivated at random so that the adult female has

**Fig. 1** Electrophoretic patterns of G6PD (a), PGK (b) and HPRT (c) in tissue and tissue culture homogenates. M represents the *musculus* forms and C represents the *caroli* forms. 1, *musculus* kidney; 2, *caroli* kidney; 3, clone B-5; 4, clone B-1; 5, cell population C; 6, clone C-6; 7, clone C-4; 8, clone A-1. The prefix for each clone indicates the mass population from which the clone was derived. Homogenates of cells from cell population A and B and mixtures of kidney homogenates demonstrated the same phenotype as cell population C in channel 5. The apparent extra PGK band in *caroli* kidney (b, 2) is a minor anodal band in the PGK phenotype that is present at high concentrations of tissue extracts. These minor components were observed in tissues of both males and females of *M. caroli*. A similar minor component is seen in tissue extracts of *M. musculus*, but at even higher concentrations. These minor components were not observed in cell culture extracts.

**Table 1** Distribution of gene markers in clones of cultured cells derived from a *M. musculus* × *M. caroli* foetus

Population	Total clones	Six linked enzymes			NP	Autosomal enzymes

		C	C	C	H	H	H
B	2	MC	MC	MC	H	H	H
		C	C	C	H	H	H
C	5	M	M	M	H	H	H
	5	MC	MC	MC	H	H	H
	3	C	C	C	H	H	H
	3	M	M	M	H	H	H
	16						

For each clone, all enzymes were analysed on the same cell homogenate. M denotes *musculus* origin; C denotes *caroli* origin; MC denotes both *musculus* and *caroli* contributions; and H denotes a hybrid phenotype with parental and heteropolymeric electrophoretic forms.

two populations of cells; one expressing the maternal and the other the paternal X.

If G6PD, HPRT and PGK are X-linked in *Mus* species, we reasoned that both *musculus* and *caroli* forms would be expressed in a hybrid female foetus and only the *musculus* form would be expressed in a male foetus. We therefore expected that a primary cell culture of hybrid cells would have both *caroli* and *musculus* electrophoretic forms if the foetus were female, or only *musculus* forms in the case of a male. The resulting cell lines from the hybrid foetus had both *caroli* and *musculus* electrophoretic forms of G6PD, HPRT and PGK and were presumed to be female. In the case of a female we further reasoned, from the Lyon hypothesis, that clones derived from single cells of the culture should uniformly express either the *caroli* or *musculus* electrophoretic forms of all three enzymes if these loci are X-linked. Hybrid foetal electrophoretic phenotypes and cloning of cultured foetal cells showed that these enzymes segregated as predicted for X-linked loci in *M. caroli* and *M. musculus*.

Foetuses were dissected from the uterus 16 d after arti-

cial insemination. Two were homogenised in equal volumes of distilled water and assayed for electrophoretic phenotypes. The third foetus was used to establish a primary cell culture: the 16-d embryo was minced in a solution of proteolytic enzymes (Viocase, Gibco) and Eagle's medium without serum, and divided into three parts, each of which were plated separately in Dulbecco's modified Eagle's medium (DMEM) (high glucose formula) with antibiotics and 10% foetal calf serum (Gibco). The cells were maintained in an atmosphere of 5–7% CO<sub>2</sub>. A monolayer of proliferating cells was obtained from each of the three original cell suspensions and designated primary cell populations A, B and C. Each cell population was maintained separately in the above medium and single cells were cloned by the procedure of Puck *et al.*<sup>17</sup>. Cell populations and clones were grown to confluency, collected for enzyme identification, and homogenised at a concentration of 7 × 10<sup>7</sup> cells per ml 0.5 M Tris at pH 7.5 (ref. 18). G6PD (EC 1.1.1.49) PGK (EC 2.7.2.3) and HPRT (EC 2.4.2.8) were analysed by starch gel electrophoresis<sup>10,19</sup>.

Electrophoretic phenotypes of *M. caroli* and *M. musculus*

**Fig. 2** Electrophoretic patterns of: NP (a), GPI (b) and GOT-1 (c) in tissue and tissue culture homogenates. M represents *musculus* forms and C represents *caroli* forms. 1, *musculus* kidney; 2, *caroli* kidney; 3, 1:1 mixture of *musculus* and *caroli* homogenates; 4, cell population B; 5, clone B-5; 6, clone B-1; 7, cell population C; 8, clone C-6; 9, clone C-4; 10, clone A-1. In cell culture extracts, the two heteropolymers migrating between the parental forms of NP indicate that NP is a trimeric enzyme<sup>21</sup>. The single heteropolymer observed for GPI and GOT-1 in cell culture extracts indicates that these enzymes are dimers. All cell culture extracts of hybrid populations demonstrate both parental and heteropolymer forms, indicating that both parental genes for each enzyme are active in each cell. The *musculus* and *caroli* tissue GPI phenotypes possess a major band and several anodally migrating minor bands at the high concentrations used for tissue extracts (b, 1 and 2). These minor bands were not observed in cell culture extracts. GPI is a dimeric enzyme and a hybrid enzyme is observed in heterozygotes for GPI electrophoretic variants in the mouse<sup>22</sup>. The band intermediate to the two parental forms in the 1:1 mixture (b, 3) is a *musculus* minor component and not a heteropolymer. A hybrid GPI enzyme, compared with the parental forms, is more intense as demonstrated by the relative intensities of the parental and hybrid enzymes in the cell culture samples. The variability between clones with regard to intensity of enzyme bands probably represents an increase in the number of

gene copies since chromosome numbers increased as a result of the foetal cells becoming established as cell culture lines. Chromosomes were examined on two hybrid clones from cell population B, one expressing *musculus* and the other *caroli* X-linked enzymes. They had mean chromosome numbers of 69 and 63, respectively, and only telocentric chromosomes were observed.

kidney HPRT, PGK and G6PD are shown in Fig. 1. The major band of activity for each enzyme has a different mobility for each species. One hybrid foetus demonstrated both *musculus* and *caroli* forms and was presumably a female, and one foetus demonstrated only *musculus* forms and was presumably male. These findings are consistent with X linkage. In each of the three primary cell populations, the electrophoretic patterns consisted of both *musculus* and *caroli* forms for each enzyme. The electrophoretic phenotypes of the three enzymes for cell population B is shown in Fig. 1 (channel 5). Sixteen clones derived from single cells were examined. The clones were established from all three populations soon after the establishment of the primary cell culture. Eight of the clones coordinately expressed only *musculus* electrophoretic types for PGK, HPRT and G6PD and eight coordinately expressed only *caroli* forms (Fig. 1 and Table 1). These findings support the prediction that the primary cell populations are mixtures of cells with either an active *musculus* X chromosome or an active *caroli* X chromosome.

The expression of three autosomal enzymes which differ in electrophoretic phenotype between the two species was tested to demonstrate that the foetuses, the cells of the primary cell populations and the clones were true hybrids with functional *musculus* and *caroli* genes in the same cell. Cytoplasmic glutamic oxaloacetic transaminase (GOT-1) (ref. 20), nucleoside phosphorylase (NP) (ref. 21), and glucosephosphate isomerase (GPI) (ref. 22) are multimeric enzymes which differ electrophoretically between *musculus* and *caroli* (Fig. 2). Each of these enzymes is coded by an autosomal locus as determined by genetic tests in *M. musculus* or man. Since these enzymes are multimeric, it was expected that electrophoretic phenotypes demonstrating both parental forms and intermediate hybrid forms would be observed if both parental genes were expressed in the same cell. Hybrid electrophoretic patterns consistent with the formation of intermediate heteropolymers by random combination of *musculus* and *caroli* polypeptide subunits in individual cells were demonstrated in the foetuses, the three cell populations and the clones (Fig. 2 and Table 1). Mixtures of *musculus* and *caroli* kidney extracts produced additive electrophoretic patterns without intermediate hybrid enzymes (Fig. 2). All 16 clones demonstrated both parental and heteropolymer bands for the autosomal enzymes (Table 1). Thus, both *caroli* and *musculus* genes were active in the original cell which formed the clones and remained active through successive cell generations. On the other hand, each clone showed only the *caroli* or the *musculus* phenotype for PGK, G6PD and HPRT. We conclude that these results are consistent with the predictions of the Lyon hypothesis that there are two populations of cells, that only one X chromosome is active in a cell, and that the same X remains active in successive cell generations. In retrospect, two populations of cells were indicated in one foetus and in the cells of the hybrid foetus used to make the primary culture by the two banded G6PD electrophoretic pattern. Because G6PD is a dimer, one expects a three banded electrophoretic phenotype like GPI or GOT-1 (Fig. 2) if both chromosomes are active in a single cell. Only both parental forms were observed, however, (Fig. 1). The electrophoretic findings of hybrid enzymes for NP, GPI and GOT-1 demonstrate that both *musculus* and *caroli* genes function in the same cell and that the foetuses were interspecific hybrids.

The strategy of analysing clones from single cells of heterozygous females has demonstrated the X linkage of HPRT, G6PD and PGK in man<sup>7-9</sup> and G6PD in mules<sup>5</sup>. In each instance only one of the two possible parental forms demonstrated by a heterozygous female was expressed. Such somatic cell genetic analyses have been confirmed in man by family studies using genetic variants of each enzyme. The segregation of PGK, G6PD and

HPRT in clones of somatic cells from an interspecific hybrid foetus and foetal extract phenotypes demonstrates an X-chromosome assignment of these enzyme loci in mice as reported from a comparison of enzyme activities in XO and XX oocytes<sup>11-13</sup>. These conclusions also agree with Ohno's hypothesis of conservation of the X chromosome among mammalian species<sup>24</sup>.

The relative amounts of *musculus* and *caroli* PGK, G6PD and HPRT expressed in the three primary cell populations were approximately equal. This suggests that the proportion of the cells with active *musculus* or *caroli* X chromosomes may have been equal in the hybrid foetus. Thus, there is no evidence that either parental X chromosome was preferentially inactivated during development or that cell selection acts to distort the proportions of the two cell populations. This finding is similar to the observation of X-chromosome expression in interspecific hybrids such as the mule<sup>4,5</sup> and in crosses of European hare species<sup>8</sup>, indicating that the genetic mechanism for X-chromosome inactivation is also conserved in the speciation of eutherian mammals.

In conclusion, although we have not yet obtained hybrid progeny developing to term, the combination of (1) multiple X-linked biochemical differences, (2) random inactivation of *caroli* and *musculus* X chromosomes in hybrid embryos, and (3) the occurrence of some hybrid foetuses which seem grossly normal at 14-16 d of development, suggests that the hybrid combination of *M. musculus* and *M. caroli* is a promising experimental system for studying X inactivation in mammalian development.

## Imperfect complementation in human-hamster somatic cell hybrids

SOMATIC cell hybridisation can reveal complementation between genetic markers<sup>1</sup>, and interspecific hybridisation provides a means to study the mechanisms involved in

complementation. When the phenotypes of both parental cells are distinguishable at the molecular level, two complementation mechanisms can be recognised<sup>2</sup>. When the allele contributed by the wild type parental cell overcomes the block in the biochemical pathway characteristic of the mutant parent, products characteristic of both species should be present in the hybrid. Alternatively, if either allele acts exclusively on its own pathway, that is the wild-type allele cannot act in *trans*, the blockage due to the mutation remains and only the wild-type product would be expected to be synthesised in the hybrid.

We have reported<sup>2</sup> complementation of a defect in the production of ribosomal RNA (rRNA) in interspecific cell hybrids. Mutant *ts422E* is a temperature sensitive (*ts*) variant of the Syrian hamster line BHK 21/13 (ref. 3). At the non-permissive temperature (39 °C) the cleavage of nucleolar 32S RNA to produce mature ribosomal 28S RNA is blocked. rRNA processing and production are otherwise normal at 33 °C<sup>4</sup>. When *ts422E* is hybridised with mouse cells the resulting hybrids produce both hamster and mouse 28S RNA at the non-permissive temperature<sup>2</sup>, indicating that in this case complementation occurs by the first of the two possible mechanisms. In an attempt to characterise further the nature of the complementation between interspecific rRNA maturation genes, we hybridised *ts422E* with human cells. We found that complementation of the defect borne by the *ts422E* hamster cell mutant is only partially achieved in hybrids with human cells. In this case the same mechanism of complementation operates as in *ts422E*-mouse hybrids, but only to a partial extent.

*ts422E* cells were fused with LW SV40-transformed human cells deficient in hypoxanthine phosphoribosyltransferase<sup>5</sup> in the presence of  $\beta$ -propiolactone-inactivated Sendai virus at pH 8.0 (ref. 6). Hybrid cells were selected in HAT medium<sup>7</sup> at 39 °C. Hybrid colonies were obtained at a frequency of about  $1 \times 10^{-5}$  of the total cells plated in selective conditions; they were isolated and propagated in HAT medium at 39 °C for one passage. Hybrid lines were propagated subsequently in normal medium at 39 °C unless otherwise stated.

We used populations of hybrids obtained on two plates. The populations grew poorly at 39 °C, but in an essentially

**Fig. 1** Hybrid population F3 growing at 39 °C was labelled for 13 h with <sup>3</sup>H-uridine (6  $\mu$ Ci, 2  $\mu$ g ml<sup>-1</sup>). Cells were washed, the cytoplasmic fraction prepared and the 28S rRNA isolated after centrifugation in sucrose gradients as described before<sup>2</sup>. The RNAs were analysed by polyacrylamide gel electrophoresis. Electrophoreses were run for 24 h at 5 mA per gel. Gels were sliced and counted as described in ref. 2. Samples were run with <sup>14</sup>C-labelled markers prepared from BHK or HeLa cells. *a*: ●, 28S <sup>3</sup>H-RNA from population F3; ○, HeLa <sup>14</sup>C-28S RNA. *b*: ●, 28S <sup>3</sup>H-RNA from population F3; ○, BHK <sup>14</sup>C-28S RNA.

**Fig. 2** Plates containing hybrid 53-99 C6 were incubated for 5 d at 33 or 39 °C and labelled for different times with <sup>3</sup>H-uridine (16, 8 or 4  $\mu$ Ci; 2, 4, or 8  $\mu$ g ml<sup>-1</sup>). At the end of the pulse cells were fractionated as described in caption for Fig. 1. RNA from cytoplasmic fractions was purified by double phenol extraction and precipitated with 2 volumes of 95% ethanol at -20 °C. RNA was subjected to polyacrylamide gel electrophoresis in the conditions described in Fig. 1. Electrophoreses were run for 4.5 h. 28S and 18S rRNA peaks were integrated in each case and the ratio of c.p.m. in the 28S peak relative to the amount of radioactivity in the 18S peak (28S:18S ratio) was determined. ●, Data corresponding to 39 °C; ○, data corresponding to 33 °C.

normal manner at 33 °C. Giemsa banding by a modification of Seabright's method<sup>8,9</sup> showed that the hybrid F3 contained human chromosomes 3, 14, 15, 17 and 20 and two abnormal chromosomes, probably of human origin. The hybrid F31 had human chromosome 3 and one abnormal human chromosome. It is also expressed human mannose phosphate isomerase (MPI). All hybrid cells contained the entire complement of hamster chromosomes.

The 28S rRNA made by the populations F3 and F31 at 39 °C was analysed in 2.6% polyacrylamide gels, where hamster 28S RNA migrates faster than human 28S RNA<sup>10</sup>, as described in Fig. 1. F3 synthesised mostly hamster 28S rRNA but some human rRNA was also present; results were similar for population F31 (Fig. 1).

For subsequent studies we used a clone of the F3 population. The clone 53-99 C6 also grew poorly at 39 °C. It contained human chromosome 3 in five and human chromosome 17 in two of 20 metaphases analysed. These hybrid cells also expressed human MPI activity, but not human pyruvate kinase 3 or hexosaminidase A, suggesting that they contained only a portion of human chromosome 15 (refs 11 and 12). Table 1 compares the doubling times of the 55-99 C6 hybrid at 33 and 39 °C with those of wild-type BHK, the hamster parent *ts422E* and one of the mouse-*ts422E* hybrids, hyC7. Growth in all *ts*<sup>+</sup> cells was faster at 39 than at 33 °C, with the exception of the *ts422E*-human hybrid, suggesting inefficient, although positive, complementation.

To determine whether the slower growth at 39 °C was a consequence of reduced production of 28S rRNA, the kinetics of labelling of rRNA were studied at this temperature. The amount of radioactivity in 18S rRNA was used as a reference as 18S rRNA is normally synthesised in the parental *ts* mutant at either temperature<sup>3</sup>. 53-99 C6 cells were labelled for different times, and cytoplasmic RNA was isolated as before and analysed in polyacrylamide gels<sup>4</sup> (Fig. 2). At 33 °C the ratio of label in 28S RNA to that in 18S RNA increased, to reach a steady state at ~1.9 after 24 h. At 39 °C the steady state was reached more slowly and the ratio never exceeded 1.2. Similar results were obtained with the original F3 and F31 hybrid populations. Thus, the slow growth of the hybrid at 39 °C was probably due to impaired production of 28S rRNA.

At either temperature, hybrid 53-99 C6 synthesised 28S rRNA of hamster origin only (Fig. 3; results obtained at

**Table 1** Doubling times of several cell lines at 33 and 39 °C (h)

	33 °C	39 °C
53-99 C6 ( <i>ts422E</i> -human hybrid)	29	37
C7 ( <i>ts422E</i> -mouse hybrid)	23	18
<i>ts422E</i>	18	∞
wild-type BHK21	16	12

Plates (60 mm) were seeded with  $5 \times 10^4$  cells per plate and incubated at 33 or 39 °C. Every 24 h duplicate plates from each temperature were trypsinised and the cells counted with a Coulter counter.

39 °C were identical). This suggests that the human nucleolar organisers<sup>13,14</sup> have been segregated out in this hybrid, although alternative hypotheses cannot be ruled out.

To determine whether the reduced production of 28S RNA in the hybrids at 39 °C was the expression of the defect of the *ts422E* parent, corrected only to some extent, we analysed the pattern of nucleolar RNA processing. *ts422E* cannot produce 28S RNA because of a block in the processing of the 32S RNA precursor, which, after production is mostly degraded, although a portion of it accumulates to levels 8–10 times greater than in wild-type cells<sup>4</sup>.

Table 2 summarises the distribution of label in nucleolar 32S RNA and cytoplasmic 28S rRNA in hybrid 53-99 C6 after an 11-h pulse at 33 or 39 °C. Data for BHK and *ts422E* at 39 °C are also included. As 32S (28S) and 18S RNAs are derived in a 1:1 molar ratio from a common 45S RNA precursor<sup>13,14</sup>, the 32S:18S or 28S:18S ratios enable us to normalise the differences due to causes other than the mutation itself, such as differences in uridine pools or uptake in different cell lines. At 39 °C the 28S:18S ratio in the hybrid is intermediate between the values for wild-type and mutant cells; the same was true for the 32S:28S ratio. The 32S:18S ratio showed clearly that much more 32S RNA accumulated in the hybrid at 39 °C than in wild-type BHK, the degree of accumulation being similar to that in *ts422E* cells. The accumulation of 32S RNA in the hybrid, however, was greater than expected at 33 °C, perhaps because the steady state had not yet been reached (Fig. 2). Thus rRNA precursors are processed in *ts422E*-human hybrids at 39 °C in a pattern similar to that in the *ts422E* mutant, with comparable accumulation (and degradation) of the 32S RNA precursor. This indicates that the slow growth of the hybrids at 39 °C is due to imperfect complementation (albeit compatible with survival) of the *ts422E* defect.

Although we wished to map the gene(s) responsible for processing of rRNA precursors on human chromosomes all hybrids examined contained chromosomal rearrangements and it was impossible to assign the gene(s) involved in the complementation of the *ts422E* defect.

The imperfect complementation can be explained by

assuming that, although the rRNA processing machinery can act on RNAs from related species as efficiently as on RNA from the same species<sup>2</sup>, in phylogenetically distant species such as man and hamster the sites of recognition of rRNA diverged during evolution. This could result in inefficient recognition or binding of accessory preribosomal proteins to the rRNA precursors<sup>15</sup>. In this respect it should be remembered that 53-99 C6 hybrid was selected and isolated at the temperature restrictive for the parental mutant. It is thus reasonable to assume that the level of complementation found in the hybrid is the best the population could attain under the pressures imposed.

Why did no human 28S RNA appear at either temperature in the hybrid, resembling the situation found<sup>16</sup> in human-mouse hybrids? Among the hypotheses considered<sup>18</sup> the most probable is the repression of human rRNA genes due to the presence of mouse nucleolar organisers. The situations in the human-hamster hybrid 53-99 C6 could be similar, but the presence of some human 28S rRNA in hybrid populations F3 and F31 suggests that this is not compulsory. It is possible, in our case, that the disappearance of human rRNA during serial culture was due to loss of human rDNA genes.

It seems unlikely that poor complementation is due to insufficient human gene products in the hybrid. The selection of hybrid lines at 39 °C, and in particular their poor

**Fig. 3** Plates containing hybrid 53-99 C6 were incubated at 33 °C for 6 d and labelled for 11 h with <sup>3</sup>H-uridine (4.4 μCi, 2 μg ml<sup>-1</sup>). 28S rRNAs were prepared and analysed by polyacrylamide gel electrophoresis in the conditions given in Fig. 1. Electrophoreses were run for 24 h at 5 mA per gel. Samples were run with <sup>14</sup>C-labelled markers from BHK or HeLa cells. *a*, 28S rRNA (<sup>3</sup>H) from hybrid 53-99 C6 (●); HeLa 28S <sup>14</sup>C RNA (○); *b*, 28S rRNA (<sup>3</sup>H) from hybrid 53-99 C6 (●); BHK 28S <sup>14</sup>C RNA (○).

**Table 2** Distribution of radioactivity in different species of rRNA in *ts422E*-human hybrids

Cell line (temperature)	32S	28S	18S	Ratio 32S:18S	Ratio 32S:28S	Ratio 28S:18S
53-99 C6 (39 °C)	$4.4 \times 10^4$	$2.2 \times 10^5$	$3.0 \times 10^5$	0.15	0.20	0.72
53-99 C6 (33 °C)	$2.8 \times 10^4$	$2.8 \times 10^5$	$1.8 \times 10^5$	0.16	0.10	1.57
<i>ts422E</i> (39 °C)	$9.1 \times 10^3$	$1.2 \times 10^4$	$6.1 \times 10^4$	0.15	0.76	0.20
Wild-type BHK21 (39 °C)	$3.2 \times 10^3$	$3.6 \times 10^4$	$1.6 \times 10^4$	0.02	0.01	2.25

Cells were labelled for 11 h with <sup>3</sup>H-uridine (4 μCi, 2 μg ml<sup>-1</sup>) and fractionated as explained in Fig. 1. Nucleolar fractions were prepared as previously described<sup>4</sup>, and nucleolar RNA was analysed by polyacrylamide gel electrophoresis in the conditions given in Fig. 1. Nucleolar RNA electrophoreses were run for 9 h. Cytoplasmic RNAs were analysed as in Fig. 2. The data are expressed as c.p.m. per 10<sup>6</sup> cells.

growth at 39 °C, should have strongly favoured cells which had not lost the gene(s) complementing the *ts422E* defect.

It is difficult, however, to rule out the possibility that human chromosomes are lost continuously in the hybrid populations at 39 °C. Thus each population of hybrid cells, at any given moment, could be a mosaic of cells which have and have not retained the human gene(s) required for normal rRNA maturation and cell growth at the non-permissive temperature. Since data on rRNA production show that about 80% of the cells would have to be mutant-like to produce the observed results, this hypothesis implies that at every cell division the hybrids yield a high proportion of cells behaving as the parental *ts* mutant, and thus unable to grow at 39 °C. Such a mechanism would cause the rate of growth of the cell population to appear linear, rather than exponential, but the rate of growth of the hybrids at 39 °C was exponential (Table 1). We therefore believe this explanation unlikely.

Our data suggest that the human wild-type allele is dominant over the *ts422E* mutation, as it can process hamster rRNA precursors; this processing is, however, inefficient probably due to evolutionary divergence of the rRNAs of the two species.

## Cell density dependence of oscillatory metabolism

THERE is increasing evidence<sup>1-3</sup> that the behaviour of cell populations is determined not only by the behaviour of the individual cells, but also by their mutual interactions. One influence on the strength of these interactions may be cellular proximity which, in turn, is a function of cell density. For example, myoblasts fuse only when they reach a critical cell density<sup>4</sup>. The oscillatory glycolytic metabolism of the yeast *Saccharomyces carlsbergensis* has provided a convenient system for the exploration of several biochemical phenomena<sup>5</sup>. For example, whereas yeast cells are generally considered to be metabolically non-interacting, a coupling process of unknown character causes metabolic synchronisation of all cells to a common oscillatory fre-

quency and phase<sup>6</sup>. A suspension of metabolically oscillating yeast therefore behaves as a population of strongly interacting units. Because continuous monitoring of amplitude and phase by fluorometry provides a constant assay of metabolic dynamics, any perturbation of these dynamics is easily recognised as a deviation from the predictable waveform. We describe here modifications in the metabolic behaviour of intact cell suspensions achieved by manipulating the strength of their interaction through changes in cell density.

*S. carlsbergensis* was grown, collected and assayed for oscillatory metabolism as described before<sup>7</sup>. The results of one experiment are shown in Fig. 1; Fig. 1a records, for a period of 8 min in an oxygenated 0.0125% (w/w) yeast suspension, the total culture fluorescence, which correlates with the intracellular concentration of NADH. Addition of 100 mM glucose at arrow 1 caused a brief surge of intermediates through glycolysis as shown by the increase in NADH concentration preceding the aerobic steady state. On addition of 1 mM KCN to block respiration, (arrow 2) a marked increase in NADH concentration initiated a damped oscillatory approach to the metabolically anaerobic steady state. The second tracing (Fig. 1b) is similar except that the initial density of the cell suspension was 4% (320 times that in the first experiment). At arrow 3 buffer was added and caused a rapid change of suspension density to 2.66%. After a short lag during which the sensitivity of the fluorometer was increased to compensate for the decrease in cell density, metabolic oscillations continued. When this experiment was repeated, but with an initial cell density of 0.0125% (Fig. 1c) rapid density reduction (arrow 3) abolished further detectable oscillatory expression. The

Fig. 1 a, Net fluorescence (NADH concentration) is plotted against time in a 0.0125% (mg wet weight per ml) yeast suspension. Arrow 1 indicates addition of glucose (100 mM final concentration) to the oxygenated culture and arrow 2 addition of KCN (1 mM final concentration). b, Same as a but initial cell density is 4% and arrow 3 indicates addition of 1 ml of buffer to the 2 ml of culture. c, Same as b but initial density is 0.0125%.

Fig. 2 Normalised amplitude and frequency are plotted against culture density (see text). 100% amplitude corresponds to 100  $\mu$ M NADH and the normalisation standard used was a 400 mg ml<sup>-1</sup> suspension. 100% frequency corresponds to 1/38 s<sup>-1</sup>. ▼, Normalised frequency; △, normalised amplitude.

sharply peaked transient following density change was a constant characteristic only of oscillatory abolition, and was never shown by suspensions which continued to oscillate. We found that, varying with time of collection, some critical initial cell density could always be found below which no oscillatory metabolism was detected after rapid reduction of cell density.

Figure 2 plots amplitude and frequency against cell density in one such batch. The fluorometer was calibrated by adding known concentrations of NADH to non-metabolising cell suspensions of various densities. Suspensions of equivalent densities then were run as in Fig. 1a. Amplitude was assayed by measuring the height of the second peak from a line connecting the first and third troughs. This distance remained constant, within  $\pm 5\%$ , in multiple identical experiments. If cell density did not affect the dynamics of each cell, a doubling in cell concentration would be expected to produce a doubling in recorded amplitude. Thus, taking the change in NADH concentration of the second peak in a 400 mg ml<sup>-1</sup> suspension as a normalisation standard, the height in an 800 mg ml<sup>-1</sup> suspension was divided by 2 and that in a 200 mg ml<sup>-1</sup> suspension by 0.5 to correct the raw data for expected density-induced changes in recorded amplitude. We assumed that identical normalised amplitudes should result if no change in dynamics resulted from cell density differences. In Fig. 2 normalised amplitude is expressed as a percentage of the largest second peak amplitude observed in any experiment in the series, and frequency is similarly expressed. Frequency changes little within the range of cell densities tested but amplitude reaches a broad maximum at intermediate densities. This agrees with the finding (Fig. 1) that low cell densities cause a loss of oscillatory metabolic expression. It also suggests that high cell densities inhibit oscillatory expression.

Two explanations for these findings seem possible. Either each cell is affected by cell density and loses its oscillatory capacity, or the population loses synchrony. Measurements made on the total suspension cannot distinguish between these two possibilities, although asynchrony is much harder to rationalise at high densities, when tight coupling might be assumed, than at low densities. Microspectrophotometric measurements<sup>8</sup> showed previously that individual cells, when oscillating, display both the frequency and waveforms similar to those expressed by the total cell suspension. Although single-cell measurements were not designed to quantify density dependence, there was some indication that a minimal density was necessary to observe single-cell oscillations. These data support the possibility that the inhibition of metabolic oscillations observed at low densities

is not caused by population desynchronisation but by alterations in the stability properties of each cell's metabolic dynamics; that is the steady state of each cell changes from an oscillatory to a non-oscillatory metabolism.

Although the mechanism by which cells synchronise their metabolism is unknown, one might expect its efficiency and characteristics to be a function of cell density and thus underlie the phenomena reported here. This suggests that short range, intercellular communication mechanisms strongly influence not only the quantitative, but also the qualitative metabolic behaviour of cells, such as oscillatory and non-oscillatory behaviour. Furthermore, metabolic synchronisation and density dependence lead to a situation in which the behaviour of the total cell population could be quite unrelated to the sum of the behaviours displayed by individual cells in isolation: that is, biochemical synergism occurs.

## Carcinogenic nitrosamides and cell cultures

THE acylnitrosamides ethylnitrosourea (ENU) and methyl-nitrosourea (MNU) are potent carcinogens in a variety of animals. Rats, especially, provide a useful experimental system since a single dose administered at the perinatal age can be tumorigenic and in certain strains the nitrosamides in these conditions are relatively site specific in that they produce a high proportion of neural tumours<sup>1–6</sup>. Although these tumours rarely become clinically apparent before six months, the short term effects of nitrosamides have been studied both *in vitro* and *in vivo* in an attempt to elucidate the oncogenic mechanism. Thus histological examination of tissues from rats recently treated with nitrosamides has revealed a toxic effect on dividing cells<sup>7</sup> while the use of cell cultures has shown an effect on DNA synthesis and the cell cycle<sup>8</sup>. It has been assumed that both the carcinogenicity and the short term effects occur as a result of the alkylation of macromolecules, in particular DNA<sup>9</sup>. Earlier reports concerned the nature of the chemically modified bases<sup>10,11</sup> whereas more recently the turnover of such bases has become the focus of attention<sup>12,13</sup>. We present evidence that the short term effects can be explained by an alternative mechanism to the alkylation of cellular macromolecules; cyanate ions are shown to be a product of MNU and ENU breakdown and it is the cyanate ion which is responsible for short term effects and cytotoxicity.

Cell cultures were derived from the neural tissue of AS rat fetuses on day 18 of gestation, and during studies into the effect of dose and exposure time, chemical breakdown of nitrosamides was followed spectrophotometrically since they are known to decompose rapidly in physiological conditions<sup>14</sup>. Figure 1 shows the rate of decomposition in cell culture conditions and the effect of exposure time on cell survival. Since the nitrosamides decay rapidly, yet long

Fig. 1 *a*, MNU (□) or ENU (●) were taken up into warm ethanol at 40 mg ml<sup>-1</sup> and immediately added to Ham's F10 growth medium containing 10% FCS to give a final concentration of 1 mM. At intervals, aliquots of nitrosamide-containing medium were taken and difference-spectra obtained to assess the rate of decomposition. MNU has a peak at 380 nm and ENU at 375 nm. *b*, Primary cultures were set up from the neural tissue of AS rat fetuses on day 18 of gestation. 0.05% trypsin in phosphate-buffered saline (PBS) was used for 15 min to disperse the tissue after sterily removed brains had been very finely minced with scissors. The suspension obtained from one foetal brain was added to F10 medium with 10% serum and then plated out into three 90-mm Petri dishes. In one week such dishes usually achieved confluence. Cells were used before the third passage when a number of different cell types were still present. MNU (□) or ENU (●) were added to culture medium as in *a* to give a final concentration of 1 mM and this medium was immediately added to 50 mm plates of cells. At intervals, duplicate plates were washed twice and then incubated with untreated growth medium. At 30 h, all plates were viewed under an inverted microscope with phase-contrast optics. Healthy and lysed cells were easily distinguishable; > 200 cells were counted per plate and cell survival expressed as a percentage.

exposure times bring about cell death, a breakdown product is likely to be responsible for such cytotoxicity. This was confirmed by incubating either nitrosamide at 37 °C in growth medium for 3 d before adding the medium to cell cultures when it was found to be as toxic as medium containing freshly-prepared nitrosamide. To identify the breakdown-product, <sup>14</sup>C-methylnitrosourea and methylnitroso-<sup>14</sup>C-urea were synthesised. Paper chromatography with a solvent system of ethyl acetate-ethanol-water (80:15:5) was used to monitor breakdown of the radiolabelled nitrosamide. When methylnitroso-<sup>14</sup>C-urea decomposed in growth medium, the *R<sub>f</sub>* of the isotope changed from 1.0 to 0.26; this product was not urea or methylurea but when K-<sup>14</sup>CNO was applied, the <sup>14</sup>C cochromatographed with the breakdown-product. When <sup>14</sup>C-methylnitrosourea decomposed the isotope was lost from the *R<sub>f</sub>* 1.0 position, but did not appear elsewhere; this suggested a volatile breakdown product and it was shown by co-distillation with unlabelled material to be methanol. It was thus demonstrated that

>97% of MNU breaks down in culture conditions, to yield methanol, cyanate ions and gaseous nitrogen.

Cyanate ions were the only possible cytotoxic agent and indeed the cell death induced by nitrosamides is mimicked by potassium cyanate at 0.6 mM. Ethylnitroso-<sup>14</sup>C-urea was synthesised and this also yields <sup>14</sup>C-cyanate ions when incubated in growth medium. The presence of protein seems to catalyse the breakdown; for example at 37 °C the half life of ENU in physiological saline is 150 min, but this goes down to 15 min in growth medium containing serum.

At levels of nitrosamide below 0.3 mM, DNA synthesis and cell proliferation are affected but the cells remain viable. Figure 2 shows how potassium cyanate also mimics these effects.

The cyanate ions are effective by virtue of their ability to effect carbamylation reactions. When cell cultures are incubated with MNU or ENU radiolabelled with <sup>14</sup>C in the urea moiety, then the appearance of isotope in the TCA-insoluble material can easily be followed and is still increasing in a linear fashion after 6 h. In contrast, when cells are incubated with MNU of an identical specific activity, but labelled in the alkyl moiety, isotope incorporation into

Fig. 2 Cultures of foetal brain cells were set up as in Fig. 1. Before achieving confluency, 50-mm plates were refed with F10 medium containing 10% FCS and immediately treated with KCNO (●) or ENU (□) previously dissolved in warm ethanol. All plates received an identical volume of ethanol. *a*, 10 h after the addition of nitrosamide, triplicate plates at each nitrosamide concentration were pulsed for 1 h with 0.2 μCi ml<sup>-1</sup> <sup>3</sup>H-thymidine (>20 Ci mmol<sup>-1</sup>). After 3 washes with PBS, cells were scraped from the plate with a silicone policeman and treated with a 5% TCA solution. After a further wash with 5% TCA, the insoluble material was collected on a GFC filter. TCA-soluble counts did not vary between plates. The filters were counted in a liquid scintillation spectrometer (Tracerlab); the scintillant was 5 g PPO and 20 g of naphthalene in 1 l of dioxan. *b*, Duplicate plates of cells were set up as in *a* and after 4 d cells were removed by trypsinisation and the number of cells counted with a Coulter counter.

**Fig. 3** Fetuin (Sigma) at  $15 \text{ mg ml}^{-1}$  in PBS was treated with a solution of KCNO ( $100 \text{ mg ml}^{-1}$ ) to give a range of final concentrations of KCNO from 0 to  $10 \text{ mg ml}^{-1}$ . All solutions were made  $0.05 \text{ } \mu\text{Ci ml}^{-1}$  with respect to  $\text{K}^{14}\text{CNO}$  and solutions were incubated at  $37^\circ\text{C}$  for 5 h. Before and after the incubation, samples were taken and from the TCA soluble and TCA-insoluble counts the amount of carbamylation per mg protein was calculated. This is expressed in terms of carbamyl groups per fetuin molecule. Although gel electrophoresis reveals the presence of contaminating bands, a molecular weight of 46,500 has been assumed. The protein samples were exhaustively dialysed against PBS. Confluent plates of BHK cells were trypsinised and suspended in serum-less F10 and plated-out into 50 mm Petri dishes. The carbamylated fetuin preparations were then added to duplicate plates to give a final concentration of  $5 \text{ mg ml}^{-1}$ . After 16 h cells were viewed under an inverted microscope with phase contrast optics and cells were counted as "stretched" (that is, having adopted a bipolar morphology) or "unstretched" (that is, totally, spherical). Results are expressed as a percentage of stretched cells (●). After 3 d further plates were trypsinised and counted with a Coulter counter (□).

TCA-insoluble material is at least one order of magnitude lower. It was originally expected that this latter would reflect a low level of alkylation, but it was subsequently found that isotope incorporation was identical if the  $^{14}\text{C}$ -methylnitrosourea was first incubated in growth medium for 3 d. Thus it is more likely to reflect low level metabolic utilisation of methanol formed during decomposition.

While the amount of cell-associated protein in a 50-mm dish is usually  $50\text{--}75 \text{ } \mu\text{g}$  at confluency, the protein in the growth-supporting foetal calf serum (FCS) will be at least  $15,000 \text{ } \mu\text{g}$ . Carbamylation of serum proteins by nitrosamides or cyanate also takes place and a correspondingly higher number of counts become associated with serum proteins

than with cellular proteins. This carbamylation of serum protein was found to be very important since it could completely inactivate the serum in respect of its growth-promoting properties. Thus FCS treated at  $37^\circ\text{C}$  with  $10 \text{ mg ml}^{-1}$  KCNO for 4 h followed by exhaustive dialysis produces a chemically modified serum which fails to stimulate DNA synthesis and cell proliferation. FCS is an heterogeneous mixture of proteins and for this reason it is impossible to correlate loss of biological function with degree of carbamylation. We had previously shown<sup>15</sup>, however, that certain lines of established cells would grow well with a commercial preparation of the glycoprotein fetuin<sup>16</sup> as sole macromolecular source. BHK cells<sup>17</sup> grow well with  $5 \text{ mg ml}^{-1}$  fetuin. If the fetuin was carbamylated with ENU, MNU or cyanate, such growth-promoting activities were lost. Using radiolabelled cyanate, the loss of biological activity and the degree of carbamylation were compared (Fig. 3). Above three carbamyl groups per fetuin molecule, BHK cells show startling morphological changes.

BHK cells divide very rapidly and this allowed the demonstration of a very rapid effect of cyanate or nitrosamide. If the cells were in exponential growth then as little as 15 min exposure to one of the above agents could cause an inhibition of mitosis. Table 1 shows such an inhibition achieved with cyanate.

In the past, little attention has been paid to the fate of any part of the ENU or MNU molecule other than the alkyl moiety. But in the case of the more complex nitrosamides, some of which have proved useful chemotherapeutic agents, it has been shown that carbamylation of macromolecules by isocyanate species takes place<sup>18-20</sup>. Certainly in the case of 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea, carbamylation of protein has been shown to be a far more extensive reaction than alkylation of macromolecules<sup>19,20</sup>.

This communication presents evidence that MNU and ENU, on decomposition in culture, give rise to a very bioactive molecule, namely the cyanate ion, which can affect several stages of the cell cycle. The effect of nitrosamides and cyanate on serum indicates that low levels of protein modification may alter biological function. This might also be true inside the cell and in view of its activity *in vitro*, it is now necessary to determine whether the cyanate ion is responsible for any of the effects of nitrosamides *in vivo*.

I thank Mrs C. M. May for technical assistance and the Cancer Research Campaign for financial support.

**Table 1** Inhibition of mitosis of BHK cells by cyanate

Time of exposure to KCNO (min)	Increase in cell no. per plate $\times 10^{-5}$ after:			
	2 h	4 h	6 h	24 h
0	0.8	2.0	3.5	14.4
15	0	0.4	2.3	14.0
60	0	0	0.5	11.6

Replicate plates of BHK cells in exponential phase of growth were treated with  $0.5 \text{ ml}$  of a KCNO solution in PBS to give a final concentration of  $0.4 \text{ mg ml}^{-1}$ . At the end of the exposure-time cells were washed and refed with ordinary growth medium. Control cultures were treated with a similar volume of PBS and washed and refed after 1 h. At 1 h ( $t=0$ ) and intervals thereafter, duplicate plates were trypsinised and counted with a Coulter counter.

## Isolation of immunogenic tumour cells by cell-affinity chromatography

TUMOUR-HOST relationships are determined by many variables<sup>1,2</sup>, and may be altered to favour the host by the use of chemically modified cells which act as specific immunostimulants<sup>3</sup>. Furthermore, modified cells have therapeutic value in mice with small tumours<sup>4,5</sup>. Several studies have shown that conventional methods followed by administration of immunostimulants are very effective in treating tumours and inducing tumour-specific immunity<sup>6-8</sup>. Combined chemotherapy and immunotherapy of L1210 leukaemia with neuraminidase-treated (VCN) tumour cells yielded a higher percentage of long term survivors than did chemotherapy alone<sup>6,7,9,10</sup>. The therapeutic effectiveness of VCN-treated cells depended on several variables<sup>10</sup>, including proper selection of immunogenic cells<sup>7,11</sup>.

We now report that highly immunogenic cells can be isolated from the parental tumour cell population by cell-affinity chromatography with concanavalin A (con A). Immunisation with these cells after chemotherapy resulted in complete remission of L1210 leukaemia.

L1210 cells (Arthur D. Little Co.) were maintained as an ascitic tumour in BDF<sub>1</sub> (C57BL/6×DBA/2) males and athymic (*nu/nu*) mice. The cell line has also been maintained as a suspension culture using RPMI 1640 medium, supplemented with 5% foetal calf serum and antibiotics.

Cell-affinity columns were prepared by covalent coupling of con A to nylon fibres with glutaraldehyde<sup>12</sup>. L-leucine was added to the reaction mixture to compete with, and thereby "space" the con A molecules along the fibre. This technique resulted in a fourfold decrease of bound protein compared with coupling in the absence of the amino acid. The preparation and properties of the con A columns will be outlined in detail elsewhere. Recognising that the binding of cells to the con A-nylon was probably mediated through multiple (and different) sugar linkages, it was decided to elute the cells from the column by the sequential addition of sugars that possessed a decreasing order of free-solution affinity for con A<sup>13</sup>. The elution profiles for L1210 cells grown in the BDF<sub>1</sub> host, in culture, or in the athymic host are summarised in Table 1. The two cell lines grown *in vivo* seemed to represent the extremes in chromatography, since few cells were released by sugars, and the cell lines were primarily composed of cells either binding or not binding to the con A-nylon.

The immunogenic properties of the isolated subpopula-

**Table 1** Subpopulations of L1210 tumour cells (%) as a function of growth conditions

Cell fractions	<i>In vivo</i> (BDF <sub>1</sub> )	Growth conditions	
		<i>In vivo</i> (athymic)	<i>In vitro</i>
A	14.1	68.0	32.0
B	4.1	0.6	5.0
C	<0.01	0.2	0.7
D	<0.01	0.2	2.8
E	<0.01	0.03	3.9
F	81.8	30.6	56.6

Fractions A to F represent the percentage of total cells. A, eluted with phosphate-buffered saline (PBS), B, eluted with  $\alpha$ -methyl-D-mannoside; C, eluted with  $\alpha$ -methyl-D-glucoside; D, eluted with sucrose; E, eluted with  $\alpha$ -D-glucose; F, not eluted by the above sequence. Cells (ascitic tumours) grown *in vivo* were washed once in 1% ammonium oxalate, 25 °C, to lyse erythrocytes, followed by two washes in PBS. Cultured cells were washed twice in PBS. Preparation of *in vivo*-grown cells by Ficoll-Hypaque gradients<sup>14</sup> did not affect the elution profile. Affinity columns were prepared by packing 25-cm glass pipettes with brushed nylon (No. 3 denier, 1½ inch, type 200, DuPont) then incubated with equal volumes of 25% glutaraldehyde, 0.4  $\mu$ M L-leucine, and 1 mg con A (con A was Grade III, twice crystallised, all reagents Sigma), at pH 6.5 for 1 h at 37 °C. This procedure bound 1.9  $\mu$ g protein per g nylon. The column was then flushed with 50 volumes PBS, pH 7.2. Elution was at room temperature with a flow rate of 2 ml min<sup>-1</sup>.

tions were evaluated by their effectiveness in causing complete remission of L1210 tumour. The optimal protocol for this particular tumour-host model was developed by Kollmorgen *et al.*<sup>10</sup> and is based on initial reduction of tumour burden by chemotherapy. Immunotherapy consisted of a single injection of one of the different cell fractions. Survival after therapy correlated with the elution profile from the con A column (Fig. 1) with the best response observed in mice treated with fraction A. All surviving mice were immune to L1210 tumour when rechallenged with a lethal inoculum for virgin mice.

To further evaluate the immunogenic properties of these cells, the best and worst fractions (A and E, respectively) were treated with neuraminidase and used in an identical protocol. As Fig. 2 shows, the relative effectiveness of the two cell types was reversed after treatment with VCN, although long-term survival was similar. The early deaths observed in the group of mice immunised with VCN-treated fraction A cells suggests that chemotherapy with 1,3-bis-(2-chloroethyl)-1-nitrosourea (BCNU) had an immunological component which was abrogated, in this case, by immunotherapy.

These results indicated that the immunogenicity of the different subpopulations was related to the expression of cell surface carbohydrates, as defined by con A-affinity

solid line indicates the survival of tumour controls (no treatment).  $\Delta$ , Chemotherapy with BCNU only;  $\circ$ , BCNU + fraction A;  $\square$ , BCNU + fraction B;  $\bullet$ , BCNU + fraction C;  $\blacktriangle$ , BCNU + fraction D;  $\blacksquare$ , BCNU + fraction E.

**Fig. 1** Percentage survival as a function of time after tumour injection. This protocol is based on optimisation of the L1210-BDF<sub>1</sub> tumour-host model<sup>10</sup> where mice received an intraperitoneal injection of  $10^4$  cells at time zero. The mice were randomised on day 6.5 (estimated tumour burden  $10^8$  cells) and all but tumour controls received a single intraperitoneal injection of BCNU (12 mg kg<sup>-1</sup>) to reduce tumour burden. The mice were again randomised on day 8, and immunotherapy consisted of a single intraperitoneal injection of  $10^4$  cells (inactivation of the cells by one freeze-thaw generally resulted in less than 10% viability). Each group contained 20 mice. The

**Fig. 2** Percentage survival as a function of time after tumour injection. The experimental protocol is identical to that described in Fig. 1, except that fraction A and fraction E cells were treated with VCN (Grand Island Biological). The cells were concentrated by centrifugation and incubated with equal parts acetate buffer, pH 5.6 and VCN (1 U per  $10^6$  cells) for 1 h at  $37^\circ\text{C}$ . The cells were washed twice with 5 mM EDTA-saline and stored in PBS at  $-90^\circ\text{C}$  until use. Each group contained 10 mice. The solid line indicates the survival of tumour controls (no treatment).  $\Delta$ , Chemotherapy with BCNU only;  $\circ$ , BCNU + VCN-treated fraction E;  $\bullet$ , BCNU + VCN-treated fraction A.

chromatography. Further studies were designed to examine the nature of L1210 cell antigenicity. Mice were immunised with VCN-treated, cultured L1210 cells in the combination therapy protocol previously described. The survivors were boosted with  $10^6$  viable L1210 cells (to which they were immune) and bled 7 d later. The serum was then tested for complement-dependent cytotoxicity against cultured L1210 cells, in the presence or absence of various sugars. Cytotoxicity was measured by the  $^{51}\text{Cr}$ -release assay<sup>14</sup>, and the results are expressed as mmol of sugar required to cause 75% inhibition of cytotoxicity (Table 2). Of the sugars used to elute cells from the con A column, the most effective inhibitor of cytotoxicity was  $\alpha$ -methyl-D-mannoside, the sugar which released fraction B. The poorest inhibitor was  $\alpha$ -D-glucose, which released fraction E. Galactosyl-like residues have been considered as part of the binding site for "naturally-occurring" cytotoxic antibodies to VCN-treated cells<sup>15,16</sup>. Galactose and galactosamine were non-inhibitors in the study reported here, although the non-reducing sugar  $\alpha$ -methyl-D-galactoside was an effective inhibitor of cytotoxicity. Maximal inhibition of cytotoxicity was observed using fucose. Preliminary studies have shown that the percentage of cells released from fucose-specific lectin columns was three to five times higher for fraction A than for the whole tumour cell population (J.J.K., unpublished). Experiments are in progress to evaluate the immunogenic properties of tumour cells isolated by fucose-specific affinity columns.

Edelman *et al.* have shown that antigen-specific lymphoid cells can be isolated by their binding to antigen-derived

fibres<sup>17</sup>. The use of their techniques<sup>17-19</sup>, in combination with the chromatography of tumour cells described here, offers an excellent system for study of interactions between lymphoid and tumour cells.

Tumour cell populations are heterogeneous with respect to various biological<sup>20-22</sup> and antigenic properties<sup>23,24</sup>. This heterogeneity may provide clones with different membrane characteristics and nutrient requirements, and thereby influence the rate of tumour growth and extent of metastatic involvement. Metastasis may be mediated by cell adhesion<sup>25</sup>, which in turn, may be a function of cell surface proteases, glycosidases and charge density<sup>26-28</sup>. Cellular interaction of blood-borne tumour cells with lymphocytes<sup>29</sup> and platelets<sup>30</sup> can also affect the distribution of circulating tumour cells. Different growth conditions may also result in the alteration of membrane properties<sup>31</sup>, immunogenicity<sup>7,32</sup> and metastatic properties of tumour<sup>33</sup>.

These observations, together with the results reported here have important implications for the immunotherapy of cancer. We have reported<sup>11</sup> that immunotherapy was successful only when cells used for immunisation elicited immunological products that were cytotoxic for residual tumour. Animals with drug-resistant tumour required immunisation with drug-resistant cells for optimal therapeutic benefit (J.J.K., unpublished). Drug-resistant sublines expressed marked alterations in antigenicity<sup>34</sup> and serum from mice cured by immunisation with VCN-treated, drug-resistant cells had minimal cytotoxicity directed against the parental cell line<sup>11</sup>.

In the treatment of human cancer, the probable source of autologous tumour cells for subsequent immunotherapy will be preserved specimens of the primary tumour. These cells may bear little antigenic resemblance to tumour cells which emerge during treatment.

The results reported here suggest that a new approach to active, specific immunotherapy may be developed—to "antigenically match" residual tumour with isolated sub-populations from the primary (parental) neoplasm. This will require that predictive relationships be established between the antigenic properties of metastatic and drug-resistant tumour cells, and the antigenic properties of isolated sub-populations from parental tumour. In L1210 leukaemia, the immunogenic fraction A expanded when the cell line was cultured, and was the dominant cell type when tumour was grown in athymic mice, suggesting an excellent source for immunogenic cells.

Studies are in progress to extend this concept of immunotherapy to other tumour-host models, and to the therapy of antigenically distinct clones of tumour cells that may emerge after treatment with chemotherapeutic agents.

We thank Ms Ann LeFever and Mr Kirt Bierig for technical assistance, and the Experimental Immunotherapy Group, Oklahoma Medical Research Foundation for helpful

**Table 2** Carbohydrate-inhibition of complement-dependent serum cytotoxicity to cultured L1210 cells

Inhibiting carbohydrates	mM required for 75% inhibition
$\alpha$ -D-Glucose	50.00
Sucrose	1.00
$\beta$ -D-Glucose	0.30
$\alpha$ -Methyl-D-galactoside	0.01
$\alpha$ -Methyl-D-mannoside	0.007
$\alpha$ -D-Fucose	0.001
$\alpha$ -D-Fucose	0.001
Non-inhibiting carbohydrates	
D-(+)-Galactose	
D-(+)-Galactosamine	
N-Acetyl-D-glucosamine	
$\alpha$ -Methyl-D-glucoside	

Mice were treated in an identical experimental protocol as described in Fig. 1, except immunotherapy consisted of VCN-treated, cultured L1210 cells. The serum of surviving mice were pooled and cytotoxicity was determined by  $^{51}\text{Cr}$  release<sup>14</sup>. Serum was preincubated with sugars for 30 min before addition of target cells. Serum cytotoxicity without inhibitor was 40% of total releasable  $^{51}\text{Cr}$ , and all inhibitors were tested from 300 mM to 10 pmol.

suggestions. This work was supported in part by a research contract from the National Cancer Institute.

## Differential response of cells grown in light and dark to near-ultraviolet light

We have previously shown that near-ultraviolet and visible light (290-650 nm) kill mitotic and early S phase amoebae, whereas G<sub>2</sub> phase amoebae are quite resistant<sup>1</sup>. Exposure of amoebae to near-ultraviolet light alone (290-400 nm) can have similar results (our unpublished data). We report here variations in sensitivity to near-ultraviolet irradiation of amoebae grown in 12 h light/12 h dark (hereafter referred to as light-grown cells) and those grown in complete darkness. We also show that in the dark-grown cells, as well as the S phase of the light-grown cells, the repair mechanism against the induced lethal damage might be lacking or non-functional.

*Amoeba proteus* were cultured at 21 ± 1 °C, as before<sup>2</sup>. Both light-grown and dark-grown cells have a generation time of 36 ± 4 h, and an S period of 6-7 h with no G<sub>1</sub> (ref. 3). The dark-grown cells (originally from a light-grown culture) had been kept in an incubator at 20 °C for about 22 months. They were exposed briefly to light when the culture dishes were changed every third day. The intensity of light incident on the light-grown cell cultures was ~ 5 W m<sup>-2</sup> from fluorescent tubes. The amoebae grew equally well when moved from dark to light and vice versa.

Light-grown and dark-grown amoebae were exposed at different phases of the cell cycle to near-ultraviolet irradiation at an intensity of 14 W m<sup>-2</sup> for various periods. The survival curves (Fig. 1) show that both the S and the G<sub>2</sub> stages of the dark-grown cells (DS and DG<sub>2</sub>) as well as the S phase of the light-grown cells (LS) were killed within 5-7 d at an energy

fluence of ~ 1.5 × 10<sup>5</sup> J m<sup>-2</sup> of near-ultraviolet light. This dose also killed all the mitotic cells from light-grown and dark-grown cultures (not shown). In contrast, the G<sub>2</sub> phase amoebae from light-grown cultures (LG<sub>2</sub>) were highly resistant to this dose of near-ultraviolet light, although a division delay (between 48-96 h) was noted. In controls, the survival rate was > 99%.

To assess the sensitivity of the nucleus and cytoplasm of the amoebae to near-ultraviolet light, nuclear transplantation experiments (according to the method of Jeon and Lorch<sup>4</sup>) were undertaken. Amoebae exposed to the lethal dose (1.5 × 10<sup>5</sup> J m<sup>-2</sup>) of near-ultraviolet light were selected for nuclear transplantation studies. All nuclear transfers were carried out almost immediately after exposure and completed within ~ 30 min. In most cases, both the nucleus and the cytoplasm of dark-grown and near-ultraviolet-exposed cells failed to survive when recombined with the cytoplasm and nucleus respectively from control LG<sub>2</sub> or DG<sub>2</sub> phase cells. When the nucleus from a light-grown and near-ultraviolet-exposed S phase cell was grafted into the control LG<sub>2</sub> phase cytoplasm a partial recovery (~ 30%) of the treated nucleus was observed. Most of the treated cytoplasm from the light-grown cells could, however, be rescued when the nucleus from control LG<sub>2</sub> cell was implanted into them (see Table 1).

These experiments show that: first, the control LG<sub>2</sub> and DG<sub>2</sub>

Fig. 1 Survival curve of near-ultraviolet exposed light-grown and dark-grown amoebae at different phases of the cell cycle. LS, LG<sub>2</sub>, S phase and G<sub>2</sub> phase of light-grown amoebae; DS, DG<sub>2</sub>, S phase and G<sub>2</sub> phase of dark-grown amoebae. The amoebae at known cell cycle stages, (S phase, 0-1-h-old cells; G<sub>2</sub> phase 18-24-h-old cells), obtained by mechanical selection of the division spheres, were placed in a specially constructed watch glass, partitioned into four chambers. A Reichart UG-1 filter with < 1% transmission below 280 nm and above 410 nm, and having a maximum transmission of 73% at 360 nm, was placed on the top of the watch glass. The light source used was a 400-W Philips white fluorescent lamp<sup>1</sup> and the amoebae of different age groups were exposed simultaneously to near-ultraviolet light transmitted through the filter at an intensity of 14 W m<sup>-2</sup> as measured by a Schwarz linear vacuum thermopile. The temperature of the culture medium during the exposure was maintained at ~ 20 °C by means of a water-circulating thermostat (Lauda). The cells were washed after exposure with medium and kept in syracuse watch glasses together with food organisms. No difference in response was noted between cells kept in total darkness and those kept in a 12 h light/12 h dark cycle after the exposure. Between 50 and 150 amoebae were exposed for each experimental set.

**Table 1** Results of nuclear transplantation experiments between near-ultraviolet treated and control amoebae from light-grown and dark-grown cultures at different cell cycle stages

Type of transfer	No. of transplants	No. of cell deaths	Survival† (%)
$A(D)S_n^* \rightarrow (D)S_n \leftarrow \left\{ (L/D)G_c \right.$	69 38	67 4	3 90
$(D)S_c^* \leftarrow (D)S_c \leftarrow \left\{ (L/D)G_n \right.$	65 36	59 3	9 91
$B(L)S_n^* \rightarrow (L)S_n \rightarrow \left\{ (L)G_c \right.$	15 17	10 1	33 94
$(L)S_c^* \leftarrow (L)S_c \leftarrow \left\{ (L)G_n \right.$	15 14	1 2	93 86

\*Near-ultraviolet treated cells.  $n$ ,  $c$ , indicate the nucleus and the enucleated cytoplasm respectively.

S, S phase (2–3 h after mitosis); G, G<sub>2</sub> phase (18–20 h after mitosis). (D), Dark-grown cells; (L), light-grown cells; (L/D), light or dark-grown cells.

†Production of at least sixteen amoebae from a single transplant has been taken as an index of survival.

nuclei cannot repair near-ultraviolet-induced damage of the DS cytoplasm. Second, the control LG<sub>2</sub> nucleus can repair the damage of the treated LS cytoplasm. Third, the treated LS nucleus can partially recover when transferred into the control LG<sub>2</sub> cytoplasm, but the treated DS nucleus cannot recover when grafted into either the LG<sub>2</sub> or DG<sub>2</sub> control cytoplasm.

The cytoplasm and the nucleus of dark-grown cells both seem to be highly sensitive, whereas the nucleus of light-grown S phase cells is partially, and the cytoplasm fully, resistant to near-ultraviolet light. Furthermore, our data strongly suggest the presence of a recovery factor(s), for example, a repair enzyme against the near-ultraviolet-induced damage in light-grown G<sub>2</sub> phase amoebae, which might be lacking or non-functional in the other cases mentioned here (see also ref. 1). It is interesting that an LS nucleus exposed to near-ultraviolet light can partially recover in the control LG<sub>2</sub> cytoplasm, while the treated DS nucleus shows insignificant recovery in either LG<sub>2</sub> or DG<sub>2</sub> control cytoplasm. Thus, it seems that repair against damage induced by near-ultraviolet light involves, as well as a recovery factor(s) in the LG<sub>2</sub> cytoplasm, a capacity of the nucleus of the exposed cell to augment recovery—which is probably absent in the dark-grown cells.

Near-ultraviolet light induces thymine dimer formation, DNA single-strand breaks, and also inactivates photoreactivating enzyme. Because of the poor absorption of DNA and proteins in this region of the spectrum, it has been suggested that the mechanism of induction of such damage is similar to that of photodynamic effect, being mediated through an endogenous sensitiser, for example, riboflavin or ubiquinone (for review see ref. 5).

We suggest that a certain region of the visible light spectrum can repair, directly or indirectly, the damage done by 360-nm light or that it is antagonistic to the deleterious action of this light before the fixation of the damage in the cell. The reasons are as follows: first, cells exposed to near-ultraviolet light are killed much earlier (5–7 d) than those exposed to visible light (3–5 weeks)<sup>1</sup>. Second, almost an equivalent dose ( $1.5 \times 10^5 \text{ J m}^{-2}$ ) of 350–370-nm light was received by both the cells exposed to visible light<sup>1</sup> and to near-ultraviolet light, resulting in 100% lethality. At this dose, light-grown S phase nuclei exposed to visible light show almost complete recovery (88%) when transplanted into the control G<sub>2</sub> phase cytoplasm, compared with partial recovery (33%) when exposed to near-ultraviolet light.

There are some reports that growth in darkness has changed or modified cellular functions. *Nicotiana tabacum* plants, kept

in the dark, lose their ability to photoreactivate ultraviolet-treated tobacco mosaic virus RNA within a week. Such plants recover their photoreactivation ability after they are returned to the light<sup>6</sup>. Mutants have been obtained from *Rhodospirillum rubrum* cells, grown for > 100 generations in the dark, which are light-sensitive and produce only a trace amount of bacteriochlorophyll *a* (ref. 7).

Finally, it would be interesting to know the timings of the 'switch over' from resistance to sensitivity to near-ultraviolet light and vice versa in the amoebae. Our preliminary experiments suggest that dark-grown G<sub>2</sub> phase cells acquire resistance to near-ultraviolet light in 10 d, or less, after they are returned to the light. The induction of this resistance thus seems to be photoregulated.

The assistance of Mr S. S. Shetty is appreciated.

## Herpes simplex virus infection stops spontaneous beating of chick heart cells

PROFOUND modifications in the macromolecular structure of cell membranes and membrane-related functions have been demonstrated on infection with various viruses<sup>1,2</sup>. For example, shortly after infection with certain herpesviruses, synthesis and insertion of host proteins into plasma membranes cease and new virus-specified proteins begin to appear<sup>3,4</sup>. These viral proteins differ from the cell membrane proteins in size, electrophoretic mobility, extent of glycosylation and sulphate incorporation<sup>3–5</sup>. The changes in membrane structure are reflected in altered morphology, antigenic characteristics and contact interactions of herpesvirus-infected cells<sup>4,6</sup>. They also appear to affect the ion-dependent electrical properties of the cells as shown by alterations in the transmembrane potential of cells infected by herpesviruses *in vitro* and *in vivo*<sup>7,8</sup>. To elucidate further alterations in membrane-related cell functions, as well as virus-cell interactions associated with herpesvirus infection, we are studying the effects of herpes simplex viruses (HSV) type 1 and 2 on chick embryo heart cells, which provide a useful system, particularly when aggregated into spontaneously beating spheroidal clusters<sup>10–13</sup>. We found that these viruses stopped the spontaneous beating of the cells before cell 'death'.

Cell monolayers were prepared from 7-d-old chick embryo hearts by a multicycle trypsinisation procedure described before<sup>10</sup>. Dishes (35 mm diameter) containing 2 ml of medium 818A were seeded with  $2 \times 10^5$  cells per dish and incubated at 37 °C in a water-saturated atmosphere of 5% CO<sub>2</sub>, 10% O<sub>2</sub> and 85% N<sub>2</sub>. Cell aggregates were prepared from the dissociated heart cells by incubating Erlenmeyer flasks (50 ml) containing 10 ml of medium and  $1 \times 10^6$  cells per flask (gassed with 5% CO<sub>2</sub>) at 37 °C on a shaker gyrating at 75 r.p.m. (ref. 11). After 18–20 h of incubation, cultures were washed and examined on the constant-temperature (37 °C) stage of an inverted microscope, in 5% CO<sub>2</sub> atmosphere.

Heart cell monolayers and aggregates were inoculated for most experiments with HSV-1 (VR<sub>3</sub> strain) at multiplicities of infection (MOI) between 0.25 and 200 plaque forming units (PFU) per cell. After 90 min of viral adsorption at 37 °C, the preparations were washed with fresh

**Fig. 1** Embryonic chick heart cell monolayers (*a*, *c* and *e*) and aggregates (*b*, *d* and *f*) inoculated with herpes simplex virus (●) or mock inoculated with inactivated virus (○). *a* and *b*, Percentage of heart cells in monolayers or aggregates beating. *c* and *d*, Beating rate (beats per min). *e* and *f*, Percentage of cells exhibiting HSV antigens by immunofluorescence in monolayer or aggregated heart cells.

medium and reincubated as before. To confirm that cultures were infected, supernatant medium or homogenates of the cells were subinoculated into cultures of primary rabbit kidney cells. In addition, HSV antigens were detected in the virus-inoculated heart cells by a direct immunofluorescent technique<sup>14</sup>. Heart cultures mock inoculated with virus inactivated at 56 °C for 3 h served as controls.

HSV infection of heart cells in monolayer culture caused the cells to round up within 6–12 h and stop beating. In a typical test, the number of beating cells in monolayers inoculated with virus (MOI=100) fell from 43% at the time of inoculation to 4% 6 h later (Fig. 1*a*). Only a few cells beat arrhythmically and with variable rates 9 h after inoculation. At 12 h, none were beating; contractions were not restored by a change of medium. No significant alterations were observed in the beating activity of cells mock inoculated with heat-inactivated virus.

When the virus inoculum was added to cell suspensions on a gyratory shaker at the beginning of aggregation, cells either failed to aggregate or formed irregular clumps of loosely attached cells. For this reason, preformed spheroidal aggregates were inoculated with HSV after 24 h of gyration. Rounding of cells occurred at the periphery of the aggregates. At the time of inoculation, 98–100% of the aggregates beat, but only 14% continued beating 9 h later; none of the aggregates beat 12 h after inoculation (Fig. 1*b*). Preliminary recordings of aggregates impaled with intracellular electrodes at intervals after HSV infection indicated that action potentials ceased and membrane resting potential declined slightly when the beat stopped.

The mean beating rate of cells and aggregates increased

by 25–30% over the control rate 3 h after inoculation, and then declined gradually before beating stopped (Fig. 1*c* and *d*). Mock inoculated control aggregates continued to pulsate without significant change in rate. The transient increase in beating rate after virus inoculation resembles the initial increase in beating rate of aggregates partially depolarised by ultraviolet light<sup>15</sup>, and may be attributable to depolarisation.

Inoculation with the VR<sub>3</sub> strain of HSV-1 in a range of MOI between 0.25 and 200 PFU per cell demonstrated that an MOI greater than 2.5 was required to stop the beating of either single cells or aggregates within 24 h. Infection with two other HSV-1 strains (F and HEA) at MOI of 100 produced effects on the heart cells similar to those observed with the VR<sub>3</sub> strain, while two HSV-2 strains (MS and G) stopped the beat at the same time with an MOI of 20.

Three hours after inoculation with the HSV-1 (VR<sub>3</sub>) at an MOI of 100, viral antigens were detected by immunofluorescence in about half the cells in monolayer culture, when the percentage of beating cells had dropped from 45 to 18% (Fig. 1*a* and *e*). Thereafter, as the number of beating cells continued to fall, there was a concomitant increase in the percentage of HSV antigen-positive cells. In contrast, 95% of the aggregates continued to beat 6 h after inoculation, when about half of their constituent cells exhibited viral antigens (Fig. 1*b* and *f*). The number of beating aggregates declined abruptly to 15% 3 h later, when antigen-positive cells had increased to 70%. The difference in response between monolayer cells and aggregates may be attributed to the depolarisation in the tightly coupled aggregates<sup>11,12</sup>, as well as to a difference in the rate of viral multiplication in aggregated cells as compared to monolayer cells due to the differences in topography.

It is noteworthy that 12 h after infection, at the time all cells and aggregates had stopped beating, 92% of the cells in monolayers were found to exclude Trypan blue dye. Similarly, when the 12-h-infected aggregates were dissociated with trypsin, 95% of their component cells excluded the dye. This indicates that viral infection at this time had not caused the cell membranes to become permeable to molecules the size of Trypan blue, and suggests further that the loss of beat and electrical activity did not result merely from non-selective leakiness of the cell membranes. Although virus-infected cells eventually die, the brief interval (3–6 h) between viral inoculation and the effects on beating rate reported here argues for more subtle alterations in the infected cell membranes as the underlying cause of these physiological changes. More work is needed to discover how such changes are correlated with those that have been observed with biochemical and immunological methods at the same early time interval<sup>4,8</sup>.

As far as we know, no earlier investigations of the pathological effects of viruses on embryonic heart cells have been reported, except that such cells infected with mumps virus in conditions somewhat different from those we used, continued beating<sup>16</sup>.

## Unrelated animal viruses share receptors

THE specific receptors for several non-enveloped viruses are present on cells in only limited numbers ( $1 \times 10^4$ – $10 \times 10^4$ ), and can therefore be saturated with excess virus<sup>1-5</sup>. An

excess of inactivated poliovirus type 1 inhibits the attachment of infectious poliovirus of all 3 serotypes, but not the attachment of other viruses, including B Coxsackie viruses<sup>6</sup>. Most of the B Coxsackie viruses probably share the same receptor<sup>7</sup>, but Coxsackie viruses B1 and B3 do not compete for the poliovirus receptor<sup>1</sup>. Adenovirus 2 and 5 also appear to share the same receptor, since their attachment to host cells is blocked by an excess of the adenovirus type 2 fibre protein, which seems to be the receptor-recognising portion of the virus particle<sup>2</sup>. A number of other adenoviruses may also belong to the same receptor family since soluble antigens block their attachment to erythrocytes<sup>8</sup>. We here report results which permit the construction of a 'receptor map' for a number of non-enveloped viruses.

These experiments measured attachment of highly purified <sup>14</sup>C-, <sup>35</sup>S-, or <sup>32</sup>P-labelled virus particles to HeLa cells. The HeLa cells had either not been exposed to another virus, or exposed to excess purified virus or viral antigen to saturate most of the available receptor sites of one type. Pretreatment with excess virus was usually for 15 min at 34.5 °C

**Fig. 1** Attachment of labelled virus particles to untreated cells (●) or to cells treated with excess unlabelled CB3, Ad2 or Ad2-fibre protein (○). Attachment of <sup>14</sup>C-CB3 was inhibited by excess homologous virus (a), and by excess Ad2 (b) or by excess Ad2 fibre protein (c). Attachment of <sup>35</sup>S-Ad2 was inhibited by excess CB3 (d), by excess homologous virus (e) or excess fibre (f). CB3 did not inhibit attachment of CA21 (g). Excess Ad2 particles partly inhibited attachment of HRV-2 (h) but the fibre protein did not (i). Non-radioactive virus ( $1 \times 10^5$ – $3 \times 10^5$  particles per cell) or Ad2 fibre protein ( $8 \mu\text{g ml}^{-1}$ ) was incubated for 15 min at 34.5 °C with HeLa cells ( $1 \times 10^7 \text{ ml}^{-1}$ ), or cells were 'mock' incubated without added virus or fibre. The suspensions were cooled to 0 °C and a labelled virus was added ( $\sim 1\%$  by volume,  $1 \times 10^4$  particles per cell). Aliquots of cells were incubated at 34.5 °C, washed twice with cold medium and counted. Attachment of labelled virus is expressed in % of total added. Preparations of virus were usually dialysed against the MEM medium used for the cell suspension (adenovirus was in a buffer containing 10% glycerol, 0.001 M  $\text{MgCl}_2$ , and 0.02 M Tris-HCl, pH 7.8; this was also used with 'mock' treated cells. Adenovirus fibre protein ( $2 \text{ mg ml}^{-1}$ ) was purified by chromatography on DEAE cellulose, hydroxylapatite and Sepharose 6B<sup>11</sup>. The method of preparing, handling and counting the radioactivity of the cells has already been described<sup>3</sup>. 'Rhino-HeLa cells' were used in panels c, f, and i.

(Fig. 1), but 60 min at 22 °C or no pre-incubation but using a larger excess of unlabelled particles, gave compatible results (not shown). Excess unlabelled human rhinovirus type 2 (HRV-2) and type 14 (HRV-14), Coxsackie virus type A21 (CA21) and type B3 (CB3), poliovirus type 2 (P2), and adenovirus type 2 (Ad2) were employed for saturation of cellular receptors. These and other viruses were prepared and purified by methods already reported<sup>2,3,9,10</sup>. The concentration of picornaviruses<sup>10</sup> or adenoviruses<sup>2</sup> was estimated in particles per ml by ultraviolet adsorption. Pools of purified virus contained  $1 \times 10^{13}$ – $3 \times 10^{13}$  particles per ml, and when labelled,  $0.6 \times 10^8$ – $6 \times 10^8$  c.p.m. per ml.

Two lines of suspension-grown HeLa cells were used. The human rhinoviruses and Coxsackie virus A21 appeared to attach significantly more rapidly to one of these, 'rhino-HeLa-cells' than to the other, but the two lines otherwise showed no qualitative differences in competition experiments.

Efficient attachment of radioactive virus to cells required warming of the mixture. The rate of attachment varied from one type of virus to another and from experiment to experiment depending upon the cell line employed. Homologous competition for receptors was tested and detected in every experiment using excess virus or antigen.

Figure 1 illustrates representative results of experiments employing excess CB3, Ad2, or Ad2-fibre. As expected, attachment of <sup>14</sup>C-labelled CB3 was inhibited by excess homologous virus (Fig. 1a), but unexpectedly, attachment of CB3 was also inhibited by excess Ad2 (Fig. 1b) or Ad2-fibre (Fig. 1c). In a reciprocal way, attachment of <sup>35</sup>S-Ad2 was blocked by excess CB3 (Fig. 1d) as well as by excess Ad2 particles or fibre protein (Fig. 1e and f). Thus, CB3 and Ad2 clearly share HeLa cell receptors.

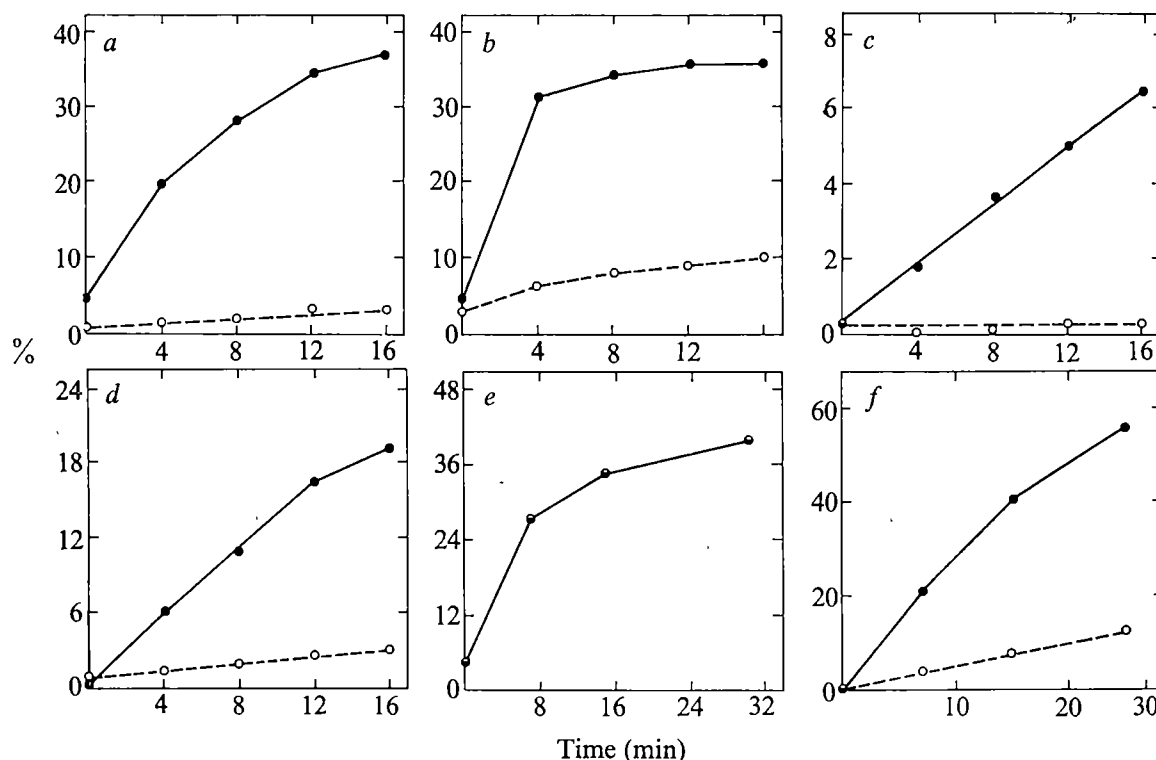

Excess unlabelled CB3 did not inhibit attachment of labelled HRV-2, HRV-14, P2 (not shown) or labelled CA21 (Fig. 1g). A different picture emerged with unlabelled Ad2 which produced a clear twofold reduction in the rate of attachment of labelled HRV-2 (Fig. 1h). This was not

reciprocal, however, and excess HRV-2 had no effect on attachment of labelled Ad2 (not shown). Treatment of cells with the relatively small (molecular weight 200,000 (ref. 11)) Ad2 fibre protein had no effect on HRV-2 attachment (Fig. 1i), indicating that the large bulky Ad2 particles on one site may interfere with attachment of HRV-2 to a separate site by steric hindrances. Alternatively, adenovirus may induce cross linking of components of the cell surface, which may lead to alteration or internalisation of the receptors for HRV-2. HRV-2 and Ad2 may thus recognise either separate determinants on the same macromolecule or determinants on adjacent macromolecules. It would be interesting to determine if isolated purified receptors for Ad2 will interact with HRV-2 particles as well. Cells treated with excess Ad2 also showed a barely detectable (~10%) reduction in attachment of HRV-14, CA21, and P2 (not shown).

Figure 2 shows some of the effects of treating cells with excess CA21 or excess HRV-14 on the attachment of other viruses. Excess CA21 is able to inhibit attachment of both labelled homologous virus (Fig. 2a) and also labelled HRV-14 (Fig. 2c). Competition for receptors by excess HRV-14 was more difficult to demonstrate, probably because HRV-14 attaches slowly to HeLa cells<sup>3</sup>. Thus cells treated with excess HRV-14 attached significant amounts of CA21 or HRV-3 (Fig. 2b and f), but there was clear evidence for interference. Similar data have been found for the attachment of HRV-41 (ref. 3) and some other labelled rhinoviruses (HRV-5, 15, 39, 51) to cells treated with excess HRV-14, and they probably all share the same receptor with the poorly attaching HRV-14. It is interesting to note that although the B Coxsackie viruses also probably share one receptor, the rates of attachment differ widely and show entirely different pH optima<sup>12</sup>. Neither CA21 nor HRV-14 were able to inhibit attachment of HRV-2, P2, CB3, or Ad2 (not shown, see also ref. 3 and Fig. 2e).

Our results are summarised in Table 1. There are four receptor families. The first family contains HRV-2,

**Fig. 2** Attachment of labelled virus particles to untreated cells (●) or to cells treated with excess unlabelled CA21 or HRV-14 (○). Attachment of <sup>14</sup>C-CA21 was inhibited by excess CA21 (a) or excess HRV-14 (b). Attachment of <sup>14</sup>C-HRV-14 was inhibited by excess CA21 (c) or HRV-14 (d). <sup>32</sup>P-P2 was not inhibited by excess CA21 (e); HRV-3 was inhibited by excess HRV-14 (f). The method used is described in the legend to Fig. 1. 'Rhino-HeLa cells' were used in panels b, d, e, and f.

CA21	—	+	+	—	—	—
P2	—	—	—	+	—	—
CB3	—	—	—	—	+	+
Ad2	±§	(-)	(-)	(-)	+\$	+

\*Strains of virus used: HRV-2(HGP), HRV-14(1059), CA21(48654), P2 (P217-Ch2ab), CB3 (Nancy), Ad2 (Adenoid 6), HRV-1A (2060), HRV-1B (B-632), HRV-3 (FEB), HRV-5 (Norman), HRV-15 (1734), HRV-39 (209), HRV-41 (56110), HRV-51 (F01-4081).

†In addition to competition (+) with attachment of homologous virus, excess HRV-2 also inhibited attachment of HRV-1A and HRV-1B (ref. 3, and Lonberg-Holm, unpublished data). Excess HRV-14 did not inhibit attachment of HRV-1A or HRV-1B.

‡In addition to the homologous and reciprocal inhibitions (+) indicated, excess HRV-14 also inhibited attachment of HRV-3, -5, -15, -39, -41, and -51. Excess HRV-2 did not inhibit these viruses (ref. 3, and Lonberg-Holm, unpublished data).

§Adenovirus fibre protein and intact Ad2 blocked attachment of CB3. Intact Ad2, but not excess fibre, partially inhibited attachment of HRV-2.

||Attachment of HRV-14, CA21 and P2 was inhibited by ~10% following treatment of cells with excess Ad2.

HRV-1A and HRV-1B. The second family contains HRV-14 and CA21. Other experiments, with excess HRV-14, indicate that HRV-3, -5, -15, -39, -41 and -51 belong in this family (unpublished data, see also Fig. 2f and ref. 3). The third family contains poliovirus type 2, and therefore all three serotypes of poliovirus<sup>6,12</sup>. The fourth family contains Coxsackie virus B3 and thus probably all or most of the other B Coxsackie virus<sup>7,12</sup>. Ad2 and probably at least several other adenoviruses are in this family<sup>2</sup>.

It is possible that receptor specificity influences virus tropism in tissues and organs, and thereby contributes to patterns of viral pathogenesis<sup>13,14</sup>. The finding that Coxsackie virus A21 ('Coe virus') shares receptors with a large number of human rhinoviruses may be related to its ability to produce cold-like symptoms<sup>15</sup>. Both B Coxsackie viruses<sup>1,16</sup> and adenoviruses<sup>17</sup> produce persistent infections in HeLa cells cultured in the presence of human serum. It will be important to determine if receptors for CB3 and Ad2, or CA21 and HRV-14 are covariant in different tissues or different host species.

Future work should attempt to determine the physiological and biochemical identity of the specific virus receptors, this could be rewarding because virus receptors have been used as markers in cytogenetic studies<sup>4,18</sup>.

We thank L. B. Gosser for plaque purification and confirmation of the serological identity of HRV-3, HRV-15, and HRV-39, and D. J. Reardon for assistance.

## Two kinds of cholinoreceptors on the membrane of the completely isolated identified *Planorbarius corneus* neurone

We have found that an identified neurone of the *Planorbarius corneus* left pedal ganglion (LPed-2 neurone, Fig. 1) responds with depolarisation to nicotinomimetics and with hyperpolarisation to some muscarinomimetics. The LPed-2 neurone of *P. corneus* contains dopamine<sup>1</sup> and is the dopaminergic interneurone sending depolarising and hyperpolarising impulses to some neurones of the visceral and the left parietal ganglion<sup>2</sup>. Acetylcholine (ACh) alone produces depolarisation like a nicotinomimetic; in the presence of tubocurarine, ACh hyperpolarised the cell membrane like a muscarinomimetic. The suggestion has been made that two kinds of cholinoreceptors (ChR) exist on the membrane of the LPed-2 neurone, differing in both the pharmacological properties and the ionic permeability changes they control<sup>3</sup>. Two different types of ChR have been described on the membrane of some identified *Aplysia* neurones<sup>4,5</sup>. Experiments<sup>3</sup> performed on the LPed-2 neurone in the ganglionic ring where it receives synaptic inputs from various interneurons which also can respond to ACh do not exclude the possibility that the two kinds of responses are attributable to the interference of some interneurons masking the actual effect of ACh on the LPed-2 neurone.

To resolve this problem we performed experiments on completely isolated LPed-2 and LPed-3 neurones (Fig. 1). The method described by Kostenko<sup>6</sup> was used. The ganglionic

Fig. 1 Diagram of the dorsal surface of *P. corneus* circumoesophageal nerve ring. Cerebro-cerebral connective is cut to expose the pedal ganglia. Ganglia: LPed, left pedal; LCer, left cerebral; LPI, left pleural; LP, left parietal; V, visceral; RP, right parietal; RPI, right pleural; RCer, right cerebral; RPed, right pedal. LPed-2 (2) and LPed-3 (3) neurones can be easily identified: LPed-2 is the biggest of the left pedal ganglion<sup>1</sup>; LPed-3 can be identified by its position between LPed-2 and statocyst (S) and by the characteristic red colour of the surrounding glial cells.

circumoesophageal ring was treated with 0.3% Pronase solution for 30–40 min, then the sheaths were removed and single identified neurones were isolated using electrolytically sharpened tungsten needles. The isolated neurone was placed in a chamber (1.5 ml) perfused with saline solution (50 mM NaCl, 1.6 mM KCl

**Fig. 2** Effects of nicotinomimetics and muscarinomimetics on the completely isolated LPed-3 neurone. All records were obtained in the same experiment. The resting transmembrane potential was equal to  $-60$  mV. Drugs were added to the perfusion fluid at the upward arrow and washed out at the downward arrow. Calibration  $10$  s,  $10$  mV here and in Fig. 3 refers to de- and hyperpolarisation but not to the spikes. *a*, Depolarising responses to nicotinomimetics. Approximately equally effective concentrations were chosen. Nic, nicotine; BuCh, butyrylcholine; D-6, suberyldicholine<sup>17</sup>  $(\text{CH}_3)_3\text{N}-\text{CH}_2\text{CH}_2-\text{O}-\text{CO}-(\text{CH}_2)_6-\text{CO}-\text{O}-\text{CH}_2\text{CH}_2-\text{N}(\text{CH}_3)_3$ ; TMA, tetramethylammonium. *b-d*, Hyperpolarising responses to muscarinomimetics. *d*, Methylfurmethide (Mfm); note that at Mfm concentrations of  $10^{-8}$  M hyperpolarisation is greater in the presence of tubocurarine showing that Mfm activates at this concentration both kinds of ChR hyperpolarising response being partly masked by simultaneous depolarisation. *b*, Acetyl- $\beta$ -methylcholine (Mech). *c*, dioxolan F-2268.

Note that F-2268 is the most potent: its equeffective hyperpolarising doses are three orders of magnitude smaller than those of Mech or Mfm.

$4$  mM  $\text{CaCl}_2$ ,  $8$  mM  $\text{MgCl}_2$ , Tris-buffer  $0.25$  g l<sup>-1</sup>,  $\text{HCl} \leq \text{pH}$   $7.5$ ) and impaled with a microelectrode filled with  $2.5$  M KCl. Membrane potential was recorded using the standard intracellular technique<sup>7</sup>. Drugs were added to the perfusion fluid.

After isolation the LPed-2 neurone retains the rhythmic spontaneous activity which it characteristically displays in the ganglion. In the ganglion the LPed-3 neurone showed non-rhythmic discharges or permanent oscillations of transmembrane potential. After isolation it usually became silent or discharged rhythmically.

We found that LPed-2 and LPed-3 neurones in the isolated state are depolarised by nicotinomimetics (Fig. 2*a*) and hyperpolarised by muscarinomimetics (Fig. 2*b*, *c*, and *d*); this means that the isolated neurones respond in the same way as when they are *in situ* in the brain. The response to ACh is more complicated and depends on the concentration used (Fig. 3). Small ACh concentrations ( $5 \times 10^{-8}$  M– $2 \times 10^{-7}$  M) caused hyperpolarisation. With greater concentration the cell begins to repolarise in the presence of ACh; after washing out the hyperpolarisation reappears. This response suggests that ACh

\*Normal saline

†D-6 (suberyldicholine)<sup>17</sup> is a nicotinomimetic agent deprived of any muscarinic properties.

**Fig. 3** Effect of tubocurarine on the responses of the completely isolated LPed-3 neurone to ACh. All records were obtained in the same experiment. Note that with small ACh concentrations there is no difference between control responses (left column) and those in the presence of tubocurarine (right column); probably N-ChR are not excited by these ACh concentrations. At  $2 \times 10^{-7}$  M hyperpolarising response is greater in the presence of tubocurarine. Higher ACh concentrations caused a two-component potential change in the control but pure hyperpolarisation in the presence of tubocurarine (with the exception of response to ACh ( $4 \times 10^{-6}$  M) where a slight repolarisation can be seen, suggesting that the tubocurarine concentration ( $2 \times 10^{-5}$  M) is not high enough to protect the nicotinic ChR against ACh concentration as high as  $4 \times 10^{-6}$  M. The resting potential was equal to 43 mV. Tubocurarine ( $2 \times 10^{-5}$  M) was added to the perfusion fluid 2 min before the addition (upward arrow) of the solution containing both ACh and tubocurarine. Calibration 10 mV, 10 s.

activates two kinds of ChR, with those mediating hyperpolarisation being sensitive to lower ACh concentration. Nicotinic ChR (N-ChR) of *P. corneus* and *Limnaea stagnalis* neurones are blocked by tubocurarine<sup>8,9</sup> as are those of *Aplysia* neurones<sup>10</sup>. We observed that in the presence of tubocurarine ACh caused pure hyperpolarisation, as do muscarinomimetics (Fig. 3). These results indicate that two kinds of ChR coexist on the membrane of the completely isolated neurones, LPed-2 and LPed-3, with the isolated cells much more sensitive to ACh and cholinomimetics (especially muscarinomimetics) than non-isolated neurones.

Of the two types of ChR found on the membranes of the isolated neurones those mediating depolarisation are similar to N-ChR in vertebrates: they are excited by all nicotinomimetics and are blocked by tubocurarine. Receptors mediating hyperpolarisation seem to resemble the muscarinic ChR (M-ChR) of vertebrates less closely. We have studied the hyperpolarising potency of a series of drugs known to excite M-ChR: dioxolan F-2268 (ref. 11); methylfurmethide, acetyl- $\beta$ -methylcholine; oxotremorine; arecoline; carbacholine; pentyltrimethylammonium. All of those drugs (with the exception of oxotremorine) caused hyperpolarisation. The most potent proved to be F-2268 ( $EC_{50} = 2 \times 10^{-8}$  M) which is very active on vertebrate M-ChR (refs 11 and 12). Other muscarinomimetics—even those known to have a high potency on vertebrate M-ChR (such as methylfurmethide and oxotremorine)—were far less potent than F-2268 in producing mollusc neurone hyperpolarisation. For example, methylfurmethide proved to be 350 times as weak as F-2268. Oxotremorine produced no hyperpolarisation even in high concentration. It seems, therefore, that mollusc neurone ChRs mediating hyperpolarisation differ in their chemical sensitivity from vertebrate M-ChR.

The difference becomes even more evident when studying the potency of typical muscarinolytics. Neither atropine nor scopolamine can prevent the hyperpolarisation caused by ACh or by muscarinomimetics. The alkylating agent benzilylcholine mustard (A-5 ref. 13), known to block selectively and irreversibly vertebrate M-ChR (refs 14 and 15), was found to block

neurone hyperpolarisation selectively and irreversibly as well, without changing the depolarising (nicotinic) response. The concentration needed ( $2 \times 10^{-4}$  M for 15 min) was, however, five orders of magnitude greater than that needed to block M-ChR in the guinea pig ileum. Like the slow hyperpolarisation of *Aplysia* neurones<sup>5</sup>, the hyperpolarisation of LPed-2 and LPed-3 neurones can be prevented by tetraethylammonium ( $5 \times 10^{-5}$  M).

The study of the ionic basis of the depolarising and hyperpolarising responses are in progress; Table 1 shows the preliminary results. We have found (Table 1) that the replacement of 38 mM (one half) of the chloride ions in physiological solution by 38 mM of sulphate or propionate ions increases the depolarising responses to ACh, nicotine and the nicotinomimetic agent suberyldicholine (D-6), (ref. 16). The replacement of one half (25 mM) of sodium chloride in physiological solution by an equal concentration of lithium chloride did not change the depolarising response to D-6. These results suggest a chloride dependence of the depolarising response to ACh and to nicotinomimetics. As we used microelectrodes filled with KCl it can be concluded that the depolarising response to ACh and nicotinomimetics is attributable to the increase of the intracellular chloride concentration (as a result of the diffusion of chloride from the microelectrode) which in turn leads to the change in the chloride equilibrium potential and finally to the change in the sign of response. To check this possibility the microelectrodes filled with potassium citrate (1 M),  $K_2SO_4$  (0.5 M) and  $Na_2SO_4$  (1 M) were used in several experiments. Nicotinomimetic agents still caused depolarisation with these microelectrodes and there was a depolarising phase in the response to ACh.

No change in the hyperpolarising effect of F-2268 was observed when the chloride concentration was halved (Table 1). Halving (doubling) the potassium concentration increased (decreased) the hyperpolarising response to F-2268 (Table 1b). Thus this response seems to be potassium dependent.

Two kinds of ChR found on completely isolated *P. corneus* neurones seem to closely resemble those on the neurones of

the *Aplysia* pleural ganglion<sup>6</sup> in both pharmacology and ionic dependence.

## Fluorescence changes during electrical activity in frog muscle stained with merocyanine

NERVE membranes stained with various fluorescent dyes show changes in fluorescence intensity concomitant with changes in transmembrane potential<sup>1–4</sup>. Cohen *et al.*<sup>4</sup> described a number of dyes that exhibit changes in fluorescence emission which vary linearly with transmembrane potential. Two of these have been used to investigate the excitation-contraction process in skeletal muscle<sup>5–7</sup>. Whole muscles and single fibres stained with Nile Blue A were reported to give fluorescence intensity changes on stimulation arising from the membranes of the sarcoplasmic reticulum<sup>5,6</sup>. Muscles and fibres stained with Merocyanine 540 on the other hand, give very early changes in fluorescence intensity when stimulated electrically<sup>8,7</sup>. Landowne<sup>7</sup> proposed that since the merocyanine signal disappeared after detubulation in snake costocutaneous muscles, the fluorescence change must arise from the T-system membranes.

We describe here experiments in which the extrinsic fluorescence signal is compared with the membrane potential in bundles of frog skeletal muscle fibres stained with Merocyanine 540. Our results partially agree with Landowne's conclusion that this dye monitors electrical activity in the T-system membranes; they do indicate, however, that the surface membrane also contributes to the fluorescence signal. The proportion of the contributions from both membrane systems can be roughly estimated as 9:1 (T-system-surface membrane) but important assumptions underlying this value must be investigated in detail.

Bundles of 40–200 fibres from the sartorius and the semitendinosus muscles of the Chilean frog, *Calyptocephalella gayi* were used instead of single fibres to extend the life of the preparation exposed to the toxic effects produced by the merocyanine dye in the presence of light and oxygen (see below and ref. 4). They were dissected and mounted horizontally in the narrow trough of a lucite chamber. The trough was separated into three compartments with Vaseline. The central compartment (4 mm wide) had one

of the walls and the bottom made of glass to allow light transmission. The other wall was a platinised Pt plate used to pass current through the muscle fibres to the lateral compartments. The bundles were stimulated in two different ways; mode A, by passing current between the central compartment and the lateral ones to give simultaneous polarisation of the fibres in the central compartment; and mode B, by passing current between two Pt plates in one of the lateral compartments to propagate action potentials travelling to the central compartment. The bundle was kept in place by connecting one tendon to a strain gauge transducer and the other to forceps. The chamber was placed on an optical bench so that the light coming from a tungsten-halogen lamp could be filtered and focused on the bundle in the central compartment of the chamber. At 90° with respect to the illuminating beam, the light was filtered and collected by a photodiode connected to the recording apparatus (for details see legend of Fig. 1 and ref. 5). As fibres stained with Merocyanine 540 were damaged by exposure to light in the presence of oxygen in the bathing medium, the illumination periods were minimised and nitrogen was bubbled in the bathing solution between experimental runs. Nevertheless, after several periods of illumination, action potentials became wider and the fibres eventually lost their excitability.

Figure 1 shows the relationship between the fluorescence signal (trace a) and tension development (trace b) in a bundle of about 40 sartorius fibres stimulated by a single-current pulse in mode B. The bundle had been exposed to the staining solution for 45 min and then transferred to Ringer's solution for recording. Figure 1a shows a transient fluorescence signal followed by a movement artefact when tension starts to develop (trace b). To eliminate this artefact, and to observe the recovery phase of the early

**Fig. 1** Merocyanine fluorescence signal (a) and tension (b). The change in fluorescence is expressed as the ratio of change in light intensity to resting fluorescence light intensity. An increment in fluorescence intensity is indicated by the arrow. Temperature 21 °C. In all experiments a Baird-Atomic interference filter (35-15-16) with a central wavelength of 548.6 nm was used as a primary filter to render the incident light quasi-monochromatic. The light from the bundle was filtered by a barrier filter (Schott RG-610) which absorbed wavelengths shorter than 610 nm. This was used to filter the light emitted at 90° with respect to the source and was placed beneath the bottom of the central compartment of the chamber. Below the secondary filter, the light was collected by a photodiode (PV-444, E. G. & G.) followed by a current-voltage converter. The electrical signals from the photodiode were filtered by a bandpass filter (time constant 0.2 ms), amplified by a Tektronix 3A3 amplifier and then fed with either the membrane potential from a microelectrode amplifier or the tension signal from the transducer into a digital machine which will be described elsewhere. This machine enabled us to average the signal and to record the output using a standard high-fidelity tape recorder or chart recorder. The Ringer's solution contained 115 mM NaCl, 2.5 mM KCl, 1.8 mM CaCl<sub>2</sub>, 2.15 mM Na<sub>2</sub>HPO<sub>4</sub> and 0.85 mM NaH<sub>2</sub>PO<sub>4</sub>, pH = 7.1 (ref. 8). The staining solution was Ringer's plus 0.05 mg ml<sup>-1</sup> Merocyanine 540 (Eastman Kodak), Pluronic F-127 0.02% (BASF Wyandotte) and 1% ethanol.

**Fig. 2** Fluorescence signal and action potential. *a*, A single sweep displaying the change in fluorescence intensity on stimulation of a bundle of more than 100 fibres from the semitendinosus muscle. *b*, Action potential recorded by a microelectrode impaled in a fibre with a resting potential of  $-86$  mV in the centre of the illuminated region of the central compartment. Both records were taken simultaneously for a single stimulus of  $0.2$ -ms duration in the depolarising direction. Capacitive pick-up by the microelectrode distorted the membrane potential record at short times after the stimulus pulse was given. The bundle was stretched to  $1.4$  times its slack length and was immersed in  $345$  mM NaCl hypertonic Ringer's solution (see text). The tension record was flat. Temperature  $22^{\circ}\text{C}$ .

signal it was necessary to block development of tension. This was achieved by stretching the bundles to between  $1.3$  and  $1.5$  times their slack lengths and immersing them in hypertonic solutions with  $230$  mM NaCl added to Ringer's solution<sup>5</sup>. Figure 2 shows the results of an experiment in those conditions. The bundle was stimulated with a  $0.2$ -ms

**Fig. 3** Fluorescence intensity changes with prolonged stimulation. *a*, Fluorescence intensity change during a depolarising current pulse after  $10^{-6}$  M TTX was added to the Ringer's solution. *b*, The resulting fluorescence signal during a hyperpolarising pulse of equal amplitude. Both records are the average of 20 sweeps. The time courses of the stimulus pulses are shown below each trace. The bundle was stretched to about  $1.5$  times its slack length and it was immersed in hypertonic Ringer's to prevent movement during depolarisation. Temperature  $20^{\circ}\text{C}$ .

depolarising current pulse in mode A. The complete time course of the transient fluorescence signal is displayed, without the movement artefact, in trace *a*. Trace *b* is the simultaneous record of an action potential obtained by impaling a single fibre from the bundle with a microelectrode positioned in the centre of the illuminated region. The rising phase of the action potential ( $t_{1/2}=0.5$  ms) is steeper than the rising phase of the fluorescence signal ( $t_{1/2}=1$  ms) and the recovery phase of the latter ( $t_{1/2}=1.2$  ms) is slower than the repolarisation of the action potential ( $t_{1/2}=0.95$  ms). One reason why records 2*a* and *b* are different could be that the fluorescence signal is recorded simultaneously from a population of fibres of the bundle. The non-synchronous activation, due to different thresholds among fibres of the bundle, would be seen as an apparently slower signal. This possibility was tested by impaling several fibres in the illuminated region and different delays were found between the peak of the action potential and the peak of the fluorescence signal. In the experiment shown in Fig. 2, the impalement of five fibres showed that the peak of the fluorescence signal preceded, or was delayed with respect to the peak of the action potential within a range of  $0.85$  ms. This range would explain the differences on the rising phase half times between the fluorescence signal and the action potential. This argument, however, is less convincing in explaining the differences in the falling phase half times because the repolarisation of the action potential is a slower process. An alternative, but not exclusive, explanation for the differences between the action potential and the light signal time courses would be that the latter is monitoring the slower potential changes of the T-system membranes<sup>9</sup>. In fact, the merocyanine fluorescence signal recorded from a single fibre by Oetliker *et al.*<sup>9</sup> has a similar time course to that shown in Fig. 2*a*.

Figure 3 shows the fluorescence signals recorded in a bundle after addition of  $10^{-6}$  M tetrodotoxin (TTX) to the external solution, when  $45$ -ms hyperpolarising (Fig. 3*a*) and depolarising (Fig. 3*b*) pulses were applied in mode A. The characteristic 'creep', produced by the anomalous rectifier, is observed in Fig. 3*b*. The time constant of the membrane as monitored by the dye was calculated from these and three more experiments to be  $17.9 \pm 1.22$  (s.e.) ms ( $n=7$ ). This value is close to those measured with microelectrodes<sup>12,13</sup>. If most of the fluorescence signal is coming from the T-system membranes, the optical time constant should be slightly longer than the electrical one. This difference, however, might be within experimental error in our measurements.

To obtain more information about the membrane systems monitored by the merocyanine dye, we carried out a series of detubulation experiments using the procedure described by Eisenberg *et al.*<sup>10</sup>. In this method the bundle is transferred from the glycerol-containing solution to Ringer's containing  $5$  mM Ca and  $5$  mM Mg which maintains the resting potential at around  $-82$  mV (ref. 15). Figure 4*a* corresponds to a propagated fluorescence signal before detubulation of a bundle of less than  $60$  fibres immersed in hypertonic solution and stimulated in mode B. The bundle was stimulated  $19$  mm away from the illuminated region and the propagated signal was detected about  $11.3$  ms after the stimulus pulse. The speed of propagation of the signal can be roughly calculated to be  $168$  cm s<sup>-1</sup>, which agrees with previous measurements of action potentials speed<sup>14</sup>. After detubulation, the fluorescence signal changed (Fig. 4*b*). The amplitude of the signal is reduced by a factor of ten and the propagation velocity increased to  $229$  cm s<sup>-1</sup>,  $36\%$  faster than before detubulation. The decay phase of the light signal in the detubulated bundle (Fig. 4*b*) is faster than that shown in Fig. 4*a*.

The fluorescence signal was used in two experiments to measure the time constant of the membrane, obtained with long pulses applied to TTX-treated bundles. The average

**Fig. 4** Propagated fluorescence signals before and after detubulation. *a* and *b* were obtained from the same bundle of 60 semitendinosus fibres in 345 NaCl hypertonic Ringer's solution and stretched to about 1.5 times its slack length. *a*, A single sweep before detubulation; *b*, average of 40 sweeps after detubulation. The arrow indicates the time the stimulus pulse was applied. Pluronic 127 was not used in the staining solution. Temperature 20 °C.

value was  $7.33 \pm 0.79$  (s.e.) ms ( $n=6$ ), significantly faster than in intact bundles. No significant 'creep' was observed during hyperpolarising pulses. These results demonstrate that detubulation has a similar effect on the fluorescence signal and the membrane potential recorded with microelectrodes. The amplitude of the fluorescence signal, however, is reduced by the glycerol treatment, but the action potential amplitude is virtually unaffected<sup>16</sup>. If we assume that the magnitude of the signal is proportional to the amount of membrane stained, we estimated that  $\sim 10\%$  of the total membrane is not affected by detubulation. In other experiments this value ranged from 4% to 20%. It could be argued that the 90% decrease of the light signal is produced by damage during detubulation. Apart from evidence that the glycerol treatment, using raised Ca and Mg concentrations, gives a better survival of the fibres<sup>10,15</sup>, there are several observations which make this explanation unlikely. First, the increased speed of the falling phase of the fluorescence signal after detubulation is consistent with the idea that Merocyanine 540 monitors the electrical activity of both surface and T-system membranes in intact fibres, but predominantly surface membrane in detubulated fibres. Second, the faster time constant of the light signal in response to long pulses in TTX-treated fibres after detubulation is also compatible with the loss of T-system membrane capacity—which is predominant in intact fibres and there produces a longer time constant for the light signal. Finally, in the experiments performed in normal Ringer's, tension was reduced by detubulation to a lower proportion (0.4–2.2%) than the light signal amplitude (4–20%), indicating that most of the remaining fluorescence signal came from fibres that were inactivated mechanically; this in turn, indicates that the signal originated partially in the surface membrane. More detubulation experiments will be required to study in detail the relative contribution of the surface and tubular membranes and the qualitative changes in the

time course of the fluorescence signal before and after detubulation.

Merocyanine 540 very probably does not penetrate to the interior of the fibres because a larger and slower signal would be expected from the sarcoplasmic reticulum, like that seen with the lipid-soluble dye Nile Blue A<sup>5,6</sup>. Also, recent experiments in squid axon microinjected with Merocyanine 540 suggest that the dye, with its fixed negative charge, does not cross the neuronal membrane rapidly (B. M. Salzberg, personal communication).

The results presented here may prove useful for those investigations in which monitoring membrane potentials from a population of muscle fibres is required. They complement information obtained with other dyes<sup>5,6</sup> that monitor membrane potential changes in the sarcoplasmic reticulum. Using Merocyanine 540 and Nile Blue A it is now possible to study separately the potential changes across different membrane systems, some of them inaccessible to microelectrodes and intimately involved in the chain of events of the excitation–contraction coupling in skeletal muscle.

We thank Drs B. M. Salzberg, C. M. Armstrong and M. Cahalan for their comments and suggestions on the manuscript. This work was supported by a grant-in-aid from the Muscular Dystrophy Association of America and the Oficina Técnica de Desarrollo Científico of the University of Chile.

## Effect of temperature and pressure on polymerisation equilibrium of neuronal microtubules

MICROTUBULES are fibres, sometimes many micrometres long, present in all eukaryotic cells, formed by the reversible polymerisation of the protein tubulin. These fibres not only have a structural role, but the process of their assembly and disassembly itself controls several cell functions<sup>1</sup>.

We have investigated the effect of temperature and pressure on this process, and show here that their main influence is on the nucleation equilibrium. With this reanalysis of the data, we make some speculations about some of the molecular processes involved.

No detailed molecular model of the reaction is yet available. Depolymerisation, either by adding calcium or cooling to 4 °C, gives a mixture of a 6S protomer (an  $\alpha\beta$ -dimer of total molecular weight 120,000) and a 36S fraction<sup>2</sup>. This 36S protein is a ring or spiral-like structure of  $\sim 23$  protomers, formed in the presence of the 'τ factor'<sup>3</sup>. Copolymerisation of the 6S and 36S fractions leads to the formation of the microtubules.

Until now equilibrium data for the polymerisation have always been analysed in terms of a propagation equilibrium constant, the reciprocal of the critical concentration. In this way Gaskin *et al.*<sup>4</sup> were able to calculate an apparent reaction enthalpy change for propagation of 21 kcalorie mol<sup>-1</sup>, for temperatures < 25 °C, and the corresponding entropy change of 100 EU. At temperatures between 25 and 37 °C the enthalpy change is essentially zero and the entropy change is ~ 10 EU. The effect of pressure has been analysed<sup>5,6</sup>, using the same assumption, at a single protein concentration. It was found that propagation is accompanied with a volume change of 90 ml mol<sup>-1</sup>.

Essential in all these analyses is the assumption that the protomer concentration remains constant from the critical protein concentration on. This is, however, true only in the limits of very high protein concentration, and not in the range usually studied, as shown by ultracentrifugation<sup>7</sup> and by the data of Fig. 1. Here the change of turbidity at 350 nm is plotted as a function of total protein concentration, at different temperatures. The reversibility was checked in separate experiments. The data clearly show that the protomer concentration is not constant, both because the concentration range studied is rather low, and because an additional equilibrium, the nucleation equilibrium, determines the protomer distribution.

The effect of pressure was analysed at 35 and 15 °C, by measuring light scattered at 90 °C, as described earlier<sup>8</sup>. Experiments were done in conditions of complete reversibility which was maintained up to 1,000 atm at 35 °C. The increase in pH of the MES buffer with increasing pressure was very small and so was neglected. The results are given in Fig. 2, which shows that the nucleation equilibrium is again important. The results of Fig. 2 also show that there is a link between the effect of pressure and temperature. At 15 °C, 500 atm is sufficient to produce complete dissociation, while at 35 °C only a small pressure effect is observed. A link between the effect of pressure and temperature is also found for a number of other proteins, such as flagellin<sup>9</sup> and glutamate dehydrogenase<sup>10</sup>, although the effect is much less pronounced for these. O'Connor *et al.*<sup>11</sup> did not find a measurable pressure effect at 37 °C and 700 atm, and

**Fig. 1** The effect of temperature on the turbidity of microtubules at different total concentrations. Rat brain tubulin was prepared according to Shelanski<sup>16</sup>. After the third polymerisation cycle it was dialysed against MES buffer at pH 6.4, with the following composition: 50 mM MES, 70 mM KCl, 1 mM EGTA and 0.5 mM MgCl<sub>2</sub>. After dialysis GTP was added up to 1 mM. Protein concentration was determined with the method of Lowry<sup>17</sup>. The quality of the microtubules was checked by electron microscopy.

**Fig. 2** The effect of pressure on light scattering by microtubules at different total concentrations. The same buffer as in Fig. 1 was used. The accuracy of the measurements is much less than in Fig. 1, because all the measurements had to be done on samples from different preparations. For the sake of clarity only a limited number of data are given. The measurements are corrected for window effects and lowering of the incident light intensity as a consequence of turbidity. ○, data at 1 atm at 35 °C; △, 500 atm at 35 °C. ●, ▼, ▲, for 1, 200, 500 atm respectively at 15 °C.

they claim that neurotubules are therefore different from other microtubules on the basis of a different pressure sensitivity, without taking into account the effect of the temperature. At 20 °C, where microtubules of non-neuronal origin are usually studied, neurotubules also show a large pressure dependence.

We have attempted to analyse these data quantitatively in terms of an equilibrium constant for nucleation and propagation. The system behaves completely reversibly in the presence of an excess of GTP, whose role is not, however, clear. The thermodynamic parameters obtained are therefore equilibrium parameters for the polymerisation coupled to GTP-hydrolysis, or activation parameters in the case of an irreversible consumption of GTP and the development of stationary states.

We assume that there is a nucleation step and that growth only occurs at the nuclei or tube ends (see ref. 13). (In fact Dentler *et al.*<sup>14</sup> show that growth occurs only at one end of the tube.) The relationship between  $c_p$ , the number concentration of protomers present in polymers, and  $c_1$  the protomer concentration is then:

$$c_p = Ac_1/(1-Kc_1)^2 \quad (1)$$

Here  $K$  is the propagation equilibrium constant, which is assumed to be independent of the degree of polymerisation ( $i$ ) for  $i > n$ , where  $n$  is the number of protomers involved in the nucleus.  $AK^{n-1}$  gives the nucleation equilibrium constant, with  $A$  a dimensionless equilibrium constant that corresponds to the destabilisation of the nucleus with respect to an  $n$ -mer in the middle of the polymer. This equation does not necessarily give the right distribution for the intermediate stages between protomers and nucleus. The contribution of these terms is, however, negligible. Equation (1) can then be rearranged

$$(c_1/c_p)^{1/2} = A^{-1/2}(1-Kc_1) \quad (2)$$

and the data are analysed accordingly.

Gaskin *et al.*<sup>4</sup> showed that light (wavelength  $\lambda$ ) scattered by microtubule solutions is nearly independent of the length of the tubules which can be proved directly by sonication of the

tubules, and also by the dependence of the scattering on  $\lambda^{-3}$ . We found that this dependence is maintained down to 8 °C, while at 4 °C a  $\lambda^{-4}$  dependence was found. This indicates that light scattering is indeed a good means of measuring  $c_p$  even at the lowest degrees of polymerisation.

Assuming that the steepest slope in Fig. 1 corresponds to the specific turbidity of the polymers, as checked by ultracentrifugation,  $c_1$  and  $c_p$  can easily be calculated. As in previous treatments<sup>4,6</sup>  $c_1$  is defined as the total number concentration of protomers, regardless of their distribution between 6S and 36S forms. Figure 3 shows that equation (2) fits the data well. The parameters  $A$  and  $K$  can be calculated simply and their logarithm plotted against  $T^{-1}$ , as shown in Fig. 4a. These data show that in the range of 25–10 °C the enthalpy and entropy changes are much larger for the parameter  $A$  than for the propagation equilibrium constant. In this case the theory predicts that at low temperatures, where the nucleus is destabilised, a small number of very long tubules will be present. This is confirmed both by the inverse third power dependence on the wavelength and by electron microscopy.

In the range of 35–30 °C smaller values for the thermodynamic parameters are found (see ref. 4). This change may be caused by a conformational transition of the protein, although the presence of a small amount of inactive protomer would cause a deviation in the low values of  $(c_1/c_p)^{1/2}$ .

The influence of pressure can be analysed similarly. Because of the limited accuracy of the measurements, however, a whole range of parameters can give a good fit to the data of Fig. 2. The logarithm of the extremes of these values are plotted against  $P$  in Fig. 4b. Although it is not possible to calculate accurate values for the volume changes, it is clear that the pressure sensitivity is larger at 15 °C, and this is more pronounced for the parameter  $A$  than for the propagation equilibrium constant. This may again be explained by a conformational transition between the two temperature ranges.

These results give some indication of the type of bonds involved. The small pressure dependence at temperatures between 25 and 35 °C is probably the consequence of the dominance of hydrophobic interactions, which are usually associated with small volume changes; large volume changes are generally found in ionic interactions<sup>15</sup>. It is thus possible that lowering the temperature decreases the stability of hydrophobic interactions, and changes the conformation which leads to the exposure of charged groups. Independent evidence for this conformational change comes from the large difference in affinity of colchicine for the protomers, at 4 and 35 °C and from circular dichroism studies<sup>18</sup>. This conformational change seems

Fig. 3 Linearisation of the data of Fig. 1 using equation (2). ▼, -10 °C; □, -15 °C; ■, -20 °C; ○, -25 °C; ▲, -30 °C and ●, -35 °C.

Fig. 4 a, Temperature dependence of the equilibrium constants. (1) For the propagation equilibrium constant  $K$  a value of  $\Delta H = 10$  kcalorie  $\text{mol}^{-1}$  and  $\Delta S = 34$  EU was found in the temperature range 25–10 °C. In the temperature range 35–30 °C, the values are halved. (2) For the nucleation parameter  $A$  the following values were obtained:  $\Delta H = 25$  kcalorie  $\text{mol}^{-1}$  and  $\Delta S = 80$  EU in the range 25–10 °C. At higher temperatures the values are about one-fifth of these. b, Pressure dependence of the equilibrium constants. Log  $K$  was plotted against  $P$  at 35 °C (1) and at 15 °C (2). The associated volume changes are 26 and 50  $\text{ml mol}^{-1}$  respectively. Log  $A$  was plotted against  $P$  at 35 °C (3) and at 15 °C (4). The estimated volume changes are 12 and 120  $\text{ml mol}^{-1}$  respectively.

to have its largest influence on the process of nucleation. It remains to be investigated whether other factors also exert their main influence on the nucleation equilibrium. This seems attractive, as a number of *in vivo* observations may be explained by the control of the nucleation process and the stability of the tube ends.

## Androgen-sensitive midbrain sites and visual attention in chicks

NEUROANATOMICAL networks within the preoptic-hypothalamic continuum of the avian brain contain neurones that are androgen-sensitive<sup>1</sup> and involved in the control of precocial copulation<sup>2</sup>. In autoradiographic studies of the male chick brain, one of us (C.C.M.) has found midbrain structures, nucleus intercollicularis (ICo) and nucleus isthmo-opticus (IO) that concentrate radioactive testosterone or its metabolites. Neither of these structures has been implicated in the expression of sexual behaviour. Rather, there is evidence that both are involved in visual responsiveness that is not specifically associated with sexual behaviour. We wish to present the autoradiographic findings and relate them to the existing evidence of the functions of these two nuclei and testosterone in visual attention.

The technique has been described in detail elsewhere<sup>3</sup>. Male chicks were assigned to either an isolation ( $n=3$ ) or isolation and testosterone primer ( $n=3$ ) group. In the latter chicks 20 mg of testosterone propionate was subcutaneously injected on day 6 after hatching. On either day 15, 16 or 17 after hatching, male chicks received 200  $\mu$ Ci (1.3  $\mu$ g) of 1,2-<sup>3</sup>H-testosterone subcutaneously. Animals were decapitated 2 h after injection, their brains were removed, frozen in powdered CO<sub>2</sub>, sectioned in a microtome-cryostat, and the sections were mounted on slides precoated with photographic emulsion. After exposure for 121-161 d, the autoradiograms were developed and stained with thionin. Quantitative analyses of reduced silver grains beneath neurones were conducted by reviewing 50 cell bodies for each neuroanatomical area surveyed in every animal. Results, which will be published in full elsewhere, showed high mean concentrations for silver grains in neurones of the ICo, both in isolated ( $\bar{x}=13.77 \pm 1.26$  s.e.m.) and isolated and testosterone primed ( $\bar{x}=10.09 \pm 1.07$  s.e.m.) subjects, which appear to be even greater than in the nucleus praepopticus paraventricularis magnocellularis ( $\bar{x}=9.36 \pm 0.82$  s.e.m. isolates;  $\bar{x}=6.68 \pm 0.73$  s.e.m., isolates and testosterone primer). This medial preoptic nucleus is known to contain androgen-sensitive neurones and to be involved in the development of precocial copulation in male chicks<sup>1,2</sup>. In some animals autoradiograms extend into the posterior midbrain where the concentration of silver grains indicated a relatively high uptake of radioactive testosterone in the IO. Qualitative surveys for other midbrain areas, such as the tectum, nucleus mesencephalicus lateralis pars dorsalis, and central mesencephalic grey, did not show similar patterns of testosterone uptake. Control subjects receiving cold testosterone averaged no more than 1.80 grains per neurone in any brain region, and slides fogged with light before exposure showed no fading of the latent image. Although autoradiographic data from the songbird *Fringilla coelebs*<sup>4</sup> also indicate that ICo is androgen sensitive, no other report has established that the IO contains androgen-sensitive cells.

Andrew reviewed studies of the ICo<sup>5</sup>. He points out that electrical stimulation of this nucleus induces calling and

alerting in chicks while lesions produce muteness and impaired visual targetting behaviour, including loss of scanning behaviour in an open field, and a reduction of inspection and absence of exploratory pecking of moving targets and 'novel objects'. Andrew and de Lanerolle<sup>6</sup> have summarised these effects by saying that the lesioned chick "... ceases to treat visual (and probably other) stimuli as if they were conspicuous or highly valent". In previous studies Andrew<sup>7</sup> found that testosterone injections in chicks produced, in addition to precocial copulation, an increase in persistence in attending to objects. His subsequent work<sup>8</sup> has established that testosterone increases the probability of sustained visual attention to a particular stimulus or type of stimulus in competition with other distracting stimulation. In fact the effect seems to be the reverse of that produced by lesions of ICo so that the injected chick calls and orients to stimuli as if they were unusually conspicuous or valent. The facilitation of calling associated with the uptake of hormone by ICo may be part of the general attentional syndrome rather than the primary effect proposed by Zigmond *et al.*<sup>4</sup>, for Andrew<sup>10</sup> has made the point that all chick calls may belong to a general set of attention behaviours expressing an attentional state. We suggest, therefore, that the ICo is part of a neural system for facilitating orientation behaviour. Such a system has been suggested by Salzen and Parker<sup>11</sup> to arise in the archistriatum which is responsible for facilitating the subtelencephalic systems that execute head and body orientations to objects in response to decisional commands from other striatal regions. Certainly ICo receives fibres from the archistriatum through the tractus occipitomesencephalicus. Andrew<sup>12</sup> has also outlined an archistriatal source of descending influence on the ICo through a diencephalic periventricular and central mesencephalic grey system and has proposed that the intercollicular area modulates the efferent flow from tectal systems for positive targetting, and/or enhances the tectal processes themselves. Thus, much of the chick lesion data can be understood in terms of tectal and brainstem systems for head and body orientation for visual fixation which are facilitated through an archistriatal-intercollicular pathway. The non-sexual behavioural effects of testosterone can then be seen as the results of selective facilitation of these tectal orientation systems, and the uptake of this hormone by the ICo could account for these effects.

The occurrence of a similar uptake of testosterone by the IO is interesting because this nucleus projects solely to the retina, and according to the electrophysiological studies of Miles<sup>13</sup>, activity in this nucleus effectively enhances retinal responses to both large and small stimuli by removing inhibitory surrounds and facilitating the excitatory centres of retinal ganglion cell response fields. Miles has suggested that the centrifugal system provides a rapid local transient dark-adaptation system for improved detection in shadowed areas during visual search. This is consistent with the findings of Rogers and Miles<sup>14</sup>, that lesions of the IO impaired the discrimination of food from sand grains in the darker areas of a variegated brightness field. These birds also pecked at food and non-food objects in an apparently indiscriminate and exploratory fashion with closed bill. They were also poorer at responding to a novel object introduced into the posterior visual field while feeding. These observations suggest an impairment of object recognition or target distinctiveness, permitting less selectivity within the attentional system and resulting in more general behavioural effects than would the loss of a local dark-adaptation system. We suggest, therefore, that androgen uptake in the IO increases target distinctiveness and so contributes to the observed enhanced visual orienting and attentional behaviour of the hormone-injected chick. The interest in both these midbrain nuclei being androgen sensitive is that they are parts of neural systems that could operate in orientation behaviour to specific focal visual stimulation

and so provide a neural basis for the perceptual and "non-sexual" behavioural effects of testosterone.

## Interspecific variation in products of animal mitochondrial protein synthesis

THE DNA of mammalian mitochondria (mtDNA) exists as a single class of circular molecules about 5  $\mu$ m long<sup>1,2</sup>, and codes for two ribosomal RNA species and several transfer (4S) RNA components<sup>3,4</sup>. The function of the remaining 80% of the genome is unknown, although it has been suggested that the residual coding capacity provides messenger RNA (mRNA) which is translated exclusively by mitochondrial ribosomes producing about ten protein components which are associated with the inner mitochondrial membrane. Not all protein synthesis in mitochondria, however, may be directed by mtDNA—some could represent translation products of nuclear-coded messages imported into the organelles<sup>5,6</sup>. We report here on differences between electrophoretic profiles of proteins synthesised in mitochondria of a wider variety of animal cell lines. Evidence is also presented suggesting that mtDNA has a role in determining the pattern of proteins observed.

It is widely assumed that the proteins synthesised in cells treated with inhibitors of cytoplasmic protein synthesis are of mitochondrial origin. We have shown previously that about ten major proteins are selectively labelled by culturing cells in the presence of <sup>35</sup>S-methionine and the inhibitor emetine<sup>7,8</sup>. The labelled proteins copurified with mitochondria on cell fractionation and their synthesis was blocked by chloramphenicol, a known inhibitor of mitochondrial protein synthesis. Our preliminary investigations demonstrated that the patterns for human and mouse mitochondrially-synthesised proteins, as resolved by electrophoresis in sodium dodecyl sulphate (SDS)-polyacrylamide gels, were different<sup>7</sup>.

A typical profile of the proteins detected by the technique of selective labelling followed by electrophoresis and autoradiography is illustrated in Fig. 1. This pattern obtained with human cells shows about eight predominant bands which were labelled in the presence of the cytoplasmic protein synthesis inhibitor emetine. The approxi-

mate molecular weights were determined by calibrating the gel with marker proteins of known size.

Using cells from various species, we have observed some differences in the profiles for animals more closely related than humans and mice. Thus, among the rodents (Fig. 2), profiles from rat and mouse cell lines were similar but showed small, reproducible differences from those of both hamster and rabbit. With other animal cells, there were variations in the electrophoretic mobilities of most labelled bands (Fig. 3). The total number of bands (7-11) and their molecular weight range (10,000-50,000), however, were fairly constant. Some of the components detected were common to profiles of most species examined—for example, the band of apparent molecular weight 45,000—whereas others varied considerably so that homologies were difficult to establish. The patterns for man, chimpanzee and the African green monkey showed an overall similarity, but differed somewhat from those of marmoset (a New World monkey). In all species studied, no more than about 3  $\mu$ m DNA would be required to code for these mitochondrially synthesised proteins (based on apparent molecular weight determinations). This is within the coding capacity of animal mtDNA. Bands of molecular weight above 50,000 were generally not sensitive to chloramphenicol. Furthermore, experiments with human cells demonstrated that

**Fig. 1** Electrophoretic profile of proteins synthesised *in vivo* by mitochondria of human cells. HeLa cells, labelled with <sup>35</sup>S-methionine for 4 h in presence of 50  $\mu$ g ml<sup>-1</sup> emetine, were solubilised in buffer containing SDS and 2-mercaptoethanol. Samples were electrophoresed on a 12% (w/v) polyacrylamide slab gel and labelled polypeptides detected subsequently by autoradiography. Details of procedures for incorporation, electrophoresis and autoradiography have been described previously<sup>7</sup>. Marker proteins (*a*, bovine serum albumin; *b*, bovine glutamate dehydrogenase; *c*, rabbit lactate dehydrogenase; *d*, equine cytochrome *c*) were run on the same slab gel to provide a calibration for molecular weight determination. Labelled material of molecular weight about 42,000 consists of two closely spaced bands. Additional components which are sometimes detected in the system are marked by dashed lines. Addition of phenylmethylsulphonylfluoride (1 mM) before solubilisation was found not to affect band pattern observed. Errors in molecular weight assignment could result from differences in hydrophobicity between marker and mitochondrial proteins. O, Origin; F, front.

**Fig. 2** Electrophoretic profile of mitochondrially-made proteins from various rodent cell lines. R, Rabbit; Rt, rat; M, mouse; H, Chinese hamster. Cells were labelled with  $^{35}\text{S}$ -methionine for 4 h in presence of  $50 \mu\text{g ml}^{-1}$  emetine, before solubilisation, electrophoresis and autoradiography. O, Origin; F, front.

they could be eliminated by purification of mitochondria before electrophoresis. These bands of higher molecular weight may represent the residual products of cytoplasmic protein synthesis.

We have also examined the spectrum of proteins synthesised by mitochondria of human-mouse somatic cell hybrids. Profiles obtained with 17 independently-derived hybrid cell lines were similar to those of mouse parental cell lines. No human components, which could be distinguished from the mitochondrially-synthesised proteins of the mouse, were detected. Similar observations on four such hybrid cell lines have been reported previously<sup>7</sup>. Karyotypic analysis indicated that every human chromosome (with the possible exception of the Y) was represented in at least one of the hybrids examined (ref. 9 and E. Solomon *et al.*, unpublished). Since human mtDNA seems to be eliminated from man-mouse hybrids in which the mouse parent is an established cell line<sup>10,11</sup>, the detection of only mouse mitochondrially-synthesised proteins is consistent with the suggestion that the genes for at least some of the human proteins can be assigned to mtDNA. The absence of human mitochondrial proteins would thus reflect the loss of human mtDNA. Other interpretations based on the possible existence of dominant modification

**Fig. 3** An electrophoretic comparison of proteins synthesised by mitochondria of various animal cell lines. a, Man; b, chimpanzee; c, marmoset; d, African green monkey; e, cat; f, mouse; g, marsupial mouse (*Sminthopsis*); h, chicken; i, *Xenopus laevis*; j, *Drosophila melanogaster*. Cell lines were labelled for 4 h in presence of  $100 \mu\text{g ml}^{-1}$  emetine. Incorporations were at  $37^\circ\text{C}$  except for *Xenopus* and *Drosophila* cells ( $25^\circ\text{C}$ ). Incorporation medium for *Drosophila* embryonic cells was D22 medium<sup>17</sup>, in which yeastolate and lactalbumin hydrolysate were replaced by  $67 \mu\text{M}$  L-amino acids minus methionine. Further supplements were 0.5% (v/v) foetal calf serum and 9.5% (v/v) dialysed serum<sup>7</sup>. Details of cell lines used may be obtained from the authors on request. O, Origin; F, front.

mechanisms controlled by genes on mouse chromosomes, or on the selective repression of human nuclear genes for these proteins, can be envisaged, but require further, as yet untested, assumptions.

The observed variation in the profiles of mitochondrially-synthesised proteins in the several species examined therefore may reflect divergence in the corresponding structural genes in the mitochondrial genome. In this context, animal mitochondria have been shown to synthesise about eight species of poly(A)-containing RNA, which seem to represent messages transcribed from mtDNA. Not only does this number of messages correspond roughly to the number of proteins in this study, but there is interspecies variation in the sizes of these RNA components<sup>12,13</sup>. Furthermore, extensive divergence in the nucleotide sequences of mtDNA from various animal species has been reported<sup>14-16</sup>.

Our electrophoretic analysis indicates substantial variation in the size and/or composition of mitochondrially-synthesised proteins of different animal cell lines and a possible role of postsynthetic modification (for example, glycosylation, cleavage or aggregation) should be considered. Nevertheless, the reproducibility and stability of the profiles, together with information from the genetic analysis with human-mouse hybrid cells, suggests a lack of conservation of the proteins synthesised in animal mitochondria. Caution should therefore be exercised in extrapolations concerning their nature and function based on information from the lower eukaryotes—for example, yeast.

## Ribosome metabolism in temperature-sensitive mutant of BHK cells

CELLULAR content of ribosomes is coordinately regulated with cell growth<sup>1</sup>, either at the level of ribosome processing or ribosomal degradation. The two ribosomal subunits in growing mammalian cells are synthesised in equimolar amounts as cleavage products of a common precursor<sup>2</sup>; and it also seems that all the components of ribosomes are degraded as a unit<sup>3</sup>. The regulatory mechanism of ribosome metabolism in mammalian cells, however, remains unclear.

We have studied ribosome metabolism in the temperature-sensitive mutant, *ts422E*, derived from BHK cells, that are defective in the processing of large ribosomal subunits (28S rRNA) at the non-permissive temperature (39 °C)<sup>4,5</sup>. Synthesis of the small ribosomal subunits (18S rRNA), on the other hand, is uninhibited. The resulting transient imbalance in the ribosomal subunits at 39 °C seems to be corrected by a higher rate of degradation of the 18S rRNA in the cytoplasm. As the rate of accumulation of poly(A)-containing RNA in the polyribosomes, and the rate of protein synthesis in *ts422E* remain unchanged at 39 °C, it seems that the instability of a fraction of 18S rRNA in the mutant cells arises from their lack of participation in protein synthesis.

When shifted to the non-permissive temperature, the *ts422E* cells show a transient increase in cell number followed by an actual decline in viable cells compared with those cultures remaining at the permissive temperature (Fig. 2a, inset). Although the total ribosome content in *ts422E* cells show equimolar amounts of 28S and 18S rRNA after 25 h at 39 °C, the amounts of newly synthesised 28S rRNA at the non-permissive temperature is markedly reduced compared with cells at the permissive temperature (Fig. 1a and c). When the radioactivity in rRNA synthesised at 39 °C is chased with excess unlabelled uridine and cytidine for 42.5 h at 39 °C, however, the specific activities of 28S and 18S rRNA approach that of *ts422E* cells maintained at the permissive temperature (Fig. 1b and d). Therefore, the 18S rRNA accumulated in *ts422E* soon after shift up to 39 °C must be balanced by its faster rate of degradation. This possibility was tested directly by comparing the rate of decay of 18S and 28S rRNA in *ts422E* cells at the permissive and non-permissive temperatures.

The radioactivity in 18S rRNA from *ts422E* cells labelled

**Fig. 1** RNA synthesis in *ts422E* at 39 °C. Cultures of *ts422E* cells were maintained at 33 °C in Dulbecco-Vogt modified Eagle's Medium (DME) supplemented with 10% calf serum. Eight 100-mm culture dishes were shifted to 39 °C and labelled between 15 and 17 h with 10  $\mu$ Ci ml<sup>-1</sup> <sup>3</sup>H-uridine (specific activity 25 Ci mmol<sup>-1</sup>). After <sup>3</sup>H-uridine incubation, labelled RNA was chased by substituting the medium with fresh DME supplemented with 5 mM uridine plus 2.5 mM cytidine at 39 °C for 8 h (a) and 42.5 h (b). Control cultures maintained at the permissive temperature were pulse-labelled and chased as above (c and d). The chase was terminated by washing cells with chilled (2–4 °C) balanced salt solution (Earle's). Cells were detached by trypsin treatment, washed twice with cold Earle's solution and disrupted by Dounce homogenisation in RSB buffer (0.01 M Tris-HCl, pH 7.6, 0.01 M NaCl, 1.5 mM MgCl<sub>2</sub>). Nuclei and large cell particulates were eliminated by successive centrifugations at 1,000g for 3 min and 12,000g for 10 min, and the ribosomes were precipitated from the postmitochondrial supernatant with the addition of 70 mM MgCl<sub>2</sub> for 45 min at 4 °C (ref. 10). Ribosomes were pelleted by centrifugation at 12,000g for 10 min and the pellets resuspended in 5 ml NETS buffer (0.01 M Tris-HCl, pH 9.0, 0.01 M EDTA, 0.1 M NaCl, 0.2% SDS) and the RNA extracted with equal volume of phenol-chloroform-isoamyl alcohol (25:24:1) until no visible interphase was present. RNA was precipitated from the aqueous phase with two volumes of ethanol, collected by centrifugation and resolved by centrifugation in 15–30% sucrose gradients in NETS buffer. Samples were centrifuged in a Spinco SW27 rotor at 23 °C and 23,000 r.p.m. for 16 h. Gradients were eluted through a recording spectrophotometer, and samples were prepared for the determination of acid-insoluble radioactivity and counted in a liquid scintillation counter as described<sup>10</sup>. a, 8-h chase at 39 °C; b, 42.5-h chase at 39 °C; c, 8-h chase at 33 °C; d, 42.5-h chase at 33 °C. —,  $A_{260}$ ; x, c.p.m.

with <sup>3</sup>H-uridine between 15 and 17 h at 39 °C, decays at a faster rate than the radioactivity in 28S rRNA when chased in a growth medium containing excess unlabelled uridine and cytidine at 39 °C. During a similar chase period of 40–50 h there is little difference in the relative rates of decay of 18S and 28S rRNA of the mutant cells that remained at the permissive temperature (Fig. 2a). The enhanced decay of 18S rRNA in the temperature-sensitive mutants seems to be a transient adjustment to the non-permissive condition. As shown in Fig. 2b, the faster decay rate of <sup>3</sup>H-methylmethionine pulse-labelled 18S rRNA at 39 °C, on being chased with excess unlabelled methionine at 33 °C, approaches the rate of rRNA degradation in the cells that were labelled and chased at the permissive temperature. This apparent recovery from the faster rate of

**Fig. 2** Rates of decay of 18S and 28S rRNA. *a*, *ts422E* cells maintained at 33 °C were shifted to 39 °C and pulse labelled with  $^3\text{H}$ -uridine between 15 and 17 h as described in Fig. 1. Control cultures maintained at 33 °C were similarly pulse labelled for 2 h. After pulse label, the growth medium was replaced with DME containing excess unlabelled uridine and cytidine, and cells collected at indicated times after the chase. rRNA from cells after various chase periods was fractionated, and the 18S and 28S rRNA resolved on NETS-sucrose gradients as in Fig. 1. Specific activities were determined by integrating the areas under the  $A_{260}$  profiles of 18S and 28S rRNA, and adding the radioactivities of the two rRNA species. The change in the relative specific activities of rRNAs for cultures kept at 33 °C and those at 39 °C are shown: ■, 33 °C; ●, 39 °C. Inset shows changes in cell number of the cultures maintained at 33 °C and 39 °C. *b*, Cultures of *ts422E* cells were shifted to 39 °C in normal growth medium and pulse labelled with 25  $\mu\text{Ci ml}^{-1}$   $^3\text{H}$ -methylmethionine (specific activity 300 mCi mmol $^{-1}$ ) for 30 min (between 16.5 and 17 h at 39 °C) in DME lacking methionine but containing 10% calf serum. The medium was then replaced with a chase medium (DME containing 8 mM methionine plus 10% calf serum), and labelled cells restored to the permissive temperature and allowed to grow at 33 °C. Control samples *ts422E* cells maintained at 33 °C were similarly pulse labelled with  $^3\text{H}$ -methylmethionine and also chased at 33 °C. At indicated times after the beginning of the chase period, samples from cells pulse labelled at 39 and 33 °C were removed. Cells collected and rRNA purified and resolved on sucrose gradients as in Fig. 1. Relative rates of decay in the specific activities of rRNAs were estimated by integrating the areas under the  $A_{260}$  profile and the radioactivity under the 28S and 18S rRNA, as in *a*. *c*, Ten 100-mm culture dishes of *ts422E* cells were labelled with  $^{14}\text{C}$ -methylmethionine (5  $\mu\text{Ci ml}^{-1}$ , specific activity 50 mCi mmol $^{-1}$ ) for 24 h at 33 °C in DME plus 10% calf serum. After steady-state labelling with  $^{14}\text{C}$ -methionine, the medium was replaced with fresh DME and the cells grown for the first 16 h at 33 °C and then shifted to the non-permissive temperature (39 °C) for another 16 h. Cells were then pulse labelled with 20  $\mu\text{Ci ml}^{-1}$   $^3\text{H}$ -methylmethionine (specific activity 230 mCi mmol $^{-1}$ ) for 1.5 h at 39 °C and chased with fresh DME supplemented with 10% calf serum and 8 mM L-methionine. Samples were taken at indicated times after the beginning of chase at 39 °C; cells were collected and rRNAs prepared and resolved on sucrose gradients as above. The radioactivity in each rRNA species was normalised to the  $A_{260}$  of total cell DNA prepared according to Scott *et al.*<sup>11</sup>. The illustration compares the relative rate of decay of specific activities in rRNAs labelled before ( $^{14}\text{C}$ ) and after ( $^3\text{H}$ ) the shift up to non-permissive temperature.

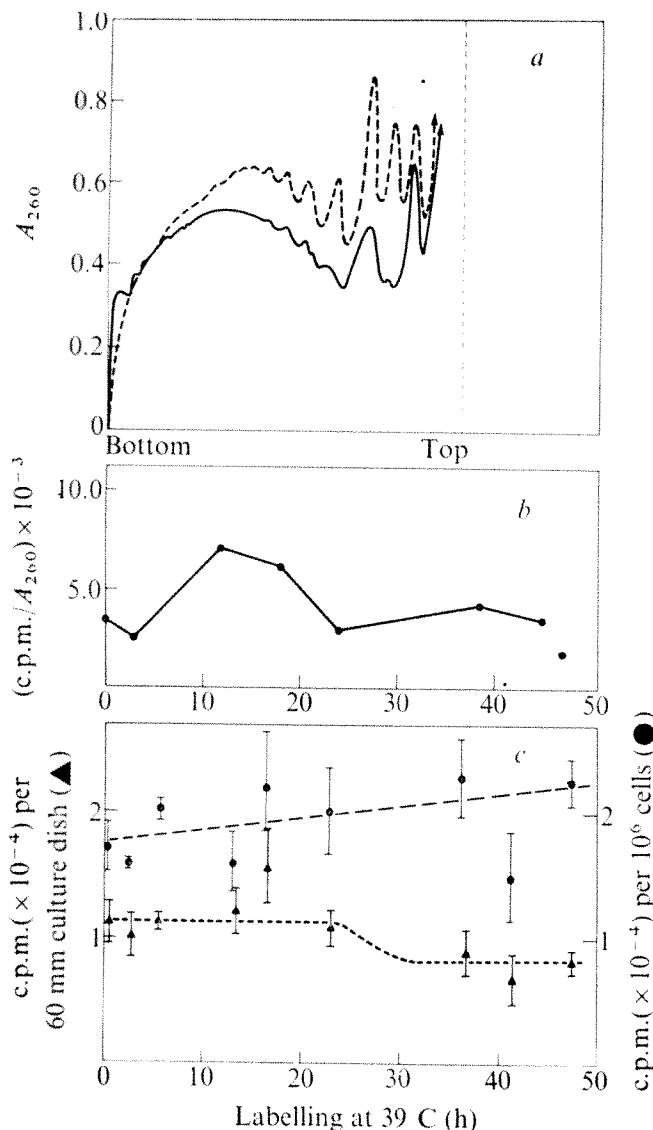

decay of rRNA at 39 °C is complete within about 24 h of restoration of the permissive growth conditions (Fig. 2b). Since the experiments so far have shown an accelerated rate of decay of 18S rRNA after a shift up to 39 °C, it is of interest to examine whether the 18S rRNA synthesised at the non-permissive temperature is preferentially degraded. Although both the existing 18S rRNA ( $^{14}\text{C}$ -labelled) synthesised at the permissive temperature and that synthesised after the shift up to 39 °C ( $^3\text{H}$ -labelled) are degraded at a faster rate than the corresponding 28S rRNA, the rate of decay of 18S rRNA made after the shift to 39 °C was

**Table 1** Appearance of 18S rRNA in cytoplasm of BHK and 422E cells

Time	New		Polyribosomal Old		Ratio		New		Native subunits Old		Ratio	
	$^3\text{H}$ (c.p.m./10 <sup>7</sup> cells)	422E	BHK	422E	BHK	422E	BHK	422E	BHK	422E	BHK	422E
30 min	—	72	—	213	—	0.33	437	508	770	929	0.56	0.83
60 min	395	192	243	220	1.62	0.87	2,052	1,871	886	506	2.31	3.70
90 min	1,085	3,060	381	1,257	2.85	2.43	8,452	2,866	1,256	493	6.73	5.81
24 h	11,189	4,654	2,105	1,370	5.32	3.39	5,080	5,622	763	1,023	6.65	5.50

Proportions of old and new 18S rRNA within polysomal and native subunit fraction of BHK and 422E cells determined by incubating cultures of both types of cells at permissive temperature with 2.5  $\mu\text{Ci ml}^{-1}$   $^{14}\text{C}$ -methylmethionine (specific activity 58 mCi mmol $^{-1}$ ) in complete medium for 24 h. Growth medium then replaced twice within 8 h with fresh DME at 33 °C and cultures transferred to 39 °C. After 17 h at non-permissive temperature, cells pulse labelled with 25  $\mu\text{Ci ml}^{-1}$   $^3\text{H}$ -methylmethionine in DME lacking methionine and samples removed at 30, 60 and 90 min thereafter. Remaining fraction of each of labelled BHK and *ts422E* cultures washed and grown for 24 h in chase medium containing excess (40 times normal concentration in DME) unlabelled methionine. Cells collected, homogenised and postmitochondrial supernatant resolved through 8 ml 5–20% (w/w) sucrose gradient in RSB, layered over a 2-ml cushion 60% sucrose in RSB, and centrifuged in a Spinco SW41 rotor at 36,000 r.p.m. for 3.5 h at 4 °C. Polysomal and native 40S subunit regions collected and RNA phenol extracted as before, purified by oligo-d(T)-cellulose chromatography, and poly(A)-lacking RNA further resolved on 15–30% sucrose-NETS gradients as in Fig. 1. Radioactivity in old ( $^{14}\text{C}$ ) and new ( $^3\text{H}$ ) 18S rRNA from each sample corrected for background and spill, normalised to number of cells in each fraction.

**Fig. 3** Polyribosomal RNA and protein synthesis in *ts422E* at 39 °C. *a*, Cultures *ts422E* cells maintained at 33 °C shifted to 39 °C for 3 h (broken line) and 24 h (solid line). Cells were collected, washed and disrupted by Dounce homogenisation in RSB buffer as described<sup>10</sup>. Postmitochondrial supernatant was prepared by centrifugation at 12,000 *g* for 10 min, and polyribosomes from the supernatant resolved by centrifugation in 15–30% (w/w) sucrose gradient in RSB. Centrifugation was done in a Spinco SW27 rotor at 26,000 r.p.m. for 2.5 h and 4 °C, and the sample eluted through a continuously recording spectrophotometer.  $A_{260}$ ; —, 3 h at 39 °C; - - - - -, 24 h at 39 °C. *b*, Polysomal poly(A)-containing RNA was estimated from cultures labelled for 2 h with <sup>3</sup>H-adenosine (50  $\mu$ Ci ml<sup>-1</sup>, specific activity 40.8 Ci mmol<sup>-1</sup>) before isolating polyribosomes as in *a*. Pooled polyribosomes were extracted twice with phenol-chloroform-isoamyl alcohol (50:50:1) followed by extraction with chloroform-isoamyl alcohol (96:4) and precipitated with two volumes of 95% ethanol.  $A_{260}$  was determined on sample aliquots. Incorporation of adenosine into polysomal poly(A) was measured by incubating samples with T<sub>1</sub> RNase (20 U ml<sup>-1</sup>) and RNase A (20  $\mu$ g ml<sup>-1</sup>) at 37 °C for 20 min in 0.5 M NaCl and 0.01 M Tris-HCl buffer. The mixture was run through an oligo(dT)-cellulose column and washed extensively with the same buffer. The amount bound was determined by eluting poly(A) with 0.1 M Tris, pH 7.4, buffer and determining the c.p.m. in the eluate. ●, c.p.m. in polysomal poly(A)/ $A_{260}$  of polysomal RNA. *c*, Rate of protein synthesis was determined in 60-mm cultures of *ts422E* cells shifted to 39 °C and pulse labelled with 2  $\mu$ Ci ml<sup>-1</sup> <sup>3</sup>H-L-amino acid mixture (NET-250) for 1 h. Each point represents an average of three determinations (vertical bar represents the range of counts in each of the three 60-mm cultures). The first time point was taken soon after the shift from 33 to 39 °C and the subsequent ones at indicated time intervals after transfer to 39 °C. Incorporation was terminated by the addition of 5 ml cold (2–4 °C) balanced salt solution, and cells collected and washed as before. Cells were then lysed and prepared for the determination of acid-insoluble radioactivity as described<sup>10</sup>.

faster than that of the pre-existing 18S rRNA (Fig. 2c).

As shown in Fig. 3a, there is an increase in the amount of free 40S subunits, which presumably represents the excess 18S rRNA not yet utilised in protein synthesis. Since there is no shift towards slower-sedimenting polyribosomes at the non-permissive temperature (Fig. 3a), it is likely that the increased quantity of free 40S subunits in *ts422E* after 24 h at 39 °C represents an inhibition of translational initiation.

The rate of accumulation of poly(A)-containing (poly(A)<sup>+</sup>) pulse-labelled polyribosomal RNA is *ts422E* (Fig. 3b) is not significantly altered after 40 h at the non-permissive temperature. The initial increase in the accumulation of poly(A)<sup>+</sup> polyribosomal RNA may represent an enhanced rate of incorporation in acid-precipitable RNA at 39 °C compared with 33 °C since there is no change in the acid-soluble pool at the two temperatures (A.K., E.B. and W.T.M., unpublished). Thus it seems that there is little change in the rate of messenger RNA (mRNA) processing in the temperature-sensitive mutants at the non-permissive temperature.

The rate of protein synthesis in *ts422E* cells is slightly increased when shifted from 33 to 39 °C (Fig. 3c), an effect similar to that of increased incorporation of acid-precipitable RNA at 39 °C. On a per-culture basis, however, there is a slight decline in the rate of protein synthesis after about 25 h at 39 °C, largely because of the loss in the number of viable mutant cells on prolonged incubation at 39 °C (Figs 3c and 2a, inset).

The fact that pre-existing small ribosomal subunits are degraded at a slower rate at 39 °C than those synthesised after shift up to the non-permissive temperature (Fig. 2c) may suggest that the pre-existing ribosomes, having been used in protein synthesis, are more stable than the nascent ribosomes.

An estimate of the amounts of existing 18S rRNA and the new 18S rRNA synthesised at 39 °C in the polyribosomal and native subunit fractions (Table 1) further suggests that more existing 18S rRNA enters the polyribosomes in *ts422E* cells at the non-permissive temperature than in the wild-type cells within 90 min of equilibration.

During the transition from resting to growing fibroblasts there is a marked increase in the stability of rRNA<sup>6,7</sup>. One of the early events in the re-initiation of cell growth seems to be an increased use of ribosomes<sup>8,9</sup>, indicated by the enhanced rate of protein synthesis. Since the two ribosomal subunits are functionally coupled in mRNA translation, it seems that the stability and thus the control of degradation of ribosomes in mammalian cells depends on their use in protein synthesis.

## Magnitude and significance of NAD turnover in human cell line D98/AH2

In the oxidation-reduction metabolism of a cell the pyridine nucleotide NAD is used catalytically; any NAD that is reduced is reoxidised. But NAD is consumed in certain metabolic reactions in which it serves as a substrate. In eukaryotic cells, the most intriguing of these reactions is the cleavage of NAD to form nicotinamide and a unique polymer, poly adenosine diphosphoribose (poly ADPR) (Fig. 1); the reaction is catalysed by the enzyme poly ADPR synthetase<sup>1-4</sup>. Other well studied reactions involving the destruction of NAD include the cleavage of NAD to form AMP and NMN by bacterial DNA ligases<sup>5,6</sup> and the breakdown of NAD (with the concomitant inactivation of protein synthesis) by diphtheria toxin<sup>7,8</sup>.

What is the magnitude *in vivo* of the reactions which consume NAD? We present here data for D98/AH2, a human cell line derived from HeLa<sup>9</sup> which answers this question and which makes possible calculation of the fraction of NAD biosynthesis that compensates for breakdown and the fraction that expands the NAD pool during growth.

D98/AH2 cells were grown in medium containing <sup>14</sup>C-adenine and <sup>3</sup>H-nicotinic acid, both precursors of NAD, for 6 h and then moved to unlabelled medium. At various times after transfer, intracellular nucleotides were extracted with acid and analysed by paper chromatography. The data obtained from one such experiment are shown in Table 1. These data permit a precise calculation of the breakdown rate of NAD *in vivo* (Table 2). Several experiments of this general type have been performed; all yield values for the *in vivo* half life of NAD of about  $1.0 \pm 0.3$  h for D98/AH2 cells<sup>10</sup>. This value is equivalent to a breakdown rate of  $96,000 \pm 30,000$  per s per cell. Because the generation time of D98/AH2 is 24 h and the NAD pool size is  $5 \times 10^8$  molecules per cell (ref. 11), a net synthesis

Table 1 Relative amount of <sup>14</sup>C-adenine in ATP and NAD pools as a function of time

Time (h)	<sup>14</sup> C-adenine in: NAD pool ( $D_t/D_0$ ) (expressed as a ratio to the radioactivity at $t=0$ )	ATP pool ( $A/A^0$ )
0	1.0	1.0
1	0.87	0.86
3	0.70	0.47
8	0.39	0.24

Four equivalent D98/AH2 cultures ( $\sim 2 \times 10^6$  cells) were grown in 5 ml Falcon flasks for 8 h in F12 medium which contained  $0.2 \mu\text{g ml}^{-1}$  nicotinic acid ( $0.1 \mu\text{g ml}^{-1}$ ,  $5 \times 10^8$  c.p.m.  $\mu\text{mol}^{-1}$ ) and <sup>14</sup>C-adenine ( $0.2 \mu\text{g ml}^{-1}$ ,  $6.6 \times 10^7$  c.p.m.  $\mu\text{mol}^{-1}$ ); cells were then washed and allowed to grow in unlabelled F12 medium which contained nicotinic acid  $0.1 \mu\text{g ml}^{-1}$  and adenosine ( $20 \mu\text{g ml}^{-1}$ ) for the time indicated. Nucleotides were acid-extracted from the cells and analysed by chromatography on DEAE paper as described previously<sup>11</sup>. The total <sup>14</sup>C in the ATP peak and <sup>3</sup>H and <sup>14</sup>C in the NAD peak was calculated for each chromatogram. The <sup>14</sup>C-adenine in the ATP and NAD pools could then be determined, using the <sup>3</sup>H in NAD to normalise to time ( $t$ ) zero. The amount of radioactivity in each pool for the culture collected at  $t=0$  is: <sup>14</sup>C-adenine in ATP, 159,000 c.p.m.; <sup>14</sup>C-adenine in NAD, 21,000 c.p.m.; <sup>3</sup>H-nicotinamide in NAD, 165,000 c.p.m.

rate of only 4,000 molecules per s per cell is needed to maintain the pool size of NAD during growth. Thus, the true rate of NAD biosynthesis is approximately  $10^5$  molecules per s per cell and about 95% of this replaces the NAD that is catabolised, and only 5% maintains the NAD pool size during growth.

We have already studied NAD turnover in enucleated D98/AH2 cells<sup>12</sup>. Cells were grown in <sup>3</sup>H-nicotinic acid, enucleated by cytochalasin treatment and centrifugation<sup>13</sup>, and then incubated in unlabelled medium. The rate of loss of <sup>3</sup>H-NAD was measured by an autoradiographic method developed for pyridine nucleotides<sup>14</sup>. The observed half life of the labelled NAD in enucleated cells was 10 h (ref. 12). Because enucleated cells cannot synthesise NAD<sup>12</sup>, the observed 10 h half life of the label is a direct measure of

Fig. 1 A substrate reaction of NAD: the formation of poly ADPR.

**Table 2** Constants calculated from the experimental data in Table 1

	Adenine in NAD ( $D$ )	Adenine in ATP ( $A$ )
Apparent decay constant, $K$	$3.3 \times 10^{-5} \text{ s}^{-1}$	$5.2 \times 10^{-5} \text{ s}^{-1}$
Apparent half life	5.8 h	3.7 h

True rate of breakdown of NAD,  $R_B$ : 124,000 molecules per s per cell  
 True half life for adenine in NAD,  $\tau$ : 0.78 h  
 $R_B$  was estimated by the equation:

$$\ln D_t/D_0 = -\frac{R_B t}{n_D} + \frac{(R_u + R_B)\{1 - \exp[-(K_A - K_D)t]\}}{(K_A - K_D)}$$

where  $D_t$ ,  $D_0$  are the radioactivity of adenine in the NAD pool at times  $t$  and 0 respectively, and  $K_A$  and  $K_D$  are the decay constants above,  $n_D$  is the pool size of NAD (no. of molecules per cell),  $R_u$  the number of NAD molecules synthesised to increase NAD pool size during growth. The quantity  $(R_u + R_B)$  therefore represents the total rate of NAD synthesis. A derivation of this equation with a complete kinetic analysis of this and similar data is represented elsewhere<sup>10</sup>.

$$\tau = \frac{0.693 n_D}{R_B}$$

the rate of breakdown of NAD. As described above, NAD has a 1 h half life in nucleated cells. Together, these observations strongly indicate that NAD breakdown occurs primarily in the nucleus, although other more complex possibilities cannot be rigorously excluded.

The picture begins to emerge of the nucleus as an organelle in which NAD is actively synthesised and broken down. It has been known for many years that NAD pyrophosphorylase, one of the key NAD biosynthetic enzymes, is located within the nucleus<sup>15</sup>. Indeed, this enzyme is used as the characteristic marker enzyme of chromatin<sup>19</sup>. The data reported here, which indicate that most NAD biosynthesis compensates for NAD breakdown in the nucleus provide a rationale for the well established location of this NAD biosynthetic enzyme.

In isolated nuclei, poly ADPR synthetase is the major enzyme causing NAD breakdown<sup>3,4</sup>. Although direct and conclusive evidence is not available, we suggest that this also holds true in the intact cell. Several features of the reaction catalysed by the synthetase suggest that the enzyme may be involved in nuclear function. The enzyme requires DNA and histones for activity<sup>17</sup>. The product of the reaction, poly ADPR, which incidentally, is both polynucleotide and polysaccharide, has been reported to be covalently bound to histone F1 (ref. 18). The synthetase has been found in all types of eukaryotic cells, from the slime mould *Physarum*<sup>19</sup> to human tissue culture cells; this is consistent with a vital (and therefore evolutionarily conserved) role for the enzyme in the eukaryotic nucleus.

Our measurements indicate a surprisingly high rate of NAD breakdown; during one cell cycle, for example, there is twice as much adenine leaving NAD as is being incorporated into DNA. If poly ADPR synthesis were indeed responsible for a substantial fraction of NAD breakdown, then the amount of poly ADPR synthesised in one cell cycle would be of the same order of magnitude as the amount of DNA synthesised. A high steady-state level of poly ADPR, however, would not necessarily accumulate if breakdown were rapid. Indeed, two enzymes able to degrade poly ADPR have been isolated from mammalian nuclei<sup>20,21</sup>.

The existence of a cellular NAD turnover cycle was first proposed by Gholson in 1966 (ref. 22). He argued that such a cycle "... had an important but as yet unknown function ... in cellular metabolism". This statement still applies; it seems likely that in eukaryotic cells, NAD has some other major function in addition to the classical cytoplasmic role in oxidation and reduction (which utilises

the nicotinamide moiety). Our results indicate that most NAD is synthesised to be consumed in a still poorly understood nuclear NAD metabolism, in which the non-nicotinamide (ADPR) part of the NAD molecule may have the major role.

## Translation of oncogenic virus RNA in *Xenopus laevis* oocytes

OOCYTE injection as developed by Gurdon *et al.*<sup>1-3</sup> is efficient and reliable for the assay of faithful translation of heterologous messenger RNA<sup>2-6</sup>. But, working in collaboration with Gurdon<sup>7</sup>, we found that oncogenic viral RNA was not translated to a detectable extent in oocytes. Only in a cell-free system derived from *Escherichia coli* could we translate viral RNA into distinct polypeptides in the molecular weight range of the viral group-specific proteins<sup>8</sup>. Recently we achieved translation of Rauscher leukaemia virus (RLV) RNA and avian myeloblastosis virus (AMV) RNA in various cell-free systems, using immunoprecipitation for the analysis<sup>9,10</sup>. This verified that our failure to find virus-specific polypeptides in the oocyte system programmed with oncogenic viral RNA was due to the inadequacy of the methods available to detect translation when it occurs at low efficiency. We now report the synthesis of AMV-specific precursors and structural proteins in the oocyte system, detected by specific immunoprecipitation and scintillation autoradiography.

AMV contains single stranded RNA encapsulated by several proteins and a lipid envelope. The four major proteins, the so-called group-specific (gs) antigens immunologically indistinguishable among all avian oncornaviruses<sup>11</sup>, are within the viral envelope<sup>12</sup>.

There are additional glycosylated proteins, carrying the type-specific (ts) antigens, on the surface of the virion<sup>13</sup>. It is not known how many proteins are encoded by the viral RNA and how many cellular proteins become encapsulated in the virions during budding. To determine virus-specific proteins it is important to characterise the coding capacity

of the viral RNA in conditions closely related to the *in vivo* situation.

The results of a typical translation experiment of AMV RNA are shown in Fig. 1. Because of the relatively high rate of endogenous protein synthesis of this system, immunoprecipitation with specific antisera is a prerequisite for

**Fig. 1** Autoradiography of an SDS gel electrophoresis pattern of immunoprecipitates. *Xenopus laevis* oocytes were injected by the method of message-injection described by Gurdon *et al.*<sup>1</sup> AMV was obtained from viraemic plasma<sup>18</sup> and treated with SDS and Pronase. The 60S component of AMV RNA was isolated by centrifugation in isokinetic glycerol gradients<sup>8</sup>. Isolated 60S AMV RNA was denatured by heating at 100 °C for 3 min. The AMV-specific polypeptides synthesised in the oocytes in the presence of 2 µCi <sup>35</sup>S-methionine (specific activity 478 mCi mmol<sup>-1</sup>) per oocyte were detected by indirect immunoprecipitation<sup>16</sup> with an antiserum directed against the gs antigens of AMV. Primary cultures of 1 × 10<sup>6</sup> chick embryo fibroblasts infected with AMV were pulse labelled for 30 min with 50 µCi <sup>35</sup>S-methionine (specific activity 210 Ci mmol<sup>-1</sup>) in Earle's saline. After lysis in buffer indirect immunoprecipitation was carried out to detect virus-specific polypeptides. The immunoprecipitates were analysed on sodium dodecyl sulphate (SDS)-polyacrylamide slab gel gradients (7–18%) according to Berns *et al.*<sup>17</sup>. After staining and destaining, the slab gel was treated with DMSO-PPO<sup>18</sup>, dried under vacuum and exposed in contact with a Kodak X-ray film for 3 d. *a*, Each of 20 oocytes was injected with 25 nl of sterilised distilled water; *b*, each of 10 oocytes was injected with 25 nl of native 60S AMV RNA (1 mg ml<sup>-1</sup>) in distilled water; *c*, each of 10 oocytes was injected with 25 nl of heat-denatured 35S AMV RNA (1 mg ml<sup>-1</sup>); *d*, immunoprecipitate from pulse-labelled chick embryo fibroblasts infected with AMV; *e*, immunoprecipitate from pulse-labelled uninfected chick embryo fibroblasts. PR, precursor polypeptide; VP, virion polypeptide. Numerals denote molecular weight in kdaltons.

**Fig. 2** Autoradiograph of an SDS gel electrophoresis pattern of immunoprecipitates. Primary cultures of 1 × 10<sup>7</sup> chick embryo fibroblasts either uninfected or infected with AMV were pulse labelled for 30 min and immunoprecipitated as described in Fig. 1. The immunoprecipitates were analysed on slab gel gradients and exposed in contact with a Kodak X-ray film for 3 d. *a*, 1 × 10<sup>7</sup> infected cells precipitated with anti-AMV serum; *b*, 1 × 10<sup>7</sup> uninfected cells precipitated with anti-AMV serum.

detection of the viral proteins. Injection of native 60S AMV RNA results in synthesis of virus-specific polypeptides with molecular weights of 76,000, 66,000, 32,000, 25,000, 18,000 and 12,000. In contrast, denatured 35S AMV RNA leads to the synthesis of a small quantity of the precursor polypeptide with molecular weight 76,000. In chick embryo fibroblasts (CEF) infected with AMV the same precursors and structural polypeptides are found as have been synthesised after injection of oocytes with native 60S AMV RNA (compare Fig. 1*b* and *d*).

In addition to the five precursor polypeptides already described<sup>14</sup> we found in AMV-infected CEF a sixth unstable precursor of molecular weight 85,000 not present in uninfected CEF (Fig. 2). This pr85 was, however, not detectable after injection of AMV RNA into oocytes. Incubation of native 60S AMV RNA in a reticulocyte cell-free system (Fig. 3) resulted in the synthesis of the same precursors and structural polypeptides found in the oocyte system, but in

different proportions (compare Figs 1 and 3). In this cell-free system pr76 is the predominant product and almost no cleavage products are present. This probably means that the processing of AMV precursors in the oocyte and in infected CEF is almost identical, whereas in the reticulocyte cell-free system almost no cleavage occurs. In other reticulocyte preparations processing of the 76,000-dalton precursor resembled the situation *in vivo* (Fig. 4). Whereas the synthesis of the 76,000-dalton precursor polypeptide in a reticulocyte cell-free system is detectable even without immunoprecipitation (Fig. 3), as a rule immunoprecipitation procedures are necessary to visualise the small amount of virus-specific polypeptides. The specificity of the immunoprecipitation was checked as follows. Immunoprecipitation of control injections without mRNA (Fig. 1), by addition of anti-AMV serum, gives rise predominantly to two polypeptides with molecular weights of 190,000 and 50,000, respectively. The latter aspecific polypeptide is also always found when the reticulocyte lysate is the assay

**Fig. 3** Autoradiograph of the SDS gel electrophoresis pattern of products synthesised in reticulocyte cell-free incubations. Native 60S AMV RNA was incubated for 60 min at 30 °C in a reticulocyte cell-free system as described elsewhere<sup>10</sup>. The final incubation volume was 25 µl. 2 µl of the incubation mixture was analysed directly on the SDS slab gel and another 20 µl was immunoprecipitated<sup>14</sup> and analysed. The Kodak X-ray film was exposed in contact with the dried gel for 2 d. *a*, Incubation in the reticulocyte cell-free system with lens 14S mRNA; *b*, control incubation without mRNA; *c*, incubation programmed with native 60S AMV-RNA; *d*, immunoprecipitate of an incubation with native 60S AMV RNA; *e* immunoprecipitate of polypeptides present in pulse labelled AMV-infected chick embryo fibroblasts.

**Fig. 4** Autoradiography of immunoprecipitated products synthesised in the reticulocyte cell-free incubation and analysed by SDS gel electrophoresis. The analysis of the virus-specific polypeptides synthesised in the reticulocyte cell-free system were as described in the legend to Fig. 3. The X-ray film was exposed in contact with the dried gel for 3 d. *a*, Immunoprecipitation of an incubation in the reticulocyte cell-free system with native 60S AMV RNA; *b*, immunoprecipitate of an incubation in the reticulocyte lysate with denatured 35S AMV RNA.

system. The same two polypeptides are detected as the only components after injection of AMV 60S RNA into the oocyte system followed by the addition of an antiserum directed against the non-related murine RLV (not shown).

From results obtained *in vivo* and *in vitro* we conclude that AMV RNA is translated into several precursor polypeptides which are cleaved into structural viral proteins, presumably by the same relatively unspecific enzymes present in chick embryo fibroblasts, oocytes and reticulocytes. We therefore believe that the oocyte system provides a useful tool for the study of the regulation processes involved in the expression of different viral functions *in vivo*.

We thank Dr John Gurdon for hospitality to M.S. We also thank Mrs Anne-Marie Selden-Versteegen for technical assistance, Dr J. W. Beard for viraemic chicken plasma

and Dr G. de Boer for leukosis-free chick embryos. This work was supported in part by the Netherlands Foundation for Chemical Research and the Netherlands Organisation for Pure Research.

*Note added in proof:* We have also succeeded in translating Rauscher leukaemia virus RNA in oocytes. The precursor of the gs antigens p65 and the processed polypeptides p30 and p15 have been detected.

## Homology of myosin DTNB light chain with alkali light chains, troponin C and parvalbumin

THE interaction of actin and myosin which occurs during muscle contraction is regulated by changes in intracellular  $\text{Ca}^{2+}$  concentration. In vertebrates  $\text{Ca}^{2+}$  regulation is associated with troponin and tropomyosin in the thin filaments, and the myosin ATPase activity in the presence of pure actin is not  $\text{Ca}^{2+}$  sensitive. Most invertebrates possess a myosin-linked (thick filament) control system, usually in conjunction with actin-linked (thin filament) control<sup>1</sup>. Although the mechanism of thin filament regulation is fairly well characterised, that of thick filament control remains somewhat obscure (for reviews, see refs 2 and 3). This letter presents evidence for a structural and evolutionary relationship between proteins which have central roles in the two types of regulatory systems.

Myosin is composed of two heavy chains and four light chains. In rabbit white skeletal muscle, there are two structurally distinct<sup>4</sup> classes of light chains, most commonly known as alkali light chains (ALC) and DTNB light chains (DLC)<sup>5</sup>. ALCs have long been thought to have an essential function in the ATPase activity of myosin, but until recently no function could be demonstrated for DLCs. Although there is some evidence that  $\text{Ca}^{2+}$  exerts a direct effect on rabbit skeletal myosin, and that DLCs may somehow be involved in regulation of actin-myosin interaction<sup>6-11</sup>, as yet there has been no direct demonstration of myosin-linked  $\text{Ca}^{2+}$  control. DLCs, either isolated or as part of the whole myosin molecule, bind one  $\text{Ca}^{2+}$  per mol<sup>8-9,10,12</sup> but  $\text{Mg}^{2+}$  competes strongly and so significant amounts of  $\text{Ca}^{2+}$  may not be bound in physiological conditions<sup>12</sup>. In scallops (which

seem to lack troponin) specific light chains (the EDTA light chains, or ELCs) can be partially dissociated from the myosin, causing a loss of  $\text{Ca}^{2+}$  sensitivity which is restored on recombination<sup>13,14</sup>. Even though DLCs may not function as regulatory proteins in rabbit skeletal myosin, they can substitute for scallop ELC in binding and restoring  $\text{Ca}^{2+}$  sensitivity to desensitised scallop myosin<sup>15</sup>. ELCs also bind to rabbit myosin from which DLC have been partially removed, but this hybrid is not  $\text{Ca}^{2+}$  sensitive. It thus seems that both scallop and rabbit myosins contain 'regulatory' light chains, and that lack of  $\text{Ca}^{2+}$  sensitivity in rabbit myosin is due to mutations in the heavy chains<sup>3</sup>. The amino acid sequence of rabbit skeletal DLC has been determined, using standard procedures previously applied to other muscle proteins<sup>16-18</sup>; experimental details will be published elsewhere. Comparison of the DLC sequence (Fig. 1) with the partially completed sequence of ELC (R. Jakes and J. Kendrick-Jones, unpublished) further confirms that the two proteins are closely related.

Previous comparative sequence studies<sup>16,19</sup>, subsequently confirmed by more detailed analyses<sup>20-25</sup>, have suggested that the following rabbit skeletal muscle proteins are homologous (that is, they are descended from a common ancestor) and similar in three-dimensional structure: troponin C (TnC), the  $\text{Ca}^{2+}$ -binding regulatory protein of the thin filaments; ALCs, which do not bind  $\text{Ca}^{2+}$  in physiological conditions (J. Kendrick-Jones, personal communication); and  $\text{Ca}^{2+}$ -binding parvalbumin (CBP), a soluble protein of unknown function. By analogy with a carp CBP of known three-dimensional structure<sup>26</sup>, the structure of TnC seems to consist of four very similar regions (I, II, III, IV), each of which contains a 12-residue  $\text{Ca}^{2+}$ -binding segment stabilised by short  $\alpha$ -helices on either side. ALCs probably have a similar structure, although mutations in the four  $\text{Ca}^{2+}$ -binding segments have caused the loss in ability to bind in physiological conditions. The common ancestor of TnC, ALC and CBP was formed after two successive gene duplications produced a protein four times the length of an ancestral protein with a single  $\text{Ca}^{2+}$ -binding site. TnC is most closely related to the ancestor, since it has the strongest internal sequence repeats. CBP evolved by incomplete copying of the gene for the TnC-like precursor, causing deletion of region I and loss of  $\text{Ca}^{2+}$  binding in region II.

Analysis of the DLC sequence shows that it is also related to TnC. The sequences of rabbit skeletal muscle DLC, ALC (ref. 27), TnC (ref. 19) and CBP (ref. 28) are shown in Fig. 1 aligned with a uniform residue numbering system<sup>25</sup> based on the predicted structure of TnC. DLC are about equally similar to either TnC or ALC (an average of one of four residues are identical), less similar to CBP (about one of six identical residues). Of the two classes of light chains, ALC are slightly more similar to TnC. The phosphoserine-containing peptide isolated from DLC by Perrie *et al.*<sup>29</sup> is located near the N-terminus (residues NA8-NA18). As is the case with ALC, four homologous regions can be recognised in DLC, but the internal sequence repeats are very weak. Following the procedure used to predict the four  $\text{Ca}^{2+}$ -binding sites in TnC (ref. 16), the single  $\text{Ca}^{2+}$ -binding site of DLC is probably located in region I (residues abl-B3). The pattern of hydrophobic residues predicted to form the internal core of TnC is highly conserved in both DLC and ALC, suggesting that all these proteins have similar three-dimensional structures.

The finding that muscle cells contain a homologous group of structurally related proteins with seemingly diverse functions raises a number of important questions which may be answered by further comparative sequence studies. What are the structural alterations that caused the two classes of myosin light chains to evolve different functions? Since TnC and DLC are related, what further similarities exist between the two types of muscle  $\text{Ca}^{2+}$ -regulatory

**Fig. 1** Alignment of the complete amino acid sequences of rabbit white skeletal muscle troponin C (TnC), myosin DTNB light chain (DLC), myosin alkali light chain (ALC) and Ca<sup>2+</sup>-binding parvalbumin (CBP). Amino acid residues are numbered in accordance with the predicted three-dimensional structure of TnC: helices are denoted A to H, from the amino to the carboxyl termini; interhelical loops are called ab, bc, and so on; residues preceding helix A are designated NA. Residues identical in two or more proteins are in capital letters, and those presumed to be involved in Ca<sup>2+</sup> binding are underlined. Asterisks indicate residues predicted to form the hydrophobic core of TnC.

systems? What differences cause TnC to bind to troponin I and troponin T in the thin filaments, whereas ALC and DLC bind to myosin heavy chains in the thick filaments? These questions bring to mind Laki's proposal<sup>30</sup>, that myosin could be considered as a complex of actin and tropomyosin (troponin had not then been discovered).

## Erratum

In the article "Entropy production in black holes" by W. Kundt (*Nature*, **259**, 30; 1976) the second paragraph should read:

To begin with, it must be remembered that in 'normal' conditions, matter has an entropy per particle  $s \sim 1$  ( $s = SN^{-1} k^{-1}$  where  $N$  = particle number):  $s$  varies between  $\sim T/T_F \lesssim 1$  (for temperatures  $T$  below the Fermi temperature  $T_F$ ) and  $\lesssim 90$  (for dispersed hydrogen of critical cosmological density at  $\gtrsim 10^8$  K);  $s \sim 4$  for an extreme relativistic ideal gas...  $S_{bh}$  is  $10^{10} (M/M_\odot)$  times larger than  $S$  at formation.

The second  $s^a$  in line 6 and  $s^a$  in line 15 of paragraph 4 should read  $s^a$ ,  $a$ , the divergence of  $s^a$ .

# reviews

GORDON PASK has always been something of an enigma on the educational and psychological scene. Operation from a private research company, although common in the States, is still a source of puzzlement in Britain. For many years Pask remained outside any comprehensible 'establishment' with a reputation and stature that developed, and was recognised, far more outside his own country than within it. His diversity of interests, from deep epistemological problems and system theory to practical training and the construction of elaborate electromechanical automata exhibiting 'learning' or inducing training, have also made him difficult to place. His writings\* make few concessions to the reader, rarely simplifying what Pask already regards as an oversimplified view of a very complex world, and expressing it in a wide vocabulary appropriate to the richness and breadth of his conception of that world. Although one may admire an attempt to face up to a major part of the world of human acquisition of knowledge in its own terms, one may, however, also question its timeliness with regard to the intellectual and computational tools currently available to us.

Although there are few nowadays who would question the depth or logical consistency of Pask's approach, there may be many who will question its wisdom. The history of science is full of premature attempts to consolidate major areas of knowledge, before the correct viewpoint, reasonable objectives, or appropriate logicomathematical tools have been established. Pask adopts the all-embracing methodologies of Wiener's cybernetics and Bertalanffy's general systems theory and applies them to the highest levels of human behaviour and to practical problems of teaching and training. To what extent is he successful? I cannot give a clear-cut answer to this question. Neither will I pretend that the answer lies in this one book. What is clear, however, from grappling with the material in this book, both in its original form (as published papers) and in its present integrated form, is that the questions of 'success' cannot be answered negatively.

\**Conversation, Cognition and Learning: A Cybernetic Theory and Methodology*. By Gordon Pask. Pp. xi+570. (Elsevier: Amsterdam, Oxford and New York, 1975.) Dfl.96; \$36.95.

## Common sense and the computer

**"Pask has put much effort into the development of actual teaching systems for major subject areas . . . and the practical experience and exemplary material developed is used to give life and content to the abstract, theoretical concepts put forward . . .**

**No-one who takes the trouble to immerse himself in the work can fail to gain from the experience."**

Gordon Pask

Pask has put much effort into the development of actual teaching systems for major subject areas, such as probability theory and statistics, and the practical experience and exemplary material developed is used to give life and content to the abstract, theoretical concepts put forward. There is a healthy atmosphere of operationalism throughout the work that convinces one that the cybernetic terminology is significant and applicable. No-one who takes the trouble to immerse himself in the work can fail to gain from the experience—Pask teases at basic problems from many directions at many levels and the discussion throughout is highly stimulating.

Although psychologists and system theorists will find the book of interest, its most immediate contribution is probably to studies of computer-based instruction (CAI). Pask's own use of the computer is slight—indeed, perhaps much of the insight he gives is because his structures are natural ones not distorted to fit a standard 'flow-chart' or use the keyboard of a teleprinter! His discussion of the learning and training strategies appropriate to the 'serialist' and 'holist' thinking on the one hand, and his demonstration of the complex entailment structures of comparatively simple subject areas on the other, illu-

minate major problems of CAI (and other forms of programmed instruction).

There is a paradox in our ability to develop teaching systems that work quite well for a wide range of individuals, whereas we know that there is a massive variation in student's tutorial requirements. Pask shows how performance feedback in adaptive teaching systems can tailor tuition to the individual without requiring detailed identification of his traits, provided broad differences in learning strategies can be recognised and the structure of the subject area has been thoroughly analysed. To the practising teacher such insights may seem common sense but no-one has so far successfully incorporated the common sense of the human teacher in a computer program. It is fundamental work, such as that described by Pask, that is essential if this is to become a reasonable objective.

The evaluation of Pask's work must be left to posterity—one hopes that this book will have several successors, developing and elucidating his theories and techniques. The present work must be welcomed as an opportunity to analyse, evaluate and utilise a substantial body of original and stimulating psychological and educational research.

## Steroid biochemistry

*Biochemistry of Steroid Hormones.* Edited by H. J. Makin. Pp. x+358. (Blackwell Scientific: Oxford and London, 1975.) £16.50.

THE stated aims of this book are to provide a simple and concise source of information on steroid biochemistry for preclinical and BSc students, and an introduction to the subject for postgraduates. In seven chapters, several experts deal with the subject from structure and nomenclature of steroids through biosynthesis of cholesterol and steroid hormones, to control of steroidogenesis and catabolism and excretion. Two useful chapters on methods of estimation of steroids follow. The remaining five chapters deal with the physiology and pathology of steroid endocrine systems, and include chapters on the endocrinology of the menstrual cycle and pregnancy, inborn errors of corticosteroid biosynthesis and molecular mechanisms of steroid hormone action.

Generally speaking, the book fulfils its aims very well, in that it provides a comprehensive and reasonably up-to-date account of this enormous and frequently daunting subject, well illustrated by means of key experimental data, without burdening the reader with an indigestible welter of detail. Perhaps the most forbidding aspect of steroid biochemistry to a newcomer is the apparent complexity and variety of structure and interminable pathways of biosynthesis and catabolism. These problems, although not hedged, are dealt with in a sympathetic and matter-of-fact fashion. The difficulty is acknowledged and the aim is to establish and reveal the order and logic behind the structure and metabolism of these compounds. These aims are started in the first

paragraph of the first chapter, by Professor Kellie, which in itself should go a long way to allaying the fears of the reader.

As always, criticisms can be made of details, and these are inevitably subjective to some extent. For example, in Fig. 4.10, the major biosynthetic route to  $11\beta$ -hydroxy-4-androstenedione in the adrenal cortex is presented as proceeding from cortisol. Although this may be a conversion product of secreted cortisol, the major route to its biosynthesis in the adrenal gland itself is surely from C-19 precursors. Also, at the end of the book there is a pull-out scheme of steroid biosynthesis designed to assist readers of individual chapters, which may be too scanty in detail to achieve its aim.

These are, however, inevitable and minor criticisms of what is a very pleasing and useful book, which should prove of great benefit to student and teacher alike, although the price, at £16.50, might be somewhat daunting to both.

## Tracking down nuclear particles

*Nuclear Tracks in Solids: Principles and Applications.* By Robert L. Fleischer, P. Buford Price and Robert Walker. Pp. xix+605. (University of California: Berkeley, Los Angeles and London, November 1975.) £20.50.

FOR scientists in the UK the field of nuclear tracks in solids must surely be a frustrating example of the one that got away! Work at Harwell in the late 1950s showed that damage trails in mica produced by fission fragments could be made visible in the electron microscope. This observation was sufficient to initiate a tremendously fruit-

ful collaboration between the American authors of this book, who, within a few years, demonstrated that such damage trails could be enlarged by etching so as to be visible optically, showed that a whole range of materials other than mica would store similar tracks and applied the technique to a great variety of fields. They have now crowned their achievement with an excellent book which treats in detail many aspects of nuclear tracks in solids and conveys a vivid impression of how important this technique has become.

The book is divided into three parts. The first deals with formation of particle tracks, principles of track etching and methods by which particles may be identified by the damage trails they leave behind them. The second discusses the application of track techniques in the Earth and space sciences through fission track dating of rocks, glasses, and so on, the study of the present flux of energetic particles in space, and of stored records of past fluxes of such particles in meteorites and lunar rocks. The final part of the book deals in rather less detail with applications of the technique to nuclear physics, element mapping in rocks and other materials, radiation dosimetry and many other diverse areas in science and technology.

The book is very well written and beautifully illustrated with photographs and diagrams which considerably aid understanding of the text. The mix of information given and information only referred to in other sources is very well judged and the many references, given as appendices at the end of each chapter, have each been given a title which much increases their usefulness.

This is an excellent book worth every penny of its purchase price. It must rapidly become a standard work indispensable to those most directly involved and of great interest to many others in allied fields. **R. N. F. Walker**  
**P. H. Fowler**

## Analysing metal compounds

*Mass Spectrometry of Metal Compounds.* Edited by J. Charalambous. Pp. 297. (Butterworth: London and Boston, Massachusetts, 1975.) n.p.

THE first four chapters of the book deal with the theory of mass spectrometry, instrumentation and techniques. The next five chapters are concerned with specific groups of metal compounds, whereas the last chapter discusses analytical aspects

of the mass spectrometry of metal chelates. Finally, an appendix gives a table of nuclidic masses and abundances of the naturally occurring isotopes. There are over 400 references, many of which occur in the literature of the past decade or so, illustrating the rapid growth of inorganic mass spectrometry during the period.

There are a few minor criticisms of the book. In the first place it is surprising that in a comprehensive review of the energetics of molecular ionisation, no mention is made of the electron monochromator of Lossing, which provides the most accurate

method of determining ionisation and appearance potentials by mass spectrometry. Again the classical equation  $k(E) = v[(E - E_0)/E]^{n-1}$  is used in discussing fragmentation kinetics, in spite of the fact that it is known to be an extremely bad approximation. On the positive side, references are made to studies of negative ions, which are becoming increasingly important.

Within the confines of production from typescript, the book is well produced. It should become an essential addition to the library of anyone working in the fields covered.

**Allan Maccoll**

## Describing chemical methods

*Methodicum Chemicum: A Critical Survey of Proven Methods and their Application in Chemistry, Natural Science, and Medicine.* Edited by Friedhelm Korte. Volume 1: Analytical Methods. Part A. Purification, Wet Processes, Determination of Structure. Pp. x+1-628. Part B: Micromethods, Biological Methods, Quality Control, Automatisations. Pp. x+629-1218. (Academic: New York and London; Georg Thieme: Stuttgart, 1975.) \$98; £47.05 the two parts.

VOLUMES 1A and 1B comprise the start of an eleven-volume series which will give "a short critical description of chemical methods applied in scientific research and practice", the objective being "to provide the chemist and the scientist working in related areas of chemistry with a rapid and reliable source of information on the method applicable to his specific problem."

The subtitles of volumes 1A and 1B "Analytical Methods", is somewhat misleading, especially for 1A, as it is used in the sense of integral identification of a molecular entity and not in

that of conventional chemical analysis; moreover the emphasis is strongly biased towards organic and biological chemistry. With these reservations the editors and about 100 contributors, almost entirely European, have managed to compress into 1,200 pages a vast quantity of well presented information. The methods discussed, some of the less well known purposely given in greater detail than others, range from simple chemical operations to highly sophisticated instrumental techniques. The individual chapters provide a guidance to workers in the selection of methods appropriate to the problem being tackled and at the same time give sufficient theoretical background to enable the user to judge whether or not he can use the selected procedure himself or must employ the services of a specialist in the chosen field.

Part A deals with small-molecule separation, identification and structural analysis. Chemical and other methods are described for functional groups, but specialised techniques such as X-ray diffraction (40 pages) and various spectroscopic methods (200 pages) are dealt with in greater detail.

Part B first discusses some special physical methods covering such diverse topics as the determination of molecu-

lar weights, electron donor-acceptor complexes and electric dipole moments. Thereafter it deals with specific chemical, instrumental or biochemical techniques for the determination of both trace elements and organic constituents in a wide variety of organic samples including foods, fats, water, fuel and pharmaceuticals.

The work will provide a source of condensed information on newer techniques and, although it will not replace specialised monographs, adequate references up to 1969, sometimes up to 1972, are supplied for readers desiring more detailed information. The 53-page index, however, has omissions, no reference for example being given to the section on the use of flame photometry and atomic absorption for the analysis of fuel oils on p.955. The high cost of £48.05 will be beyond most private buyers but is justified by the amount of work that has been carried out by the authors and editors. The quality of production is excellent although somewhat marred by spelling errors and by the use of the symbol J for iodine in several places. If the following volumes maintain the quality of Volumes 1A and 1B, the series will become a reference work of major importance for all multidiscipline establishments.

R. O. Scott

## Molecular complexes

*Molecular Association.* Volume 1. Edited by R. Foster. Pp. xiv+365. (Academic: London, New York and San Francisco, August 1975.) £11.80; \$31.25.

THIS book contains four articles dealing with various aspects of electron-donor-acceptor (EDA) molecular complexes or charge-transfer (CT) complexes as they are commonly, but imprecisely, known, and with other molecular complexes. Z. G. Soos (Princeton) and D. J. Klein (Austin) give a detailed account (109pp, 340 refs) of charge transfer in solid-state complexes. This includes a phenomenological theory, a classification of  $\pi$ -molecular CT crystals, one-dimensional Hubbard models, magnetic properties of CT crystals, and the computation of model parameters. N. Kulevsky (Grand Forks) describes the dielectric properties of molecular complexes in solution, with particular reference to halogen complexes, complexes of  $\pi^*$ -acceptors, and halogenated alkane interactions (50 pp, 103 refs). K. M. C. Davis (Leicester) discusses solvent effects on 'CT complexes', including the position and intensity of the CT absorption and

fluorescence bands, charge-transfer-to-solvent (CTTS) spectra, vibrational spectra of complexes, nuclear magnetic resonance shifts, thermodynamic parameters, and complex-solvent interactions (63 pp, 334 refs). R. S. Davidson (Leicester) provides a comprehensive survey of photochemical reactions involving 'CT complexes' (120 pp, 449 refs). These are classified into reactions involving excited 'CT complexes', excimers (intermolecular and intramolecular) and exciplexes (subdivided into those with and without spectroscopic evidence).

There have been several recent books on molecular complexes, three of them written (*Organic Charge-Transfer Complexes*, Academic: London and New York, 1969) or edited (*Molecular Complexes*, 1 and 2, Elek Science, London; Crane Russak, New York, 1973 and 1974) by R. Foster, who has skilfully chosen the authors and contents of the present volume to cover topics he has not previously considered. It is doubtful whether there are sufficient gaps remaining in the literature to justify the initiation of a new series of volumes on molecular complexes under a different title selected "for bibliographical convenience." *Molecular Complexes*, Vol. 3, would have been a more accurate and convenient title for the present book. J. B. Birks

# obituary

**Mr Ernest Gold, CB, DSO, OBE and FRS** died on January 30 at the age of 94. He was most famous for his early work on the stratosphere. In 1907 he had become the Schuster Reader in dynamic meteorology at Cambridge, and a year later he published his paper explaining the existence of the stratosphere. That a region sharply delineated by a boundary (the tropopause), where the tendency for the temperature of the air to decrease with height abruptly stops and the temperature becomes constant, seemed paradoxical. Gold's explanation of this effect, taking into account the carbon dioxide and water vapour contained in the atmosphere is still accepted, though it is a measure of the complexity of calculations in weather science that no quantitative solutions for the effect have yet been achieved. In 1910 he left Cambridge for the Met. Office, building up its stature and importance. With the advent of aviation, the need for international weather forecasting became apparent, and it was Gold's achievement to mastermind the setting up of this service, as president of the International Commission for Synoptic Weather Information, a position he held for 28 years.

**Clair L. Stong**, conductor of the 'Amateur Scientist' column in 'Scientific American' since 1957 died on Tuesday, December 9, of cancer. He was born in Douds, Iowa, and was 73 years old.

Mr. Stong, known to everyone as 'Red', first became known as an aviator. While studying electrical engineering at the University of Minnesota and the Crane Institute, he earned his keep as a stunt pilot: for a while leading his own flying circus and performing at prairie county fairs. He joined the Western Electric Co. in 1926, working in various capacities until retiring in 1962 to devote himself full-time to the Scientific American.

In his Amateur Scientist column, he opened up the 'black boxes' of modern science. He showed his readers how to build in their kitchens and garages such formidable instruments as atomic particle accelerators and cloud chambers and scintillator counters to go with them, quartz-crystal clocks, lasers, ruling engines, high-altitude rockets and both digital and analogue computers. Experiments specified in his column ranged over the frontiers of science from molecular biology (how to make amino acids) to experimental

psychology (colour vision in pigeons) to oceanography (how to make a hydrophone) to cosmology (eclipses of stars by the mountains of the moon). His readers could rely on his instructions because he had himself built nearly all the instruments, and performed nearly all the experiments he described.

His column on hang gliding in 1973 is credited with helping to make that daring sport a national pastime. An anthology of his pieces published in 1960 has been translated into a dozen languages, and with James E. Hammesfahr he wrote 'Creative Glassblowing' in 1968, a handbook for amateurs now widely consulted by laboratory technicians.

That his experiments were performed by his readers was also evident for many years from high school science fairs across the country; the American Association for the Advancement of Science at its meeting in Boston this February has scheduled a session on the role of Mr. Stong's column in stimulating careers in the sciences.

Mr. Stong will be missed by his wife, his two children, and all his readers. The Amateur Scientist column is being discontinued. **Gerard Piel**

## announcements

### International meetings

March 11, **New Particles and New Quantum Numbers**, a discussion meeting, London (The Executive Secretary, The Royal Society, 6 Carlton House Terrace, London SW1 5AG, UK).

April 8-10, **Natural Gas Processing and Utilisation**, Dublin (Natural Gas Conference, Institution of Chemical Engineers, P.O. Box 770, Upper Merion Street, Dublin 2, Ireland).

April 12-13, **Drug Action at the Molecular Level**, organised by the Biological Council Coordinating Committee for Symposia on Drug Action, London (Miss G. Blunt, Administrative Secretary, c/o Department of Pharmacology, University College, Gower Street, London WC1E 6BT, UK).

April 12-15, **Unsteady flow in many channels**, Newcastle-upon-Tyne (The Organising Secretary, U.F.O.C. Symposium, BHRA Fluid Engineering,

Cranfield, Bedford MK43 0AJ, UK). April 12-16, **Spring Annual Meeting**, Washington D.C. (Meetings, AGU, 1909 K Street, NW, Washington, D.C., 20006).

April 15-17, **Social and Economical Significance of Animal Production Policy of EEC and The World Strategy for Zootechnical Production**, Milan, organised by the Societa' Italiana per il Progresso della Zootechnica, Milan (Professor T. Bonadonna, Milano, Via Comelico 3, Italy).

April 20-23, **Third European Meeting on Cybernetics and Systems Research**, Vienna (Secretariat of the Austrian Society for Cybernetics Studies, Schottengasse 3, A-1010 Wien, Austria).

April 20-24, **Models and Numerical Methods Applied to the Studies of Surfaces and of Adsorbates on Surfaces**, CECAM, Paris (Professor M. Simonetta, Istituto di Chimica Fisica, University of Milan, Milan, Italy).

April 22, **European Solar Houses**,

London (The Secretary, UK-ISES, The Royal Institution, 21 Albemarle Street, London W1X 4BS, UK).

April 23-24, **Historical Biogeography, Plate Tectonics and the Changing Environment**, Corvallis, Oregon (A. J. Boucot, Department of Geology, Oregon State University, Corvallis, Oregon 97331).

April 24-30, **Radiation Protection as an Example of Action Against Modern Hazards**, Paris (Mr Gilbert Bresson, General Secretary IRPA Fourth International Congress, B.P.33,92260-Fontenay-aux-roses, France).

April 25-28, **The 22nd Annual Meeting**, Philadelphia (Institute of Environmental Sciences, Betty Peterson, Executive Director, 940 East Northwest Highway, Mount Prospect, Illinois 60056).

April 27-29, **New Materials and Processing in the Textile Industry**, Manchester (Mr J. K. Jackson, Shirley Institute, Manchester M20 8RX, UK).
